Results: 107 psoriatic patients had both clinical and PDUS examination performed. 10.3% (n=11) of the patients had clinical enthesitis, whereas 70.1% (n=75) of psoriatic patients and 45% (n=9) (p=0.030; OR=2.86) of controls had PDUS findings of present or past enthesitis. 37.4% (n=40) of psoriatic

patients and 5% (n=1) of controls had active enthesitis by PDUS criteria (p=0.003; OR=11.34). Agreement between clinical exploration and PDUS to identify present enthesitis was low (Kappa index=0.182). Only 8 of the 40 patients with active enthesitis in PDUS had clinical enthesitis. Considering PDUS results as the gold standard, clinical findings showed a sensitivity of 20% (95% CI: 6.3–33.6%), specificity 95.5% (95% CI: 89.8%–100%), positive predictive value 72.7% (95% CI: 41.9%–100%), negative predictive value 66.7% (95% CI: 56.7%–76.6%). By applying CASPAR criteria, 8 (8.7%) patients would have a diagnosis of PsA based on clinical enthesitis, whereas 22 (23.9%) would have, by PDUS, a diagnosis of silent enthesal PsA.

Conclusion: The prevalence of PDUS enthesopathy in psoriatic patients without psoriatic arthritis is high, 70.1%. There is not a good agreement between clinical and PDUS findings. If active enthesitis, although clinically silent, is considered only by PDUS definitions, 23.9% of patients would meet CASPAR criteria in this study

Simple Questions in the Dermatology Office May Reasonably Exclude, but Do Not Reliably Identify Psoriatic Arthritis Patients: Results From the Center of Excellence for Psoriasis and Psoriatic Arthritis. Neha Garg, Atul A. Deodhar, Benjamin Ehst, Andrew Blauvelt, Jennifer Ku and Brian Truong. Oregon Health and Sciences University, Portland, OR

Background/Purpose: Psoriatic arthritis (PsA) affects between 10–30% of patients with psoriasis (PsO), but is often missed when assessed in a dermatology clinic. The Center of Excellence for Psoriasis and Psoriatic Arthritis (CEPPA) is a specialized multidisciplinary clinic consisting of expert dermatologists and rheumatologists experienced in diagnosing PsO as well as PsA. We wanted to identify simple clinical questions and findings on physical examination for dermatologists to screen PsO patients for PsA so as to refer appropriate patients to rheumatology.

Methods: This is a cross-sectional study of all PsO patients seen by dermatologists in the CEPPA clinic since its inception in 2006 through 2010. Possibility of PsA was assessed by four screening questions: "Do you have a history of joint pain or swelling," "Do you have morning stiffness," "Have you ever had x-rays taken"," and "Do you have PsA". Since nail involvement is known to predict development of PsA, assessment of nail changes was included as a physical finding for screening. Quality of life (QoL) measures were assessed with validated instruments (SF12, PQOL12 and RAPID3).

Results: Of 524 patients assessed in dermatology, 237 were referred to rheumatology, 34 were lost to follow up, 203 were evaluated and 128 (24.4%) were found to have PsA. Of those who answered 'no' to all the four screening questions 95.3 % did not have PsA. However, of those fulfilling all five parameters, including the four screening questions plus nail changes, 88.9 % had PsA. Table shows the sensitivity, specificity, PPV and NPV for screening questions and nail changes individually and in combination. The median age (48 years) and smoking history (in 20%) was not significantly different in patients with and without PsA. The median body mass index (BMI) and PsO body surface area (BSA) were significantly higher in patients with PsA than those without [31.5(IQR 11) vs 28.6 (IQR 8) and 10% (IQR 15) vs 7% (IQR 12), respectively, p <0.01]. PsA patients were more likely to have nail changes (OR 12.4, 95% CI: 5.9 – 26.5, P < 0.01). Onset of PsO occurred 10 years earlier in patients with a family history of PsO than those without (median age 25 vs 38, p <0.01). Six percent of patients developed PsA before, 8% with and 86% after the onset of PsO. Ninety percent were diagnosed with PsA within 25 years of PsO onset. Mean delay in PsA diagnosis from onset of joint pain was 1 year. Compared to PsO patients, patients with PsA had significantly worse QoL scores (P < 0.01). Percent of BSA involvement with PsO did not correlate with any clinical variables.

Sensitivity, specificity, negative predictive value (NPV) and positive predictive value (PPV) of four screening questions and examination for psoriatic nail changes

	Sensitivity	Specificity	PPV	NPV
Do you have joint pain or swelling	88.7	54.7	41.8	93
Do you have morning stiffness	88.5	51	39.3	92.6
Do you have psoriatic arthritis	68.1	86.6	64.8	88.2
Have you ever had x-rays taken	56.6	73.2	43.2	82.4
Have you ever had x-rays taken	85.4	68.1	70.7	83.8
All five of the above	22.4	95.9	88.9	46.1

Conclusion: In this large cohort of PsO patients, the prevalence of PsA was 24.4%. PsA patients had significantly worse QoL than those with PsO alone. A negative response to all four screening questions correctly ruled out the diagnosis of PsA in 95.3% of patients. Positive response to all four screening questions with PsO nail changes led to a correct diagnosis of PsA in 89% of patients.

Identification of Axial Spondyloarthritis Among Patients with Chronic Back Pain in Primary Care – How Does Determination of HLA B27 Influence the Performance of Clinical Assessments of Inflammatory Back Pain? Annalina Braun[1], Holger Gnann[2], Ertan Saracbasi[1], Joachim Grifka[3], Uta Kiltz[1], J. Schnittker[4], Katrin Letschert[5] and Juergen Braun[1]. [1]Rheumazentrum Ruhrgebiet, Herne, Germany, [2]Abteilung Biostatistik, GKM Gesellschaft für Therapieforschung mbH, München, Germany, [3]University of Regensburg, Bad Abbach, Germany, [4]Institut für angewandte Statistik Dr. Jörg Schnitker GmbH, Bielefeld, Germany, [5]Abbott Inc., Wiesbaden, Germany

Background/Purpose: The value of a combination of items defining inflammatory back pain (IBP) to screen for axial spondyloarthritis (axSpA) in primary care has recently been studied. However, whether and how measurement of HLA B27 may contribute to that is unclear. To study the value of HLA B27 determination for early identification of patients with axSpA in primary care.

Methods: Consecutive patients <45 years (n=950) with back pain >2 months who presented to orthopaedists (n=143) were randomized based on 4 key questions related to inflammatory back pain (IBP) for referral to rheumatologists (n=36) who made the diagnosis. HLA B27 was either assessed in primary or in secondary care in 298 patients. The predictive value of HLA B27 alone and in combination with other items for a diagnosis of axSpA was calculated. For variable selection logistic regression was applied, optimizing sensitivity, specifity and likelihood ratios using different strategies to predict axSpA.

Results: Rheumatologists saw 325 randomly selected patients. Due to missing HLA B27 values the main analysis is based on 298 patients, mean age 36 years (y), 52% female, median duration of back pain 32 months: 107 patients were diagnosed as axSpA (36%), 46 ankylosing spondylitis and 61 axial non-radiographic axSpA. A simple model with only HLA B27 as independent variable, indicates that HLA B27+ patients have an odds ratio (OR) of 12.24 to have axSpA in comparison with HLA B27- patients (sensitivity 62.6%, specifity 88.0%). The positive likelihood ratio (LR+) was 5.2 and the negative LR- 0.43. Thus, HLA B27 alone performed better than our recent 3/5 items proposal, which had a LR+ of 1.47 and LR- 0.53. Simply adding HLA B27 to those 5 criteria did not improve the LR+ substantially: for 3/6 items it was 1.64 (LR-: 0.33) and for 4/6 LR + 3.26 (LR-: 0.51). However, the simple combination of HLA B27 and/or buttock pain was 89.7% sensitive and 40.3% specific.A model based on determination of HLA B27 in primary care enabled us to analyse the performance of a two-phase strategy by dividing the patients into two groups according to their B27 status. Including additional variables to HLA B27+ patients did not improve the overall performance. However, in the HLA B27- group the following items were most relevant: improvement by movement, buttock pain and psoriasis. Moreover, a combination of this information revealed that a young patient with chronic back pain is likely to have axSpA if HLA B27 is positive and/or if 2 or 3 of the following symptoms are present: improvement by movement, buttock pain (both sided) and history of psoriasis. This combination was 80.4% sensitive and 75.4% specific (LR+: 3.27 and LR-: 0.26).

Conclusion: This study shows that patients with axSpA can be identified with or without knowledge of HLA B27 based on questions specific for IBP in primary care. However, since models including HLA B27 had better predictive results in this study, it seems to be more useful to generally determine HLA B27 in all patients with chronic back pain of young age in primary care to further reduce the delay in diagnosing axSpA.

A Reduction in Ultrasound Synovitis Score Discriminates Between Clinical Responders and Non-Responders and Is Predictive for a Favourable Clinical Outcome in Early Psoriartic Arthritis. Axel P. Nigg[1], Anna M. Malchus[1], Joerg C. Prinz[2], Mathias Gruenke[1] and Hendrik Schulze-Koops[1]. [1]Medizinische Klinik IV, University of Munich, Munich, Germany, [2]Department of Dermatology, University of Munich, Munich, Germany

Background/Purpose: Accurate monitoring of disease activity in early PsA is limited by the potential underestimation of inflammation by clinical examination, the absence of disease-specific biochemical markers and heterogeneity of clinical manifestations. Sensitive and reliable diagnostic modalities enabling visualization of early inflammatory changes are considered as useful tools for monitoring the response to therapy. The aims of this prospective study were to assess the utility of musculosceletal ultrasound (US) in detection of inflammatory changes in early PsA and to analyze the association of changes in a semiquantitative ultrasound score on the overall clinical response, defined by EULAR response criteria and MDA (minimal disease activity).

Methods: 51 patients with early PsA (onset of symptoms <5 years) naive to immunosuppressive treatment were eligible for study inclusion (disease duration 18.6 months). Patients were evaluated by US and clinically (baseline, 3/6/12 months). In each patient, 56 joints were examined by Grey-Scale-US (GSUS) and power doppler (PDUS). US findings were scored separately on a 0–3 semi-quantitative scale. US synovitis score was calculated by adding the GSUS and PDUS scores for all joints examined. Clinical assessment included TJC68, SJC66, VAS for disease activity (patient/physician), DAS28-CRP, LDI, HAQ and CRP. Treatment was initiated and modified at the discretion of the primary rheumatologist following international recommendations. Criteria for EULAR response and minimal disease activity (MDA) (Coates L. et al.) were defined for each follow-up period.

Results: Clinical responders were more likely to have higher US scores and PDUS scores at baseline and showed a significantly higher relative reduction of the mean US synovitis and the mean PDUS score during follow-up intervals compared to non-responders. A reduction of the ultrasound score after 3 months of systemic treatment was predictive for achieving or maintaining a good/moderate EULAR response (OR 3.64, p=0.21) or MDA respectively (OR 6.01, p=0.05) after 6 and 12 months. Reduction of ultrasound inflammatory activity during systemic treatment was not only detected in symptomatic joints but also in those joints with subclinical inflammation, however clinical responders showed a tendentially larger relative reduction of subclinical synovitis than non-responders.

Conclusion: Reduction of inflammatory changes detected by US during systemic treatment allows discrimination between clinical responders and non-responders (defined by EULAR response criteria and MDA) in early PsA. A reduced US synovitis score 3 months after initiation of treatment is predictive for a favourable clinical outcome after 6 and 12 months. Longitudinal analysis of subclinical synovitis in responders and non-responders reveal evidence that subclinical US findings have to be regarded as a pathophysiologically relevant pre-stage of clinical synovitis.

Performances of the ASAS Axial Spondyloarthritis Criteria for Diagnosis and Classification Purposes in Patients Visiting a Rheumatologist Because of Chronic Back Pain: The Declic Study. Anna Moltó[1], Simon Paternotte[1], Denis Comet[2], Cécile Hacquard-Bouder[3], Martin Rudwaleit[4], Pascal Claudepierre[5], Désirée van der Heijde[6] and Maxime Dougados[1]. [1]Paris-Descartes University, APHP, Cochin Hospital, Paris, France, [2]Axonal, Nanterre, France, [3]Abbott France, Rungis, France, [4]Endokrinologikum Berlin, Berlin, Germany, [5]Université Paris Est, Laboratoire d'Investigation Clinique (LIC) EA 4393, AP-HP, Hôpital Henri-Mondor, Rheumatology department, Creteil, France, [6]Leiden University Medical Center, Leiden, Netherlands

Background/Purpose: To evaluate the performances at diagnosis (sensitivity [Se], specificity [Spe], positive and negative predictive values) and study visit (classification purpose) of the ASAS criteria in axial spondyloarthritis (SpA) in patients visiting their rheumatologist for chronic back pain (CBP). Secondary objectives: identifying the most contributive item to diagnosis/classification of SpA, evaluating the performances of each arm of the ASAS criteria and other SpA criteria's performances.

Methods: Multi-centric, cross-sectional. *Patients:* history of CBP before the age of 40 visiting a rheumatologist in France. *Data:* a) items of the different sets of criteria, checking if present at diagnosis or at study visit; b) diagnosis of the rheumatologist at study visit. *Statistical analysis:* description of the population. Rheumatologist's diagnosis was considered as the "gold standard" for the estimation of all psychometric properties.

Results: 1210 patients were included for our analysis. At diagnosis, Se was 0.76 and Spe 0.94 for ASAS axial criteria and Se 0.87 and Spe 0.92 for classification. LR+ of the ASAS axial criteria was 13.6 for diagnosis and 10.30 for classification. The most contributive item to diagnosis and classification was X-ray sacroiliitis, followed by MRI sacroiliitis for diagnosis and history of uveitis for classification. MRI+ imaging ASAS criteria were more sensitive for diagnosis and classification, but as specific as ASAS clinical criteria.

Conclusion: we confirm the validity of the ASAS criteria in diagnosis and classification, in a clinical rheumatological setting of patients with CBP, with good performances compared to the other axial SpA criteria, and for any of their arms.

Eos Imaging Could Replace Conventional Computed Radiography for Ankylosis Assessment in Axial Spondyloarthritis. Anna Moltó[1], Veronique Freire[2], Antoine Feydy[2], Simon Paternotte[1], Walter P. Maksymowych[3], Mathilde Benhamou[4], François Rannou[4], Maxime Dougados[1] and Laure Gossec[1]. [1]Rheumatology B Department, Paris-Descartes University, Cochin Hospital, Paris, France, [2]Radiology B Department, Paris Descartes University, Cochin Hospital, APHP, Paris, France, Paris, France, [3]University of Alberta, Edmonton, AB, [4]Physical Medicine and Rehabilitation Service, Paris-Descartes University, Cochin Hospital, Paris, France

Background/Purpose: EOS® is a new osteoarticular imaging modality with significantly lower radiation than conventional computed radiography (CR). However, the diagnostic performance of this 2D biplanar imaging technique has yet to be evaluated and compared to CR. Diagnosis and follow-up of spondyloarthritis (SpA) by assessment of sacroiliitis and spinal ankylosis with the mSASSS is usually assessed by CR. We aimed to establish whether EOS could replace CR for SpA diagnosis and follow-up by: 1) validating the diagnosis of sacroiliitis by EOS versus by pelvic CR. 2) validating the analysis of spine involvement in SpA by EOS vs spine CR.

Methods: Study design: Observational, single center, prospective. Patients: 108 patients were included. 56 had a definite diagnosis of axial SpA (according to the rheumatologist). In order to assess the specificity of the imaging, 52 control patients with chronic mechanical back pain were enrolled. Data collected: demographic and disease data. All patients underwent CR and 2D EOS imaging of the pelvis and entire spine. Radiologic analysis: a) The diagnostic capacity of 2D EOS and CR for detection of sacroiliitis between SpA patients and controls was compared by calculation of sensitivity (Se) and specificity (Spe). b) Agreement between modalities was compared for spinal involvement scored with the mSASSS, and for sacroiliitis scored according to the modified New York (mNY) score. c) Subjective global visibility of anatomical structures and lesions on both modalities was assessed by the readers and compared by visual numeral scale (in a 0–10 scale). Two independent readers performed a blinded reading of both imaging modalities. Statistical analysis: Weighted kappa and ICC were used with a defined non-inferiority limit of 0.7.

Results: Demographics: Among SpA patients: Mean (SD) age was 48.4 (±15.1) years, sex ratio was 42 males/14 women. Disease duration was 16.6 (±11.2) years. Fifty-two (92.9%) patients fulfilled the ASAS criteria. Thirty-seven (74.0%, n=50) patients presented with sacroiliitis according to mNY criteria according to medical files. Radiologic analysis: a) *sacroiliitis diagnostic capacity:* Sen was 0.62 and 0.63 for EOS and CR, respectively, and Spec was 0.84 for both modalities; b) *agreement between the 2 imaging modalities:* Spine: ICC (95%CI) agreement between EOS and CR by mSASSS scoring was 0.82 (0.71–0.89). Sacroiliac joints: Kappa (95% CI) agreement for the scoring of sacroiliac joint abnormalities according to the mNY criteria between EOS and CR was 0.5 (0.26–0.74); c) *Subjective global visibility of EOS in SpA:* was evaluated at 7.2 (±0.8), vs. 8.2 (±0.9) for CR (p<0.0001).

Conclusion: This study suggests that EOS 2D imaging could replace CR for the diagnosis and follow-up of ankylosis of the spine in SpA, since radiation exposure is much lower However its place in the diagnosis of sacroiliitis remains unclear. Forward studies using MRI as a discriminative modality are ongoing.

Effect of Certolizumab Pegol On the Multiple Facets of Psoriatic Arthritis As Reported by Patients: 24 Week Patient Reported Outcome Results of a Phase 3 Double Blind Randomized Placebo-Controlled Study. Dafna D. Gladman[1], Roy M. Fleischmann[2], Geoffroy Coteur[3], Franz Woltering[4] and Philip Mease[5]. [1]Toronto Western Research Institute, University of Toronto, University Health Network, Toronto, ON, [2]University of Texas Southwestern Medical Center at Dallas, Dallas, TX, [3]UCB Pharma, Brussels, Belgium, [4]UCB Pharma, Monheim, Germany, [5]Seattle Rheumatology Associates, Seattle, WA

Background/Purpose: RAPID-PsA (NCT01087788) reports efficacy and safety of certolizumab pegol (CZP), a PEGylated Fc-free anti-TNF, in psoriatic arthritis (PsA).[1] The effect of different imputation methodologies on radiographic progression outcomes is reported.

Methods: The ongoing 158 week (Wk) RAPID-PsA trial is double-blind and placebo (PBO) controlled to Wk24, dose-blind to Wk48 and then open label to Wk158. Recruited patients (pts) had active PsA and had failed ≥1 DMARD. Pts could have been secondary failures to 1 previous anti-TNF. Pts were randomized 1:1:1 to PBO or 400mg CZP at Wk0, 2 and 4 (loading dose, LD) followed by either 200mg CZP every 2 wks (Q2W) or 400mg CZP every 4 wks (Q4W).[1] Pre-specified analyses included change from baseline (CFB) in modified Total Sharp Score (mTSS) (average scores of 2 independent readers), the primary endpoint, and % non-progressors (mTSS CFB ≤0). In the pre-specified imputation methodology performed in all randomized pts minimum observed baseline (BL) score for missing BL values (0) and maximum observed Wk24 score for missing Wk24 values (356.5) in pts with <2 available x-rays were imputed. Post hoc analyses used alternative methods of imputation for change from BL in mTSS for pts with <2 available x-rays, including no imputation, imputation with the median, mean or maximum CFB in mTSS scores.

Results: 409 pts were randomized. BL demographics were similar between groups. 19.1% and 19.8% of PBO and CZP (combined dose) pts received prior anti-TNF. The pre-specified imputation analysis inappropriately overestimated radiographic progression in all arms including PBO (LS mean 28.9 and 18.3 for PBO and CZP (combined dose) respectively p≥0.05) (Table) as pts with missing Wk24 values were assigned to a change from BL in mTSS of up to 356.5, which is an implausible progression with respect to clinical practice. Significantly more pts were non-progressors in both CZP groups (200mg Q2W and 400mg Q4W) compared with PBO (83.3% and 76.3% vs 34.6%, respectively, p<0.001). Multiple post-hoc analyses showed that CZP effectively inhibited radiographic progression compared to PBO (Table). ACR20 response at Wk12 was significantly higher in both CZP arms (200mg Q2W and 400mg Q4W) vs PBO (58.0% and 51.9% vs 24.3%, respectively, p<0.001). The safety profile was similar to that observed with CZP in RA.

Table. LS mean CFB in mTSS at Wk24, evaluated using an analysis of covariance model

		LS mean mTSS CFB at Wk24 (SE)			
	Imputation in pts with <2 x-rays available~	PBO (n = 136)	CZP 200mg Q2W (n = 138)	CZP 400mg Q4W (n = 135)	CZP 200mg Q2W + CZP 400mg Q4W (n = 273)
Pre-specified†	Minimum observed score (0) if missing BL Maximum observed score (365.5) if missing Wk24	28.92 (7.73)	11.52 (7.59)	25.05 (7.92)	18.28 (6.07)
Post-hoc 1*	No imputation	0.29 (0.08)	0.01 (0.08)**	0.12 (0.08)	0.06 (0.06)**
Post-hoc 2*	Median mTSS change from BL of all pts observed	0.28 (0.07)	0.01 (0.07)**	0.11 (0.08)	0.06 (0.06)**
Post-hoc 3*	Mean mTSS change from BL of all pts observed	0.28 (0.07)	0.01 (0.07)**	0.11 (0.08)	0.06 (0.06)**
Post-hoc 4*	Maximum mTSS change from BL of all pts observed	0.66 (0.13)	0.18 (0.13)**	0.52 (0.13)	0.35 (0.10)**
Post-hoc 5*	Maximum mTSS change from BL by treatment group	0.39 (0.11)	0.14 (0.11)	0.49 (0.12)	0.31 (0.09)

For PBO pts who escaped early to CZP, the Wk 24 values, if available, were ignored and linearly extrapolated
†21 pts had <2 x-rays, number of pts was equally distributed between treatment groups
*26 pts had <2 x-rays, as in post-hoc analyses the x-rays had to be at least 8 weeks apart;
~ for pts with 2 x-rays but missing Wk24 or BL film, linear extrapolation was performed in all approaches
**p < 0.05 vs PBO

Conclusion: Conventional radiographic imputation methods showed that CZP effectively inhibited radiographic progression in pts with PsA. Significantly fewer patients had progression with either CZP dose compared to placebo. The highly conservative pre-specified imputation method resulted in an unrealistic assessment of progression in all arms including PBO Differences in methodologies for imputing missing radiographic data can greatly impact assessment and reporting of mean changes from BL in mTSS.

Rapid Improvements in Patient Reported Outcomes with Certolizumab Pegol in Patients with Axial Spondyloarthritis, Including Ankylosing Spondyltitis and Non-Radiographic Axial Spondyloarthritis: 24 Week Results of a Phase 3 Double Blind Randomized Placebo-Controlled Study. Joachim Sieper[1], Alan J. Kivitz[2], A.M. Van Tubergen[3], Atul A. Deodhar[4], Geoffroy Coteur[5], Franz Woltering[6] and Robert B. M. Landewé[7]. [1]Charité University Medicine, Berlin, Germany, [2]Altoona Center for Clinical Research, Duncansville, PA, [3]Maastricht University Medical Center, Maastricht, Netherlands, [4]Oregon Health & Science University, Portland, OR, [5]UCB Pharma, Brussels, Belgium, [6]UCB Pharma, Monheim, Germany, [7]Academic Medical Center/University of Amsterdam & Atrium Medical Center, Heerlen, Netherlands

Background/Purpose: Axial spondyloarthritis (axSpA) is a form of spondyloarthritis (SpA) that includes both ankylosing spondylitis (AS) and non-radiographic axial SpA (nr-axSpA), as defined by the ASAS criteria. Both subgroups of patients (pts) have been shown to have a similar burden on Quality of Life (QoL).[1] A recent survey estimated that SpA may affect up to 1.4% of the US population.[2] Certolizumab pegol (CZP) is a PEGylated Fc-free anti-TNF that improved patients reported outcomes (PRO) in rheumatoid arthritis (RA).[3] RAPID-axSpA (NCT01087762) is the first report of the effect of CZP on PRO in axSpA.

Methods: The ongoing 158-Wk RAPID-axSpA trial is double-blind and placebo controlled to Wk24, dose-blind to Wk48 and then open label to Wk158. Recruited pts had adult-onset active axSpA as defined by the ASAS criteria,[1] Bath Ankylosing Spondylitis Disease Activity Index (BASDAI) ≥4, spinal pain ≥4 on a 10 point NRS, and CRP > upper limit of normal or sacroiilitis on MRI. Pts must have failed ≥1 NSAID. Pts could have been secondary failures to 1 previous TNF inhibitor. The pt population reflected the broad axSpA population, including AS pts also meeting the modified New York criteria and nr-axSpA pts who met the ASAS MRI or clinical criteria. Pts were randomized 1:1:1 to placebo (PBO), or 400mg CZP at week (Wk) 0, 2 and 4 (loading dose, LD) followed by either 200mg CZP every 2 weeks (Q2W) or 400mg CZP every 4 weeks (Q4W). Pts receiving PBO who failed to achieve an ASAS20 response at both Wks14 and 16 were rescued and randomized at Wk16 to receive CZP 200mg Q2W or CZP 400mg Q4W following LD. The primary endpoint was ASAS20 response at Wk12. PRO endpoints included SF-36 physical component summary (PCS), physical function (BASFI), total spinal pain (NRS), fatigue (NRS from BAS-DAI), Ankylosing Spondylitis Quality of Life (AsQoL), Sleep Problems Index II domains of the MOS Sleep scale (MOS-SPI), and SF-36 mental component summary (MCS) and domains. All PRO were analyzed on the full analysis set using analysis of covariance on change from baseline (CFB) with last observation carried forward imputation.

Results: 325 pts were randomized. Baseline characteristics were similar between groups. Improvements in the CZP-treated groups were observed in pain NRS, fatigue NRS, BASFI and AsQoL from the first measurement at Wk1 through to Wk24 compared to PBO. Pts in both CZP-treated dosage arms had greater improvements in SF-36 PCS. compared to PBO (Table). Improvements were also seen in MOS-SPI, SF-36 MCS and domains.

Table 1. Mean BL scores (SD) and mean change from baseline (CFB) at Wk12 and Wk24 in PRO

Mean (SD)			PBO (n = 106)	CZP 200mg Q2W (n = 111)	CZP 400mg Q4W (n = 107)

Utility of Dual-Energy X-Ray absorptiometry Scanning and Risk of Osteoporosis in Ankylosing Spondylitis; A Prospective Study. Marina N. Magrey[1] and Muhammad Asim Khan[2]. [1]Case Western Reserve University School of Medicine at MetroHealth Medical Center, Cleveland, OH, [2]CASE at MetroHealth Med Center, Cleveland, OH

Background/Purpose: Conventional DXA imaging of spine and hip to measure bone mineral density (BMD) has limitations in patients with ankylosying spondylitis (AS) as their spinal DXA measurements may be falsely elevated due to syndesmophyte formation and ligament ossification. Therefore, we investigated the correlation of hip and spine BMD measurements in patients with AS to determine if hip DXA will prove clinically useful while avoiding the confounding effect of spinal disease. We also studied risk factors for osteoporosis (OP) in AS.

Methods: We identified patients from our AS registry ≥ 18 years of age who met the ASAS (Assessment of Spondyloarthritis International Society) classification criteria for AS. Patients with thyroid and parathyroid disease, chronic liver or kidney disease, on anti-convulsant medications, surgical spinal fusions and hip arthroplasties were excluded. Demographic and clinical data were recorded and included HLA- B27 status, disease duration >5 years, presence of syndesmophytes on lumbar X-ray. Disease activity was measured using Bath AS Disease Activity Index (BASDI). BMD was measured using a Hologic machine and interpreted using ISCD 2005 guidelines and WHO criteria for definition of OP. Patients were divided into 3 groups- osteoporosis (T-score< −2.5), osteopenia (T-score of − 1.0 and −2.5) and normal (T-score of >−1.0). In addition, ESR and blood levels of CRP, and 25-hydroxy vitamin D were measured.

Correlation between the lowest T-scores of hip (total hip or femoral neck) and lumbar spine was measured using Spearman's correlation coefficient (rho). Chi-square and odds ratio using logistic regression were used to assess the association of the purported risk factors for OP in these patients.

Results: We identified 101 patients with AS; 26.2 % females, and 25.2 % African-Americans (AA). The mean age was 43.0 years (±13.7) in patients with normal BMD versus 47.8 years (±14.4) with OP and osteopenia (p= 0.0867), and 40.5 % of patients had syndesmophytes on lumbar Xray. Prevalence of OP = 16.8%, osteopenia = 36.6% and 46.5% had normal BMD. There was moderate correlation between the lowest T-values of hip and lumbar spine (AP view), rho= 0.59 (figure 1). The AA with AS had higher odds of having osteoporosis compared to Whites; Odds ratio (OR) = 5.3 (1.03–26.84) (95% CI), p = 0.045 and also AS patients with high CRP levels had higher odds of having OP, OR= 4.1(1.22–13.97) (95% CI), p=0.0226. There was no association between OP and age, sex, BASDI, vitamin D levels, HLAB27 positivity, and ESR.
Conclusion: Our results demonstrated a correlation between T-scores of hip and lumbar spine in patients with AS with disease duration of > five years, suggesting that DXA of the hip and the lumbar spine are useful in diagnosing OP in patients with AS. Elevated CRP level increases the risk of OP in patients with AS. African-Americans with AS are at higher risk of developing OP compared to whites.

Proteomic Profiling of Synovial Fluid Reveals Candidate Psoriatic Arthritis Biomarkers. Daniela Cretu[1], Ihor Batruch[2], Punit Saraon[1], Dafna Gladman[3], Fawnda Pellett[3], Eleftherios Diamandis[2] and Vinod Chandran[4]. [1]Department of Laboratory Medicine and Pathobiology, University of Toronto, Toronto, ON, [2]Mount Sinai Hospital, Toronto, ON, [3]Toronto Western Hospital and University of Toronto, Toronto, ON, [4]Toronto Western Hospital, University of Toronto, Toronto, ON

Background/Purpose: Psoriatic arthritis (PsA) is a unique form of arthritis occurring in 30% of psoriasis patients. There is a high prevalence of undiagnosed PsA in patients seen in dermatology clinics and identifying soluble biomarkers for PsA will help in screening psoriasis patients for appropriate referral to a rheumatologist, as well as provide further insight into disease pathogenesis. However, identification of novel biomarkers in peripheral blood is difficult and unreliable. Potential PsA biomarkers are likely to originate in sites of inflammation such as inflamed joints and subsequently enter systemic circulation. Our purpose was to identify candidate PsA biomarkers by conducting high-throughput quantitative proteomic analysis of synovial fluid from inflammatory and non-inflammatory arthritides.

Methods: Using strong cation exchange chromatography, followed by LC-MS/MS on an LTQ-Orbitrap mass spectrometer in conjunction with database searching for protein identification and quantification, we extensively characterized the proteomes of SF from 3 individual PsA patients, as well as 2 Rheumatoid Arthritis (RA), 2 Gout, 3 Late Osteoarthritis (LOA), and 3 pooled non-inflammatory (NI) controls. All samples were analysed in triplicates, and extracted ion current (XIC) intensities were used to calculate protein abundance ratios. Two strategies were then employed for identification of candidate biomarkers: (1) examination of differential protein expression between the PsA, RA, Gout, LOA, and Non-Inflammatory controls, and (2) tissue specificity analysis through mining of publicly available databases

Results: A total of 594 non-redundant proteins were identified with one peptide (384 with two-peptides or more) in SF from all arthritis subsets, with a false discovery rate <1.5%. Of the 521 high-confidence proteins that were quantified from all patient groups, there were significant quantitative differences in 89 PsA SF-derived proteins compared to other arthritides. Following additional manual filtering, we obtained a preliminary list of 35 proteins as increased in PsA compared to all arthritic and non-inflammatory controls. Gene ontology (GO) analysis classified these proteins into categories pertaining to five main biological processes: complement activation, defense response, immunoglobulin mediated response, response to wounding, and extracellular matrix remodelling, all of which are attributes of PsA. The candidate proteins include also COMP, CD14, and MMP2, all of which have been previously investigated as PsA biomarkers.

Conclusion: Quantitative proteomic profiling of synovial fluid has the potential to identify candidate PsA screening biomarkers. Verification and validation of these markers in SF and serum, respectively, is essential and is currently under way.

Performance of Magnetic Resonance Imaging in Detection of Chronic Structural Changes in Sacroiliac Joints As Compared to Conventional X-Rays in Axial Spondyloarthritis. Denis Poddubnyy[1], Inna Gaydukova[2], Hildrun Haibel[1], In-Ho Song[1] and Joachim Sieper[1]. [1]Charité Medical University, Campus Benjamin Franklin, Berlin, Germany, [2]Saratov State Medical University, Saratov, Russia

Background/Purpose: Conventional x-rays of the sacroiliac joints (SIJ) remains the first imaging method in case of suspicion of axial spondyloarthritis (SpA). Moreover, a diagnosis of definite ankylosing spondylitis (AS) according to the modified New York criteria relies on the presence of definite radiographic sacroiliitis (SI). Magnetic resonance imaging (MRI) is a reliable method of detection of active inflammatory changes in the SIJ (active SI) and is potentially able to detect also chronic structural changes (such as sclerosis, erosions, and ankylosis) visible on conventional X-rays. Furthermore, chronic changes might be better visible in MRI because of tomography and MRI is not associated with radiation exposure. However, reliability of MRI in detection of chronic structural changes in SIJ remains unclear.

This study was aimed at comparing the performance of MRI in comparison to conventional X-rays in detection of chronic structural changes in patients with axial SpA.

Methods: We included 112 patients with definite axial SpA (68 with AS and 44 with non-radiographic axial SpA – nr-axSpA), for whom sets consisting of an X-rays of the SIJ and an MRI of the SIJ (at least in a T1-weighted sequence) performed at the same time point were available. X-rays of the SIJ were scored according to the modified New York criteria (grade 0 to grade IV) and according to the recently proposed new scoring system [1], which contains separate scores for subchondral sclerosis (score 0–2), erosions (score 0–3), and joint space changes (score 0–5) in each SIJ. MRIs of the SIJ (T1) were scored in the similar way for the same structural changes. In addition, readers were asked to provide an overall impression of the damage extent on MRI according to the scoring system of the modified New York criteria. X-rays and MRIs were scored separately by two trained readers, which were blinded for all clinical data and for the diagnosis of AS or nr-axSpA.

Results: 224 SIJ from 112 patients were available for the analysis. There was a moderate agreement between MRI and X-ray regarding definite subchondral sclerosis scored by both readers (Kappa=0.46, p<0.001), rather low agreement concerning definite erosions (Kappa=0.11, p=0.07), moderate agreement regarding definite joint space abnormalities (Kappa=0.41, p<0.001) and very good agreement regarding joint ankylosis (Kappa=0.85, p<0.001). Importantly, there was a good overall agreement regarding the presence of definite SI: in 84% of the SIJ (128 out of 153) with definite X-rays SI it was also seen in MRI. Interestingly, in 16% of the cases definite SI was seen in X-rays only in 18% of the cases – in MRI only. Furthermore, on the patients' level, SI fulfilling the modified New York criteria was confirmed on MRI in 81% of the cases (55 out of 68).

Conclusion: MRI demonstrated good overall performance regarding detection of chronic structural changes in the SIJ and was able to confirm the presence of definite sacroiliitis in more than 80% of the cases.

Prevalence and Predictors of Significant Liver Fibrosis in Methotrexate Treated Rheumatoid and Psoriatic Arthritis Patients Using Transient Elastography (fibroscan). WC Chan, ML Yip and CK Loo. Kwong Wah Hospital, Kowloon, Hong Kong

Background/Purpose: Methotrexate (MTX) is an anchor drug in the treatment of Rheumatoid (RA) and Psoriatic arthritis (PSA)and is the first line therapy in RA according to international guidelines and recommendations. However, there is constant concern on drug related hepatoxicity in long term use, particularly in patients with psoriasis. Guidelines had laid out the need for liver biopsy depending on the cumulative methotrexate dose but were controversial as liver biopsy itself carries considerable risk. Fibroscan (transient elastography TE) is a newly developed non-invasive technique to examine liver stiffness and hence liver fibrosis. Validation and correlations have been made in various liver diseases for fibrosis and cirrhosis detection and screening.

Methods: RA and PsA patients in a local rheumatology clinic were recruited. Patients with known pre-existing liver diseases were excluded. Demographic variables including age, sex, alcohol use, disease characteristics, concurrent co-morbidities, cumulative and duration of MTX use were recorded. TE were performed on these patients and liver stiffness were measured. A stiffness level of 7.9 kPa was used as cut off value as probable significant liver fibrosis and liver biopsy was offered.

Results: A total of 50 PsA and 215 RA patients were contacted and 128 (33 PsA,95 RA) of them were eligible for TE. Average disease duration was 8 years (SD 6.2). Mean cumulative MTX dose was 2427.3 mg (SD 2330.6). 55 % of patients had cumulative dose of MTX > 1500 mg and 21 % had cumulative dose of MTX > 3500 mg. Mean duration of MTX use was 4.2 years (SD 3.59). PsA patients had higher body mass index (25.2 vs 23.2, p=0.02), higher percentage of insulin resistance (45.5 vs 21.1 %, p=0.07) and abnormal HDL cholesterol level (63.3 vs 37.9 %, p=0.01) at baseline but lower cumulative MTX dose use (1775 mg vs 2654 mg, p=0.06) than RA patients. Mean liver stiffness was significantly lower in RA- 4.67kPa (SD 1.42) than in PsA patients- 5.67 kPa (SD 3.34). In univariate analysis, liver stiffness determined by TE was found to be positively associated with the presence of psoriasis, age, insulin resistance, hypertension, metabolic syndrome and duration of MTX use. However, only presence of psoriasis (β=0.947; p=0.022), insulin resistance (β=0.815; p=0.043) and age (β=0.058; p<0.001) was found to be significant associative factors on multivariate analysis. At a cutoff point of 7.9 kPa, only 4.9 % of patients (3 RA and 3 PsA) had probable significant fibrosis. All 6 patients had cumulative MTX dose > 1500 mg. However, logistic regression analysis only found that hypertension (OR= 11.02, 95% CI: 1.13–107.5, p= 0.039) to be an independent risk factor for development of significant fibrosis. There is no correlation of MTX dose, duration of MTX use, and disease entity with significant fibrosis. 2 of these 6 patients had liver biopsies performed showing mild peri-portal fibrosis and steatosis.

Conclusion: PsA patient on MTX had higher liver stiffness than RA patients on TE. However, significant liver fibrosis was not common in these patients on methotrexate. Cumulative dose of MTX was probably not related to the development of significant liver fibrosis.

In Ankylosing Spondylitis, a Decrease in MRI Spinal Inflammation Predicts Improvement in Spinal Mobility Independently of Patient Reported Symptomatic Improvement. Pedro Machado[1], Robert Landewé[2], Jürgen Braun[3], Xenofon Baraliakos[3], Kay-Geert A. Hermann[4], Benjamin Hsu[5], Daniel Baker[5] and Désirée van der Heijde[1]. [1]Leiden University Medical Center, Leiden, Netherlands, [2]Academic Medical Center, University of Amsterdam and Atrium Medical Center, Heerlen, Netherlands, [3]Rheumazentrum Ruhrgebiet, Herne, Germany, [4]Charité Medical School, Berlin, Germany, [5]Centocor Inc., Malvern/Philadelphia, PA

Background/Purpose: It has been previously shown that spinal mobility in ankylosing spondylitis (AS) is associated with the level of inflammation of the spine. However an association does not necessarily imply causation and only longitudinal studies can evaluate if a change in an outcome measure translates into a subsequent change in the associated measure. Our aim was to study the relationship between change in MRI spinal inflammation and change in spinal mobility in patients with AS, taking potential confounders into account.

Methods: Baseline, 24- and 102-week data of a random 80% sample of the AS Study for the Evaluation of Recombinant Infliximab Therapy (ASSERT) cohort were used. Spinal mobility was expressed by the linear version of the Bath AS Metrology Index (BASMI), spinal inflammation by the AS spinal MRI activity (ASspiMRI-a) score and clinical disease activity by the Bath AS disease activity index or by the AS disease activity score (ASDAS). BASMI, ASspiMRI-a, BASDAI and ASDAS change scores were calculated (from baseline to 24 weeks and from 24 weeks to 102 weeks). The longitudinal association between change in BASMI (dependent variable) and change in ASspiMRI-a (independent variable) was investigated using generalised estimating equations (GEE). Potential confounders (change in BASDAI, change in ASDAS, change in C-reactive protein, gender, age, disease duration, body mass index, HLA-B27 status and baseline modified Stoke AS Spine Score (mSASSS)) and interactions were tested.

Results: In total 199 patients and 367 visits were analysed (31 patients did not have complete 102-week data). After taking potential confounders into account, multivariable GEE analysis showed that change in ASspiMRI-a, change in BASDAI and baseline mSASSS are longitudinally associated with change in BASMI (table 1, model A). When change in BASDAI was replaced by change in ASDAS in the multivariable model, only change in ASDAS and baseline mSASSS were significantly associated with change in BASMI, but not change in ASspiMRI-a (table 1, model B).

Table 1. GEE models for change in BASMI

Independent variable	Model A (with change in BASDAI) B (95% CI), p-value	Model B (with change in ASDAS) B (95% CI), p-value
Change in ASspiMRI-a	0.016 (0.001, 0.031), p=0.034	0.011 (−0.004, 0.026), p=0.152
Change in BASDAI/ASDAS	0.099 (0.065, 0.132), p<0.001	0.183 (0.122, 0.244), p<0.001
Baseline mSASSS	0.006 (0.003, 0.009), p<0.001	0.006 (0.003, 0.009), p<0.001

Conclusion: A decrease in MRI spinal inflammation predicts improvement in spinal mobility. This relationship is confounded by change in ASDAS but not by change in BASDAI. Spinal inflammation plays an important role in spinal mobility and therefore ASDAS (semi-objective) is a better means to follow (changes in) disease activity in AS than BASDAI (subjective). Therapeutic strategies specifically targeting MRI inflammation may contribute to improving spinal mobility of AS patients, independently of patient reported symptomatic improvement.

Almost 40% of Patients with Chronic Back Pain Starting Before the Age of 45 Fulfill the ASAS Axial Spondyloarthritis Criteria. Manouk de Hooge, Rosaline van den Berg, Floris van Gaalen, Monique Reijnierse, Tom Huizinga and Désirée van der Heijde. Leiden University Medical Center, Leiden, Netherlands

Background/Purpose: Chronic back pain is a very prevalent complaint in the general population but only a small proportion of these patients suffer from spondyloarthritis (SpA). Unfortunately, it is not clear when primary care or other physicians should refer a patient with chronic back pain to a rheumatologist. Many rheumatologists fear their practices will be overloaded with patients not having SpA if they have to see all patients with chronic back pain. Some have recommended inflammatory back pain (IBP) as the referral symptom but this is not an ideal criterion since many patients with SpA do not have IBP[1].

The purpose of this study is to describe how many patients with chronic back pain referred to the rheumatology outpatient clinic fulfill at least one of the classification criteria sets for spondyloarthritis (SpA).

Methods: We started the SpondyloArthritis Caught Early (SPACE)-project and included all (n=157) patients with chronic back pain (almost daily ≥3 months), starting before the age of 45 years of short duration (≤2 years). Patients were classified according to the modified New York (mNY), European SpA Study Group (ESSG), Amor and ASAS axial SpA classification criteria sets.

Results: In total, 93 (59.2%) patients fulfilled any of the criteria sets. Twelve (7.6%) patients fulfilled the mNY criteria; 68 (43.3%) patients fulfilled the ESSG criteria, 44 (28.0%) the Amor criteria and 60 (38.2%) the ASAS criteria for axial SpA. The overlap of the criteria is presented

in the table and the figure. Eight of the 12 patients who fulfill the mNY criteria also fulfilled all the other criteria sets. The one patient only fulfilling the mNY criteria and no other criteria sets has 'night pain' as only SpA feature.

Classification criteria sets	Patients (n)
No criteria set	64
Any criteria set	93
All criteria sets	8
All ASAS	60
All ESSG	68
All Amor	44
All mNY	12
Conclusion: Approximately 60% of the patients included in the SPACE-cohort fulfill at least one of the SpA criteria sets; 38% fulfill the ASAS axial SpA criteria. The selection criteria as used in the SPACE-project are easily applicable and work very well. Almost daily chronic back pain of short duration starting before the age of 45 years (in accordance with the entry criterion of the ASAS axial SpA criteria) appears to be a very good and simple referral strategy at a rheumatology department, with a high yield of patients with SpA.

Fetuin A: A New Biomarker Related with Syndesmophytes in Patients with Ankylosing Spondylitis. Tugba Tuylu[1], Dilek Solmaz[1], Ismail Sari[1], Didem L. Kozaci[2], Servet Akar[3], Necati Gunay[2] and Nurullah Akkoc[4]. [1]Dokuz Eylul University School of Medicine, Izmir, Turkey, [2]Adnan Menderes University School of Medicine, Aydin, Turkey, [3]Dokuz Eylul University School of Medicine Department of Internal Medicine Division of Rheumatology, Izmir, Turkey, [4]Dokuz Eylul University School Of Medicine, Department Of Internal Medicine, Division Of Rheumatology, Izmir, Turkey

Background/Purpose: In recent years, there is considerable interest regarding prediction and pathogenesis of syndesmophyte formation. Thus, several studies were conducted in order to identify the factors affecting this process. Today, biomarkers have become a very important field of research in spondyloarthropathy. In this regard, various biomarkers have been used to understand the underlying factors responsible from syndesmophyte forma-

tion. However, available data on this subject is still limited and additional information is required. In this study, we aimed to determine the levels of different biomarkers and analyze their relationships with syndesmophytes in ankylosing spondylitis (AS).

Methods: Lateral plain radiographs of the cervical and lumbar spine were used for scoring syndesmophytes. The anterior sites of the lower and upper portion of each vertebra were randomly and blindly scored by 2 experienced rheumatologists. Any presence of syndesmophytes or bridging syndesmophytes was categorized as positive. The following ELISA kits were studied: hsCRP, IL-6, dickkopf-1 (DKK-1), receptor activator of nuclear factor-κB ligand (RANKL), osteoprotegerin (OPG), bone morphogenetic protein-7 (BMP-7), and fetuin A.

Results: There were 86 patients (31 non-syndesmophyte, 65% male [M], 41.5±8.2 years; 55 with syndesmophyte, 71% M, 43.9±9.7 years) in the study group. Disease duration, age and sex distributions, BASFI and BAS-DAI were similar between the non-syndesmophyte and syndesmophyte groups (P > 0.05). However, BASMI values and current or past smoking history percentages were significantly different between the syndesmophyte negative and positive patients (P < 0.05, 3.18±1.5 vs. 4.53±1.9, and 86% vs. 58% respectively). Evaluation of soluble biomarkers revealed that the levels of OPG, sRANKL, DKK-1, sclerostin, and BMP-7 were comparable between AS patients with and without syndesmophytes (P > 0.05, table 2). However, fetuin A was significantly higher in the in the patients with syndesmophytes compared to non-syndesmophyte group (P < 0.05, Table 1). Correlation analysis showed that the presence of syndesmophytes were significantly and positively correlated with BASMI, current or past smoking history, and fetuin-A (P < 0.05, r= 0.3, 0.3 and 0.2 respectively). Regression analysis showed that fetuin A was the most important predictor of syndesmophytes (odds ratio, and 95% confidence interval = 31.2, and 0.94–1039).

Table 1. Laboratory characteristics of the study group

	AS patients		
	Syndesmophyte (+), n= 55	Syndesmophyte (−), n= 31	P value
DKK-1 (pg/ml)	1967±1318	1718±1054	0.37
Sclerostin (pg/ml)	143±117	130±116	0.64
sRANKL (pmol/l)	110±95	130±74	0.32
OPG (pg/ml)	1916±593	1905±493	0.93
BMP-7 (pg/ml)	7.8±14	8.4±17	0.87
Fetuin-A (mg/ml)	1.15±0.17	1.08±0.12	0.04
hsCRP (mg/ml)	9.9±6.4	9.2±7.1	0.62
IL-6 (ng/ml)	0.003±0.001	0.003±0.001	0.86

Conclusion: We suggest that fetuin A may be used as a novel biomarker to predict new bone formation in patients with AS.

Effect of TNF Antagonists On Radiographic Progression in Psoriatic Arthritis: Systematic Review and Meta-Analysis of Randomized Controlled Trials. Radjiv Goulabchand[1], Gael Mouterde[1], Cédric Lukas[1], Thomas Barnetche[2], Jacques Morel[1] and Bernard Combe[1]. [1]Montpellier 1 University, Lapeyronie Hospital, Montpellier, France, [2]CHU Bordeaux Pellegrin, Bordeaux, France

Background/Purpose: Psoriatic arthritis (PsA) can cause important structural damages which can lead to disability. TNF antagonists have shown their clinical efficacy in PsA, but only limited data are available regarding their structural effect.

To determine whether TNF antagonists have an effect on radiographic progression in patients with PsA by performing a systematic review and meta-analysis based on data from randomized controlled trials (RCTs) versus placebo. To evaluate whether the combination with methotrexate (MTX) has an additional efficacy over monotherapy.

Methods: A systematic review of literature was performed until March 2011. Bibliographic references were selected from Embase and Medline databases, and from the two last EULAR and ACR annual meetings. Radiographic progression was scored by Sharp method modified for PsA (mTSS). Primary endpoint was the proportion of patients showing no radiographic progression at week 24 (defined by a mTSS variation score ≤ 0.5). Secondary end point included the proportion of non progressors at week 48 and mean variation of mTSS at week 24. The

Mantel-Haenszel method was used to provide a common odds-ratio (OR) estimate and 95% confidence interval (CI) in TNF antagonists (+/− DMARDs) versus placebo (+/− DMARDs) treated patients for inflix- imab, etanercept, adalimumab and golimumab RCTs. Statistical hetero- geneity was assessed by the Q test (χ^2), using a significance level of 0.05. OR and 95% CI were shown on forest plots.

Results: Search found out 206 articles and 3 abstracts. Retrieved data allowed meta-analysis on 4 articles and 1 abstract for the proportion of non progressors at week 24. Data from 1110 patients were pooled, 484/584 (82,9%) were considered as non-progressors at week 24 in the TNF antagonists group versus 362/526 (68,8%) in the placebo group (OR=2.68 [1.99; 3.60] p<0.0001), without significant heterogeneity (I^2=3%;p=0.39) (*figure 1*). Based on 3 studies, similar results were found at week 48 in favor of TNF antagonists group (OR=2.42 [1.57;3.71] I^2=0%;p=0.91). Among 533 patients receiving TNF antagonists versus 454 receiving placebo in 3 studies (4 comparisons), the mean change of the mTSS at week 24 was lower in the TNF antagonist group versus placebo (mean difference= −0,69 [−1.12; −0.27], with substantial heterogeneity (I^2=76%;p=0.006). Only two RCTs provided data on the combination with MTX: the mean or median change of the mTSS was similar in adalimumab or infliximab subgroups, irrespective of the MTX use.

Conclusion: This meta-analysis of RCTs showed that all TNF antagonists lead to a better control of structural damage due to PsA than a placebo after 24 and 48 weeks of treatment. The respective role of the additional DMARDS could not be determined due to a lack of data.

Prevalence of Psoriasis and Psoriatic Arthritis in a Northern Population of Spain. Jose Luis Fernandez-Sueiro[1], JA Pinto[1], S. Pertega-Diaz[1], Manuel Acasuso[2] and Ignacio Herrero de Padura[2]. [1]Complejo Hospitalario Univer- sitario La Coruña, La Coruña, Spain, [2]Centro de Salud, San José, La Coruña, Spain

Background/Purpose: There are few data in Spain evaluating the prevalence of psoriasis in the general population, accordingly there are not data evaluating the prevalence of psoriatic arthritis in Spain.

Objectives: to estimate the prevalence of psoriasis and PsA in the general population. To estimate the prevalence of PsA in patients with cutaneous psoriasis, referred from the primary care and the prevalence in of PsA in the general population.

Methods: All patients identified with a diagnose code of cutaneous psoriasis or PsA, from the database of a primary care centre (San José from La Coruña, northwest of Spain) were invited to participate in the study by a telephonic call. Patients were evaluated in the following way: personal and family history, criteria for inflammatory back pain (IBP), spinal and peripheral pain (VAS), peripheral joint count: tender and swollen (78/76), metrology (cervical rotation (CR), occiput to wall distance (OW), lateral lumbar flexion (LLF), modified Schober (mS)), MASES, SF12, DLQI, PASI, BSA, 'peripheral and axial x-rays, ESR, CRP, anti CCP and HLA-B27. Case definition was made according to clinical judgement. A descriptive analysis of the variables was performed. Prevalence estimates were obtained, together with their 95% confidence intervals. Adjustment to the prevalence figures was made based on detected erroneous psoriasis coding.

Results: From a referral population of 36610 persons, 458 patients were identified with a code diagnosis of psoriasis or PsA. From those, 21 had already a diagnosis of PsA, 161 agreed to participate, 126 came to the hospital. From those, 4 patients were excluded because they do not have a diagnosis of psoriasis, at the end 122 psoriatic patients without arthritis were evaluated.

From a total of 122 patients studied, 12 patients were judged to have a clinical diagnosis of PsA. This leads to an estimated prevalence of PsA in psoriatic patients of 9.8% (95% IC: 4.1%–15.5%). From these figures, the estimated prevalence of cutaneous psoriasis in the general population was 1,2% (95% CI=1,1%–1,3%), whereas the prevalence of PsA in the general population taken into account all cases was 0,17% (95% CI=0,13%–0,21%). The prevalence of undiagnosed cases was 0,06% (95% CI=0,03%–0,08%). The clinical features of the patients 12 patients diagnosed as PsA were as follows: nail involvement: 25%, dactylitis

8.3%. Nocturnal and overall spinal pain past week 3.25±3.57 and 4.17±3.35, peripheral VAS 6.33±3.31, TJC 4.50±9.04, SJC 0.00, mS 4.48±1.03, OW 0.00, LLF 14.92±4.42. CR <70°: 8.3%, enthesitis 41,7%, PASI 0,33±1,15, BSA <10%: 100%, DLQI 1.42±1.56 SF12 physical 43.09±11.39, SF12 mental 39.28±12.11, ESR≤20 70%, CRP <0.8 80%, anti-CCP ≤25 100%, Negative FR 91.7%. Negative HLA-B27 91.7%. Peripheral erosions 18.2%, sacroiliitis grade II unilateral or higher 45.5%

Conclusion: In this study, the estimated prevalence of cutaneous psoriasis in a northern general population of Spain was 1.2%. The estimate (clinically judged) prevalence of psoriatic arthritis in patients with psoriasis was 9.8%, and the estimate prevalence of psoriatic arthritis in the general population was 0,17%, of these 0,06% of the cases may be undiagnosed.

14-3-3 Eta Is a Modifiable Serum Biomarker That Marks Adalimumab Response in Psoriatic Arthritis. Anthony Marotta[1], A. W van Kuijk[2], Walter P. Maksymowych[3] and Paul Peter Tak[4]. [1]Augurex Life Sciences Corp, North Vancouver, BC, [2]Academic Medical Centre/University of Amsterdam, Amsterdam, Netherlands, [3]University of Alberta, Edmonton, AB, [4]Academic Medical Center/University of Amsterdam, Amsterdam, Netherlands

Background/Purpose: 14-3-3 eta is a synovial-derived biomarker whose serum expression is independently associated with joint damage in RA and PsA. We previously reported that 14-3-3 eta pre-treatment levels predict a Good EULAR response in RA patients on anti-TNF therapy and that the change in 14-3-3 eta titres correlates with measures of clinical improvement. We therefore examined whether a change in 14-3-3 eta expression may also serve as a useful marker of adalimumab therapy response monitoring in PsA.

Methods: Serum 14-3-3 eta levels of 24 patients (15 males and 9 females) with active PsA fulfilling the CASPAR classification criteria were measured before receiving adalimumab therapy and 8- or 12-weeks post-treatment. Clinical assessment at those time points included SJC68, PASI, CRP, ESR, DAS28 and ACR50 response. Pearson correlations (r) were performed to examine relationships between the changes in clinical variables and the change in 14-3-3 eta (Δ14-3-3 eta). Contingency analysis was used to determine if absolute decrease, increase or no change in 14-3-3 eta post-treatment levels corresponded with an ACR50 response. Regression analyses were performed to determine the predictive power of changes in CRP (ΔCRP) and Δ14-3-3 eta for that response, represented by the significance of chi-square likelihood ratios (LR). Areas under the receiver operating characteristic curves (AUC) were used to determine the accuracy of the regression model.

Results: Of the 24 PsA patients, 10 patients achieved an ACR50 response while 14 did not. Baseline 14-3-3 eta titres were predictive of an ACR50 response delivering a significant LR=5.53, p=0.02, AUC=0.75 which increased to a LR=8.35, p=0.02, AUC=0.83 when Δ14-3-3 eta was added to the model. Contingency analysis reveals that a post- treatment decrease as compared to no change or an increase in 14-3-3 eta titres in PsA patients reflected a 10.2 times greater likelihood of achieving an ACR50 response to adalimumab therapy (p=0.001) with a relative risk of 3.6 (95%CI 1.71 to 7.58). Δ14-3-3 eta correlated moderately with the following clinical response variables; ΔCRP r=0.58, p=0.004, ΔESR r=0.47, p=0.02 and ΔPASI r=0.49, p=0.02. Consistent with published data, the ΔCRP reflected ACR50 response LR=5.98, AUC=0.74, p=0.01 with the model strengthened when 14-3-3 eta baseline positivity was added LR=10.1, p=0.006, AUC= 0.87.

Conclusion: In PsA, 14-3-3 eta titres together with a decrease in the levels of 14-3-3 eta following treatment is independently associated with ACR50 response to adalimumab therapy. 14-3-3 eta enhances the predic- tive capacity of CRP and serves as a biomarker of treatment response for both RA and PsA.

Ustekinumab Improves Arthritis-Related and Skin-Related Quality of Life in Patients with Active Psoriatic Arthritis: Patient Reported Outcomes From Randomized and Double Blinded Phase III Psummit I Trial.

Arthur Kavanaugh[1], Iain B. McInnes[2], Alice B. Gottlieb[3], Lluis Puig[4], Proton Rahman[5], Christopher T. Ritchlin[6], Shu Li[7], Yuhua Wang[7], Chenglong Han[8], Alan Mendelsohn[7] and Mittie K. Doyle[7]. [1]UCSD School of Medicine, La Jolla, CA, [2]University of Glasgow, Glasgow, United Kingdom, [3]Tufts Medical Center, Boston, MA, [4]Universitat Autònoma de Barcelona, [5]Memorial University, St. Johns, NF, [6]University of Rochester Medical Center, Rochester, NY, [7]Janssen Research & Development, LLC, Spring House, PA, [8]Johnson & Johnson Pharmaceutical Services, LLC., Malvern, PA

Background/Purpose: To examine the impact of ustekinumab treatment on general and disease specific patient reported outcomes (PROs) of patients with active psoriatic arthritis (PsA) using data from PSUMMIT 1, a Phase 3 clinical study.

Methods: In PSUMMIT I, adult PsA patients (n=615) with active disease despite DMARD and/or NSAID therapy were randomized to receive ustekinumab 45mg, 90mg, or placebo (PBO) at wks 0, 4, and q12wks, thereafter. Patients treated with prior anti-TNF agents were excluded. At wk16, patient with <5% improvement in swollen and tender joint counts entered blinded early escape (PBO→ ustekinumab 45mg; ustekinumab 45mg→90mg; 90mg→90mg). Patient reported outcomes were measured with Health Assessment Questionnaire (HAQ), Dermatology Quality Life Index (DLQI), SF-36 health survey questionnaire (SF-36), Visual Analogue Scales (VAS) for impact of PsA on work productivity (0–10), patient assessment of pain (0–10) and disease activity (0–10). An ANOVA on van der Waerden normal scores was used for continuous variables and chi-square or the Cochran-Mantel-Haenszel (CMH) test for binary variables between groups.

Results: At baseline, PRO measures indicated that the study population had severe physical disability and impaired health related quality of life with a mean HAQ score of 1.25 and mean DLQI score of ≥10. At wk 24, greater improvements in HAQ, DLQI, and SF-36 PCS were observed in ustekinumab groups compared to the PBO group. Proportions of patient who achieved clinical meaningful improvements in HAQ (≥0.3), DLQI (≥5), and SF-36 PCS (≥5) were greater in the ustekinumab 45mg or 90 mg group than in the PBO group. Additionally, ustekinumab-treated patients also achieved greater improvements in patient assessment of pain, patient assessment of disease activity and greater reduction in impact of disease on work productivity than PBO-treated patients (Table).

Table. Baseline Characteristics and Change in Patient Reported Outcomes at Week 24 by Treatment Group: Results from PSUMMIT I

PROs at Week 24	PBO (N=206)	Ustekinumab 45mg (N=205)	Ustekinumab 90mg (N=204)
Age (years)	47.4	47.1	46.8
Male Gender (%)	52.4	51.7	56.9
Baseline HAQ (0–3)	1.2	1.2	1.2
Baseline DLQI (0–30)[a]	11.7	11.0	10.5
Baseline SF-36 PCS (0–100)	36.2	35.7	36.5
Baseline SF-36 MCS (0–100)	41.9	43.1	42.1
Mean improvement in DLQI	1.4	6.6++	7.5++
Achieving DLQI score of 0 or 1 (%)	8.3	37.2++	53++
Mean improvement in HAQ	0.1	0.31++	0.4++
Improvement in HAQ≥0.3 (%)	28.2	47.8++	47.5++
Mean Change in SF36 PCS	0.3	3.0++	3.3++
Improvement in SF-36 PCS ≥5 (%)	17.9	30.5+	38.1++
Mean Change in SF-36 MCS	1.2	0.5	2.5*
Improvement in SF-36 MCS ≥5 (%)	30.1	23	36.5
Percent improvement in pain	4.5	25.9++	29.6++
Percent improvement in disease activity	7.6	25.4++	27.6++
Mean improvement in productivity	0.78	1.82++	2.64++

*Data presented were mean or percent; Compared with PBO, * p<0.05, +, p<0.01; +, p<0.001;*
[a]: *Footnote DLQI only for Patients with baseline BSA>=3%.*

Conclusion: Ustekinumab improves general as well as arthritis and skin-related quality of life, and reduces the impact of disease on work productivity in patients with active PsA.

570

Randomized Controlled Trial of Adalimumab in Patients with Peripheral Spondyloarthritis.

Philip Mease[1], Joachim Sieper[2], Filip Van den Bosch[3], Proton Rahman[4], Katie Obermeyer[5] and Aileen L. Pangan[5]. [1]Swedish Medical Center, Seattle, WA, [2]Charité Universitätesmedizin Berlin, Berlin, Germany, [3]Ghent University Hospital, Ghent, Belgium, [4]Memorial University, St. Johns, NF, [5]Abbott Laboratories, Abbott Park, IL

Background/Purpose: Adalimumab (ADA) is indicated for the treatment of psoriatic arthritis (PsA) and ankylosing spondylitis (AS). Patients (pts) with peripheral spondyloarthritis (SpA) not previously diagnosed with psoriasis or PsA (non-PsA), presenting primarily with arthritis, enthesitis and/or dactylitis, may also benefit from anti-TNF therapy. ABILITY-2, the first randomized controlled trial to use the ASAS peripheral SpA criteria[1] to classify pts for study entry, evaluated the efficacy and safety of ADA in pts with active non-PsA peripheral SpA.

Methods: ABILITY-2 is an ongoing, multicenter phase 3 study. Eligible pts were age ≥18 yrs, fulfilled ASAS peripheral SpA criteria, did not have a diagnosis of psoriasis, PsA, or AS, and had inadequate response or intolerance to NSAIDs. Pts were randomized 1:1 to ADA 40 mg every other wk or placebo (PBO) for 12 wks followed by a 144-wk open-label extension. Primary endpoint was the proportion of pts achieving peripheral SpA response criteria (PSpARC 40) at wk 12: ≥40% improvement (≥20 mm absolute improvement in VAS) from baseline (BL) in Pt's Global Assessment of Disease Activity (PGA) and of pain (PGA-pain) and ≥40% improvement in ≥1 of the following: swollen joint count (SJC) and tender joint count (TJC); Enthesitis Count, or Dactylitis Count. Other outcomes analyzed included Physician's Global Assessment (PhGA), BASDAI, enthesitis indices, PSpARC 20/50/70 responses, HAQ-S, and SF-36v2. Adverse events (AE) were collected throughout the study.

Results: 165 pts (ADA 84/PBO 81) were randomized. BL demographics/ disease characteristics were similar between groups, except for mean age and % pts with dactylitis count>0. BL characteristics include (ADA/PBO): 57/52% female, 67/56% HLA-B27+, mean TJC 13.0/13.6, mean SJC 6.1/7.3, mean enthesitis count 6.7/7.3, and dactylitis count 0.4/0.7. At Wk 12, the % of ADA pts achieving PSpARC 40 was higher vs. PBO (P=0.006) (table), primarily due to the proportion of patients meeting the PGA, PGA-pain, and TJC/SJC components. Overall, improvement based on other outcomes was greater with ADA vs. PBO. AE incidence rates were similar [ADA/PBO (%)]: any AEs (54.8/54.3), serious AEs (1.2/1.2), and infectious AEs (21.4/28.4); there were no serious infections, TB, or malignancies during the double-blind period.

Table. Week 12 Efficacy Outcomes

	ADA N=84	PBO N=81	P value[a]
Primary endpoint[b]			
PSpARC 40, %	39.3	19.8	0.006
Proportion of patients achieving improvement in each PSpARC 40 component [c] (≥40% improvement, plus ≥20 mm improvement in PGA and PGA-pain VAS)			
PGA, %	54.3	28.8	<0.001
PGA pain, %	53.7	31.3	0.004
TJC/SJC, %	57.3	29.6	<0.001
Enthesitis, %	51.2	42.0	0.237
Dactylitis, %	13.6	18.5	0.392
Other efficacy endpoints			
PSpARC 20[b], %	56.0	37.0	0.015
PSpARC 50[b], %	34.5	11.1	<0.001
PSpARC 70[b], %	22.6	3.7	<0.001
PGA[d] (VAS 0–100), mm	−27.5	−16.4	0.003
PGA-pain[d] (VAS 0–100), mm	−28.9	−17.1	0.001
PhGA[d] (VAS 0–100), mm	−32.2	−18.2	<0.001
BASDAI[d]	−2.1	−1.0	0.003
TJC[d] (0–78)	−5.9	−1.8	<0.001
SJC[d] (0–76)	−3.6	−3.1	0.045
Leeds enthesitis index[d] (0–6)	−0.8	−0.1	<0.001
SPARCC enthesitis index[d] (0–16)	−1.7	−0.7	<0.001
Dactylitis count[d] (0–20)	−0.2	−0.3	0.808
SF-36v2 PCS[e]	6.7	2.4	<0.001
HAQ-S score[d]	−0.3	−0.2	0.051

Values are mean change unless otherwise indicated; Ns may vary by outcome. [a]ADA vs. PBO; [b]NRI; [c]Observed analysis; [d]LOCF; [e]Observed data (N=83/79, ADA/PBO). ADA, adalimumab; BASDAI, Bath Ankylosing Spondylitis Disease Activity Index; HAQ-S, Health Assessment Questionnaire modified for spondyloarthropathies; PBO, placebo; PGA, patient's global assessment of disease activity; PGA-pain, patient's global assessment of pain; PhGA, physician's global assessment; PSpARC, peripheral spondyloarthritis response criteria; PSpARC 20, ≥20% (≥10 mm in VAS) improvement; PSpARC 50, ≥ 50% (≥20 mm in VAS) improvement; PSpARC 70, ≥70% (≥30 mm in VAS) improvement; SF-36v2 PCS, short form-36 health status survey version 2 physical component summary; SJC, swollen joint count; SPARCC, Spondyloarthritis Research Consortium of Canada; TJC, tender joint count.

Conclusion: Adalimumab significantly improved signs, symptoms, and physical function of pts with active non-PsA peripheral SpA and was well-tolerated. ABILITY-2 results suggest that ADA may be an effective treatment option for non-PsA peripheral SpA pts with inadequate response or intolerance to NSAIDs. Further, these results suggest that the PSpARC assessment instrument, pioneered in this study to evaluate this patient population, is a responsive and discriminative outcome measure.

Description of Distribution of Active Inflammatory Lesions On Magnetic Resonance Imaging of the Sacroiliac Joints and the Spine in Patients with Early Axial Spondyloarthritis – Analysis of the Esther Trial baseline Data.
In-Ho Song[1], Christian Althoff[2], Hildrun Haibel[1], Joachim Listing[3], Anja Weiβ[4], Bruce Freundlich[5], Martin Rudwaleit[6] and Joachim Sieper[7]. [1]Charité Medical University, Campus Benjamin Franklin, Berlin, Germany, [2]Charite Medical School, Berlin, Germany, [3]German Rheumatism Research Center, Berlin, Germany, [4]German Rheumatism Research Centre, Berlin, Germany, [5]Villanova, PA, [6]Endokrinologikum Berlin, Berlin, Germany, [7]Charité Universitätesmedizin Berlin, Berlin, Germany

Background/Purpose: To address the question whether active inflammation starts at specific sites of the sacroiliac joints (SI-joints) and/ or the spine.

Methods: Wb-MRIs of 75 patients with early axial spondyloarthritis (SpA) with a disease duration of < 5 years [1] were scored for active inflammatory lesions on STIR sequences and T1 weighted images in the 23 vertebral units (VUs) of the spine and in the 8 sacroiliac (SI)-joint quadrants. Scoring was performed by two blinded radiologists.

Results: In the total group of patients, 52% (39/75) showed active inflammation only at the SI-joints (active sacroiliitis), 41.3% (31/75) in the SI-joints and the spine and 5.3 (4/75) only in the spine (isolated spinal inflammation).

Mean scores for active inflammatory changes were 6.7 (SD 5.8) out of possible 24 points for the SI-joints and 1.9 (SD 3.3) out of possible 69 for the spine.

Active inflammation in the SI-joint quadrants were found as the following (in decreasing order): quadrant I (sacral bone, upper quadrant; 66% of patients, n= 50); quadrant II (sacral bone, lower quadrant; 60%, n= 45), quadrant IV (iliac bone, upper quadrant, 53%, n= 40) and quadrant III (iliac bone, lower quadrant, 69%, n=52).

The most frequently affected sites of active inflammation in the spine were the lower thoracic spine and the lumbar spine: in decreasing order the most frequently affected VUs were T6/T7 (n= 11), T10/T11 (n= 11), T7/T8 (n= 10), L1/L2 (n= 10) and L4/L5 (n= 9) and L5/S1 (n= 9). The cervical spine was less often affected.

Table. Distribution of active inflammation in the Sacroiliac Joint Quadrants and the Spinal vertebral units

Anatomie site	Percentage of affected patients
SI-joint quadrant I (sacral bone, upper quadrant)	66%
SI-joint quadrant II (sacral bone, lower quadrant)	60%
SI-joint quadrant IV (iliac bone, upper quadrant)	53%
SI-joint quadrant III (iliac bone, lower quadrant)	69%
C2/C3	3%
C3/C4	1%
C4/C5	1%
C5/C6	4%
C6/C7	7%
C7/T1	3%
T1/T2	4%
T2/T3	7%
T3/T4	7%
T4/T5	9%
T5/T6	8%
T6/T7	15%
T7/T8	13%
T8/T9	11%
T9/T10	8%
T10/T11	15%
T11/T12	5%
T12/L1	8%
L1/L2	13%
L2/L3	9%
L3/L4	11%
L4/L5	12%
L5/S1	12%

[1] Song I.-H. et al. 2011. Ann Rheum Dis. 2011 Apr;70(4):590–6.

Conclusion: In this cohort of early axial SpA patients there was no significant predilection of SI-joint quadrants affected by active inflammtion. In the spine the thoracic and lumbar parts were mostly affected.

572

Radiographic Damage in Ankylosing Spondylitis Over 12 Years of Follow-up: A Longitudinal Analysis.
Sofia Ramiro[1], Carmen Stolwijk[2], A.M. Van Tubergen[2], Désirée van der Heijde[3] and Robert Landewé[4]. [1]Academic Medical Center, University of Amsterdam, The Netherlands and Hospital Garcia de Orta, Almada, Portugal, [2]Maastricht University Medical Center, Maastricht, Netherlands, [3]Leiden University Medical Center, Leiden, Netherlands, [4]Academic Medical Center, University of Amsterdam and Atrium Medical Center, Heerlen, Netherlands

Background/Purpose: Radiographic damage is one of the core outcomes recommended by the Assessment in Spondyloarthritis international Society (ASAS) for follow-up of patients with axial SpA. So far, the evolution of radiographic damage over a long period has not been described in detail. We aimed to describe the evolution of radiographic abnormalities over time in a prevalence cohort of patients with ankylosing spondylitis (AS).

Methods: The modified Stoke AS Spine Score (mSASSS) was calculated using 2-yearly radiographs of patients followed for 12 years in the Outcome in AS International Study (OASIS). Two readers independently scored the x-rays and scores were averaged. Status and progression scores (2- and 12-year-progression) were computed for patients with at least one 2-year interval available (n=186) and for those with an mSASSS at 12-years (n=68). New syndesmophytes at vertebral corners (VCs) "at risk" (i.e. without a previous syndesmophyte or bridge) were computed. Radiographic progression over time was investigated using generalized estimating equations. Relevant interactions with time were explored. Time was modeled in different forms (linear and non-linear) and the best model fit was assessed using the quasi-likelihood information criterion.

Results: 809 radiographs of 186 patients (70% males, mean (SD) age 43(12) years, mean disease duration 11.0(8.8) years and 83% HLA-B27 positive) were included. The mean (SD) mSASSS at baseline was 11.6 (16.2) [11.2 (15.7) in patients with mSASSS at 12-years]. The mean (SD) 2-year interval progression score (in 520 2-year intervals) was 2.0 (3.5) [2.2 (3.9) for the subset of 12-year-completers]. Over the 12 years, the mean (SD) progression was 11.7 (11.5). A new syndesmophyte was assessed in 38% by one reader (R1) and 39% by reader 2 of all 2-year intervals and, throughout follow-up, in 55% (R1) and 63% (R2) of the patients with at least one VC "at risk". In 24% of the patients (39% of the 2-year intervals) there was no progression in mSASSS. A progression ≥1 mSASSS occurred in 72% of the patients (54% of the intervals) and a progression ≥5 mSASSS in 22% of the patients (12% of the intervals). At the group level, a linear time course model fitted the observed data the best. Time was positively associated with radiographic progression, with an increase of 0.98 mSASSS/year (≈1.96 mSASSS in 2 years) (Table).

Table. Progression of radiographic damage over time

	Univariable regression analysis β (95% CI)	P-value
Time (years)	0.98 (0.84;1.12)	<0.001
Time × HLAB27		0.052
– Time in HLAB27 negative	0.70 (0.48;0.90)	<0.001
– Time in HLAB27 positive	1.03 (0.88;1.19)	<0.001
Time × gender		0.005
– Time in women	0.69 (0.57;0.80)	<0.001
– Time in men	1.11 (0.93;1.29)	<0.001
Time × HLAB27 in women		0.958
Time × HLAB27 in men		0.044
– Time in female HLAB27 positive	0.69 (0.34;1.03)	<0.001
– Time in male HLAB27 positive	1.18 (0.98;1.38)	<0.001
Time × disease duration		0.701
Time × symptom duration		0.214

Radiographic progression occurred significantly faster in males (vs females) and in HLA-B27 positive patients (vs HLA-B27 negative). HLA-B27 positive male (but not female) patients had a significantly higher progression than HLA-B27 negative males. Progression was independent of disease- and symptom duration.

Conclusion: Long-term radiographic progression in AS is more severe in HLA-B27-positive males. About 60% of all patients have at least one new syndesmophyte. Radiographic progression is dependent on time and, at the group level, linear.

573

Differential Association Between Human Leukocyte Antigen (HLA) Alleles and Joint Subluxation and Ankylosis in Patients with Psoriatic Arthritis. Vinod Chandran, Arane Thavaneswaran, Amir Haddad, Fawnda Pellett and Dafna Gladman. Toronto Western Hospital and University of Toronto, Toronto, ON

Background/Purpose: We have previously reported the association between HLA and KIR gene variants with the development of Arthritis Mutilans (AM) in psoriatic arthritis (PsA). However, severe joint damage in PsA may be further classified into disorganization, subluxation, pencil-in-cup change and ankylosis. We therefore sought to determine whether previously identified *HLA* and *KIR* variants associated with AM also associate with sub-phenotypes of AM.

Methods: Data on the presence of severe joint were obtained form a large cohort. Radiographs of the hands, feet and spine are obtained at baseline and 2-yearly intervals and scored according to the modified Steinbrocker method by at least 2 rheumatologists by consensus. Grade 4 is considered severe joint destruction Radiographs previously rated as 4 were reviewed and reclassified as disorganization (4.0), subluxation (4.1), pencil-in-cup change (4.2) and ankylosis (4.3). Data on the time when severe joint destruction was first observed was obtained on 555 Caucasian subjects with PsA satisfying CASPAR criteria who were seen in the clinic within 5 years of diagnosis. HLA typing was performed by PCR-SSO, and KIR typing by PCR-SSP. The principal outcome measure was the time to development of severe joint destruction after diagnosis of PsA. Parametric survival analyses with interval censoring using a Weibull model adjusted for age at diagnosis of PsA and sex were conducted. Gene variants previously reported to be associated with arthritis mutilans- HLA-A*11, -A*29, -B*27, -C*02, -C*03, -C*04, -DQB1*02 and KIR3DS1 were predictor variables.

Results: The 555 subjects 312 (56.2%) males, mean age at diagnosis of 40 (13.5) years, mean age at first visit 42 (13.3) years, mean duration of PsA 2.0 (1.7) years, mean tender joint count 7.9 (7.9), mean swollen joint count 4.9 (5.4)] had a median number of 3.4 (3.1) radiographic assessments during a median follow up of 6.9 (8.4) years. 102 (19%) subjects were observed to develop severe joint damage. No association between 4.0 and gene variants could be demonstrated. Univariate analyses adjusted for age and sex showed that HLA- C*02 (p=0.06) and -B*27 (p=0.004) were associated with an increased hazard of developing 4.1. Multivariate analysis with alleles significant at p<0.1 showed that only HLA-B*27 (HR 2.76, 95% CI (1.39, 5.49), p=0.004) was associated with increased hazard of developing 4.1.

When analyzing 4.2, no association with HLA alleles and only a trend for association with KIR3DS1 (HR 1.72, p=0.08) was demonstrated. Association between 4.3 and HLA-DQB1*02 (p=0.03) was found on univariate analysis adjusted for age and sex. Multivariate analysis revealed that HLA- DQB1*02 (HR 1.86, 95% CI (1.09, 3.18)), p=0.02) was associated with increased hazard of developing 4.3, and there was a trend for association with KIR3DS1 (HR = 1.61, 95% CI (0.98, 2.64), p=0.06).

Conclusion: Differential HLA association with sub-phenotypes of severe damage was demonstrated. HLA-B*27 was associated with increased risk of subluxation, whereas - DQB1*02 was associated with increased risk of ankylosis.

574

Long Term Inhibition of Interleukin (IL)-17A with Secukinumab Improves Clinical Symptoms and Reduces Spinal Inflammation As Assessed by Magnetic Resonance Imaging in Patients with Ankylosing Spondylitis. Xenofon Baraliakos[1], Jurgen Braun[1], D. D. Laurent[2], D. Baeten[3], D. van der Heijde[4], J. Sieper[5], Paul Emery[6], Iain B. McInnes[7], J. van Laar[8], R. Landewe[9], Paul Wordsworth[10], Jurgen Wollenhaupt[11], Herbert Kellner[12], Andrew Wright[2], Francois Vandenhende[13], Kath Radford[14], Babul Borah[14] and Hueber Wolfgang[14]. [1]Rheumazentrum Ruhrgebiet, Herne, Germany, [2]Novartis Pharma AG, Basel, Switzerland, [3]Academic Medical Center, University of Amsterdam, Amsterdam, Netherlands, [4]Leiden University Medical Center, Leiden, Netherlands, [5]Charitè Berlin, Campus Benjamin Franklin, Berlin, Germany, [6]University of Leeds, Leeds, United Kingdom, [7]University of Glasgow, Glasgow, United Kingdom, [8]Newcastle University, Newcastle upon Tyne, United Kingdom, [9]Academic Medical Center/University of Amsterdam, Amsterdam, Netherlands, [10]Nuffield Orthopaedic Centre, Oxford, United Kingdom, [11]Schoen-Klinik Hamburg-Eilbek Teaching Hospital of the University of Hamburg, Hamburg, Germany, [12]Centre for Inflammatory Joint Diseases, Munich, Germany, Munich, Germany, [13]Clinbay, Genappe, Belgium, Genappe, Belgium, [14]Novartis Institutes for BioMedical Research, Basel, Switzerland

Background/Purpose: In a recent proof-of-concept (PoC) trial it was shown that secukinumab, a fully human IgG1k anti-IL17A monoclonal antibody, significantly improved clinical signs and symptoms of patients with active ankylosing spondylitis (AS). Magnetic resonance images (MRI) of these patients showed reduction of spinal inflammation at week (wk) 6 and wk 28 after initiation of treatment. Here we report on a subgroup of patients (N=13) who entered the open label extension study, received and completed treatment and had MRI assessments at wk 28 and up to 24 months.

Methods: In the 28-wk PoC study, 27/30 patients had sequential MRI studies, 22 had received secukinumab 2×10 mg/kg administered intravenously 3 wks apart, and 5 patients had been randomized to placebo. Of those 27 patients, 20 entered the extension study. 13 of these 20 patients had MRI data at wk 94. Of these 13, ten had been treated with secukinumab and 3 with placebo in the core study. In the extension study, all received secukinumab 14×3 mg/kg administered 4 wks apart. MRIs (T1 and STIR) were rescored for this study by analyzing the images from baseline (BL), wk 28 and wk 94. All MRIs were analyzed together by an independent blinded reader using the ASspiMRI-a scoring system, and also recording the amount of vertebral edges (VEs) which showed inflammation or fatty degeneration at the different time points.

Results: All 13 patients completed the study. For patients receiving 2×10 mg/kg secukinumab followed by 14×3 mg/kg (n=10, group 1), or receiving placebo followed by secukinumab 14×3 mg/kg (n=3, group 2), the ASAS20 and ASAS40 responses are shown in Table 1. In group 1, ASspiMRI-a scores were reduced in comparison to BL at wk 28 – similar to the results of the core study – and these reduced scores were sustained at a similar level at wk 94 (Table 1). Of the 920 VEs evaluated, the proportion of inflammatory lesions was reduced from 9.9% (N=91) at BL to 3.7% (N=34) at wk 28 and 3.6% (N=33) at wk 94. There was no increase in the number of VEs with fatty lesions between BL and wk 28 and 94 (Table 1). In the 3 patients who had initially received placebo and who were then switched to secukinumab at wk 28 (group 2), MRI inflammatory scores at wk 94 also improved (Table 1).

Table 1. Clinical and MRI parameters in patients receiving secukinumab 2 × 10 mg/kg followed by 14 × 3 mg/kg monthly (group 1), or placebo followed by secukinumab 14 × 3 mg/kg monthly (group 2)

| | Secukinumab alone (group 1) | | | Placebo/Secukinumab (group 2) | | |
	BL	Secukinumab 2 × 10 mg/kg Week 28	Secukinumab 14 × 3 mg/kg Week 94	BL	Placebo Week 28	Secukinumab 14 × 3 mg/kg Week 94
Number of Patients	10	10	10	3	3	3
ASAS20/ASAS40 Responders	-	4/2	6/5	-	1/0	2/1
ASspiMRPa Mean ± SD	8.8+/−12.2	3.4 ± 7.3	3.3 ± 4.4	20.0+/−23.3	19.7+/−23.0	12.7+/−20.2
p value (vs BL)		0.036	0.107		0.667	0.148
Number of VEs evaluated	920	920	920	276	276	276
Number (%) of VEs with inflammation	91 (9.9)	34 (3.7)	33 (3.6)	64 (23.2)	64 (23.2)	35 (12.7)
Number (%) of VEs with Fatty lesions	124 (13.5)	132 (14.3)	126 (13.7)	18 (6.5)	21 (7.6)	16 (5.8)

BL = Baseline; VE = Vertebral Edge

Conclusion: This exploratory MRI analysis shows that the IL-17 inhibitor secukinumab may reduce spinal inflammation and this effect may be sustained for up to 24 months using a lower dose in the maintenance compared to induction phase. Interestingly, there was no change in the amount of fatty lesions in the patients treated with secukinumab–this differs from what was recently reported for the treatment with TNF-blockers. Whether this has an impact on radiographic progression needs to be studied in future trials.

Profiling of Response to Anti-TNFα Therapy by Serum Markers of Tissue Degradation End Products in Ankylosing Spondylitis Patients.
Anne Sofie Siebuhr[1], Anne C. Bay-Jensen[2], Morten Asser Karsdal[2], Efstathios Vassiliadis[1], Stephanie Wichuk[3], Claus Christiansen[4] and Walter P. Maksymowych[3]. [1]Nordic Bioscience, Herlev, Denmark, [2]Nordic Bioscience A/S, Herlev, Denmark, [3]University of Alberta, Edmonton, AB, [4]CCBR, Ballerup, Denmark

Background/Purpose: Chronic inflammatory diseases such as Ankylosing Spondylitis (AS) are diverse and therefore hard to clearly diagnose and treat. Conventional biomarkers for AS, as CRP and ESR, often reflect systemic inflammation rather than local joint inflammation. We therefore investigated the effect of anti-TNFa treatment on the level biomarkers of tissue degradation end products reflecting cartilage and synovial turnover in AS patients and whether specific biomarker profiles could be identified for anti-TNFa response.

Methods: Serum samples from AS patients (n=114, age 19–78 yrs, 80% males) were collected at baseline and 3 months following standard anti-TNF-a treatment; Infliximab (n=46), Etanercept (n=28), Adalimumab (n=25) and Golimumab (n=15). Biomarkers of tissue turnover were measured: i) MMP-degraded and citrullinated vimentin (VICM), i) MMP-degraded CRP (CRPM), iii) MMP-degraded type II and III collagen (C2M. C3M), iv) conventional CRP, v) MMP-3, and vi) ESR. All values are presented as geometric mean ± 95% CI. Data was log transformed prior to statistical analysis. Differences between before and after treatment were determined using paired Student's t-test. Pearson's correlation was used to determine correlations between the biomarkers.

Results: Serum C3M (p<0.0002), CRPM (p<0.0001), and VICM (P=0.0011) all decreased significantly after three months of anti-TNF-alpha therapy. There was no significant difference in serum C2M (p>0.05) and MMP-3 (p>0.05) before and after anti-TNF-alpha therapy, although 1/3 of the patients did decrease in response to treatment. CRP (p<0.0001) and ESR (p<0.0001) decreased significantly with treatment. There was a significant correlation between CRPM and the conventional biomarkers before treatment. However, this correlation was lost after 3 months of treatment (table). VICM was strongly correlated to C3M at both time points and to CRPM after treatment, but not at baseline. There was a significant correlation between C2M and VICM at baseline, which was lost after treatment. Before treatment CRP was correlated to C3M, but not after treatment.

		C3M	CRPM	C2M	VICM	CRP	ESR	MMP-3	Disease duration
					baseline				
C3M	r		−0.1	0.01	0.3	0.3	0.1	−0.1	−0.2
	p		ns	ns	**0.0002**	**0.006**	ns	ns	**0.05**
CRPM	r	−0.02		0.04	−0.03	0.4	0.4	0.4	−0.06
	p	ns		ns	ns	**<0.0001**	**<0.0001**	**0.004**	ns
C2M	r	0.11	0.1		0.2	0.01	0.03	0.02	−0.1
	p	ns	ns		**0.05**	ns	ns	ns	ns
VICM	r	0.3	0.5	0.01		0.2	0.1	−0.03	−0.2
	p	**0.0005**	**<0.0001**	ns		ns	ns	ns	**0.04**
CRP	r	−0.04	0.2	−0.08	−0.03		0.7	0.3	0.3
	p	ns	ns	ns	ns		**<0.0001**	**0.04**	ns
ESR	r	0.1	−0.07	−0.04	−0.02	0.6		0.3	0.06
	p	ns	ns	ns	ns	**<0.0001**		ns	ns
MMP-3	r	0.1	−0.2	−0.06	0.06	−0.1	0.09		−0.2
	p	ns	ns	ns	ns	ns	ns		ns
					post treatment				

Conclusion: Biomarkers of cartilage degradation (C2M), synovial inflammation (C3M, CRPM. VICM and MMP3) and systemic biomarkers (CRP and ESR) were decreased in response to anti-TNF-alpha treatment in these AS patients. Whereas the level of CRP and ESR was completely blocked by treatment in a majority of the patients, the suppression in the level of the other markers was patient-dependent. It was clear that each marker reflects different molecular processes in the tissue and responded differentially to the treatment. Thus specific profiles for treatment efficacy may be generated by measuring a biomarker panel of tissue degradation end products.

MRI of the Spine for Detection of Bone Spurs and Ankylosis in Patients with Ankylosing Spondylitis: Does MRI Offer Any Advantages Over Radiography? Susanne Juhl Pedersen[1], Mikkel Østergaard[1], Robert GW Lambert[2] and Walter P. Maksymowych[2]. [1]Glostrup Hospital, Copenhagen, Denmark, [2]University of Alberta, Edmonton, AB

Background/Purpose: The current gold standard for detection of disease progression in ankylosing spondylitis (AS) is conventional radiography. The most reliable method mSASSS includes the anterior parts of the cervical and lumbar spine. However, sensitivity to change is limited (1). MRI, that visualizes the total spine tomographically, may therefore improve detection of new bone formation. The aim of this study was to develop standardized definitions for new bone formation on MRI, to test the reliability of their detection in patients with AS, to compare this reliability with radiography, and to determine whether availability of radiographs enhances the reliability of detection on MRI.

Methods: The Canada-Denmark MRI working group developed standardized consensus based definitions for bone spurs and ankylosis

observed on sagittal images of T1-weighted MRI scans. The definitions included lesions at anterior and posterior vertebral corners as well as non-corner lesions in the disc space and lesions in the lateral segments. A reference image set was generated that included examples of all these lesions as well as variations in normal anatomy. In the MRI-based score, bone spurs and ankylosis were assigned a score of 2 and 3, respectively. In exercise 1, reliability for status and change scores for lesions were assessed on baseline and 2 year scans in 55 patients with AS by 3 readers scoring in known time sequence. Discrepant scans were reviewed extensively using radiography as a reference. In exercise 2, baseline/2 year pairs of radiographs and MRIs of 25 patients with AS (numbered independently) were assessed in 3 reads. Read 1: Radiographs were assessed for syndesmophytes and ankylosis; Read 2: MRI scans were assessed for new bone; Read 3: Simultaneous assessment of radiographs and MRI scans. Reliability was assessed by intra-class correlation coefficient (ICC).

Results: ICC for 3 readers reading MRI scans in the first exercise were 0.79 and 0.23 for baseline status and 2 year change scores, respectively. In exercise 2, radiography was superior to MRI in reliably detecting new bone (Table). Simultaneous availability of radiographs enhanced the reliability of detecting new bone in the C spine by MRI but this was still inferior to radiography. ICC for detection of new bone in the thoracic spine by MRI was 0.48 and 0.36 for baseline status and 2-year change scores, respectively.

Table. Intra-class correlation coefficient (ICC) for detection of bone spurs and ankylosis in exercise 2

	X-ray*	X-ray vs. MRI**	MRI 1st read *	MRI 2nd read*
C spine ICC	0.95	0.67	0.50	0.77
T spine ICC	NA	NA	0.48	0.51
L spine ICC	0.91	0.75	0.75	0.77

*ICC (status) for 3 readers
**Mean ICC for comparison of radiography and MRI

Conclusion: Standardization of MRI features, scoring methodology, and calibration of expert readers with radiography failed to show any major advantage of MRI over radiography in the reliable detection of new bone in the cervical and lumbar spine of patients with AS. Future efforts should focus on the methodology for assessment of the thoracic spine.

Assessment of the Link Between Inflammation and Fat Metaplasia in Patients with Spondyloarthritis On Non-Biological Therapy: A Long Term Magnetic Resonance Imaging Study. Zheng Zhao[1], Susanne Juhl Pedersen[2], Robert GW Lambert[3], Stephanie Wichuk[3], Mikkel Ostergaard[4] and Walter P. Maksymowych[3]. [1]Department of Rheumatology, University of Alberta and PLA General Hospital, Beijing, PR China, Beijing, China, [2]Glostrup Hospital, Copenhagen, Denmark, [3]University of Alberta, Edmonton, AB, [4]Copenhagen University Hospital at Glostrup, Glostrup, Denmark

Background/Purpose: There is growing awareness of the importance of fat metaplasia in the pathogenesis of SpA and its potential link with inflammation and new bone formation. recent data has demonstrated fat metaplasia at vertebral corners after resolution of inflammation in patients receiving anti-TNF therapies. There is no data that assesses this link in patients receiving non-biological (non-B) therapies. These processes can be reliably measured using STIR and T1-weighted (T1W) MRI sequences, respectively, and we aimed to compare these findings in patients with SpA according to treatment.

Methods: Two readers assessed MRI scans from 103 patients with SpA, males n = 81, mean age = 39.3 years, mean disease duration = 16.2 years, in a prospective cohort. MRI was conducted at intervals up to 4 years (mean 18.1 months) and 56 patients received anti-TNF while 47 received non-B therapies. Fat metaplasia was scored on T1W scans using a new scoring method, the CanDen FAt SpA Spine Score (FASSS) which scores six different types of fat lesions defined according to anatomical location. Lesions are recorded dichotomously (present/absent) at each vertebral endplate from

C2 lower to S1 upper (scoring range per disco-vertebral unit (DVU) in C spine: 0–8, and in T and L spine: 0–18). Inflammation was scored on STIR scans using the SPARCC MRI Spine 23DVU method with lesions being scored at each DVU (scoring range per DVU 0–18). We calculated SPARCC 23DVU and FASSS change scores, responsiveness by standardized response mean (SRM), and associations by Pearson c^2 and regression.

Results: Change (a decrease) in SPARCC 23-DVU score from baseline was significant in anti-TNF treated patients (p = 0.01) but not non-B patients while a significant increase in FASSS was evident in both anti-TNF (p = 0.005, SRM = 0.38) and non-B (p = 0.003, SRM = 0.45) treated patients indicating new fat lesions irrespective of treatment. For patients with at least 2 year follow up, 14(56%) and 16 (61.5%) of anti-TNF and non-B treated patients, respectively, had an increase in FASSS score while 7 (28%) and 6 (23.1%), respectively, had a decrease in FASSS score indicating resolution of fat lesions in a minority of patients. However, change in FASSS and SPARCC 23-DVU were highly correlated in anti-TNF treated patients (c^2 = −0.58, p = 3×10^{-6}) but not in non-B treated patients. Change in SPARCC 23-DVU was also independently associated with change in FASSS only in anti-TNF treated patients (β = −0.61, p <0.0001) (adjusted for age, sex, disease duration, BASDAI, CRP).
Conclusion: Long-term follow up reveals a strong link between inflammation and fat metaplasia in patients on anti-TNF while a disconnect is evident in patients receiving non-B therapies. This may have implications for pathways leading to new bone formation.

Prevalence of Psoriatic Arthritis in Psoriasis Patients According to Newer Classification Criteria. Hernan Maldonado-Ficco[1], Gustavo Citera[1], Ana Alba Porrini[2] and Jose A. Maldonado-Cocco[1]. [1]Instituto de Rehabilitacion Psicofisica - Fundacion Reumatologica Argentina Dr. Osvaldo Garcia-Morteo, Buenos Aires, Argentina, [2]Hospital Argerich, Buenos Aires, Argentina

Background/Purpose: To determine the prevalence of Psoriatic Arthritis (PsA) in a cohort of psoriasis patients according to CASPAR criteria, and compare it with that resulting from the use of ASAS peripheral and axial criteria for SpA and New York criteria for AS.

Methods: The first 100 patients that consecutively attended the Psoriasis clinic of a Dermatology Service were assessed. Demographic and clinical data were collected, and all patients were questioned and examined by a rheumatologist for joint manifestations. In all cases, rheumatoid factor and radiographies of hands, feet, cervical spine and pelvis for sacroiliac joints were obtained. All X-rays were read independently by two observers in blind fashion. Patients with objective joint manifestations, both axial and peripheral, were evaluated for their fulfillment of CASPAR, ASAS peripheral and axial, and New York criteria. Correlations were calculated by Spearman's test. Categorical variables were compared by x^2, and continuous variables were compared by Student's test.

Results: Of the 100 patients included (62 males) median age was 48 years and median duration of psoriasis 11 years. 93% of patients presented psoriasis vulgaris, and 56% nail involvement. Seventeen patients had peripheral arthritis, mono/ oligoarticular in 9 and polyarticular in 8. Median time of arthritis duration was of 8 years. Seven patients had chronic neck pain while 6 patients had chronic low back pain.13 patients had cervical spine and 6 patients lumbar spine limitation. Among all psoriatic patients, radiographic sacroiliitis grade 2 and 3 was detected in 12, and grade 4 in 2, being symmetric in 7 of the patients. At cervical level, 10 patients presented syndesmophytes and 3 had interapophyseal ankylosis. Of all patients, 17% fulfilled CASPAR and ASAS peripheral criteria, 6% New York and 5% ASAS axial criteria. Patients who met CASPAR criteria showed a signifi-

cantly higher time of psoriasis duration compared to those without arthritis (m16 vs 10 years p=0.02), and a higher frequency of nail involvement (88.2% vs 49.4% p=0.003). Five patients (29.4%) fulfilled the ASAS axial criteria; all of them presented peripheral involvement: mono/olygoarticular in 3 and polyarticular in 2 patients. Patients with peripheral and axial involvement presented a significantly higher frequency of erythrodermic psoriasis compared to the other patients (35.3% vs 1.2% p=0.0006 and 80% vs 16.7% p=0.02). Among the 95 patients without the ASAS axial criteria, 9 showed sacroiliitis grade 2 or higher. Among the 83 patients without arthritis, only 1 presented peripheral radiological changes, whereas 5 presented sacroiliitis grade 2 or 3.

Conclusion: Prevalence of PsA, for both CASPAR and ASAS peripheral criteria was of 17%. According to the ASAS criteria, 5% of patients presented axial involvement, while 6% presented axial involvement regarding the New York criteria. All cases with articular involvement presented a higher frequency of psoriasis nail involvement and skin severity. It is worth to note that few patients without signs or symptoms of arthritis had radiolcgical changes, both axial and peripheral, precluding a proper classification.

Changes in Sclerostin, Dickkopf-1 and Serum Markers of Inflammation, Cartilage and Bone Turnover in Patients with Axial Spondyloarthritis Treated with Adalimumab. Susanne Juhl Pedersen[1], Inge Juul Sørensen[2], Julia S. Johansen[3], Patrick Garnero[4], Anne Gitte Loft[5], Jens Skoedt[6], Gorm Thamsborg[1], Karsten Asmussen[7], Elka Kluger[8], Jesper Nørregaard[9], Torben Grube Christensen[10] and Mikkel Østergaard[1]. [1]Glostrup Hospital, Copenhagen, Denmark, [2]Hvidovre Hospital, Copenhagen, Denmark, [3]Herlev Hospital, Herlev, Denmark, [4]INSERM, Lyon, France, [5]Sygehus Lillebaelt, Vejle, Copenhagen, Denmark, [6]Gentofte Hospital, Copenhagen, Denmark, [7]Bispebjerg Hospital, Copenhagen, Denmark, [8]King Christian 10th Rheumatism Hospital at Gråsten, Denmark, [9]Hørsholm Hospital, Denmark, [10]Slagelse Hospital, Slagelse, Denmark

Background/Purpose: Few studies have investigated changes in plasma sclerostin and Dickkopf1 (DKK-1) in relation to other biomarkers of inflammation, cartilage and bone turnover during treatment with tumor-nckrosis-factor-alpha (TNFα) inhibitors. The aim of this study was to investigate plasma concentrations of sclerostin, DKK-1 and serum markers of inflammation, cartilage and bone turnover in patients with axial spondyloarthritis (SpA) before and during treatment with adalimumab.

Methods: In a randomized double-blind placebo-controlled trial, 52 patients with axial SpA (77% male, disease duration median 10,range 1–35 years) were allocated to adalimumab 40 mg (n=27) or placebo (n=25) s.c. e.o.w. for 12 weeks, followed by an open label extension, where all received adalimumab. Patients were included if they had: 1) SpA according to ESSG criteria; 2) sacroiliitis on MRI and/or X-rays; and 3) BASDAI ≥40 mm despite treatment with two NSAIDs. Six patients were excluded before week 12 (adalimumab n=2; placebo n=4). At week 24, 43 (83%) patients were BASDAI responders (i.e. reduction of 50% or 20 mm). P<0.005 was regarded as statistical significant. Plasma sclerostin, plasma DKK-1, serum C-reactive protein (CRP), interleukin-6 (IL-6), YKL-40, plasma vascular endothelial growth factor (VEGF), urinary CTX-II, matrix metalloproteinase 3 (MMP-3), total aggrecan (TA), cartilage oligomeric matrix protein (COMP), CTX-I and total osteocalcin (OC) were measured by ELISAs.

Results: Patients with SpA had higher (compared to healthy subjects) baseline levels of IL-6, YKL-40 and CTX-II (p<0.001) and lower levels of aggrecan (p<0.0001). Levels of VEGF, MMP-3, COMP, CTX-I, OC, sclerostin and DKK-1 were within the normal levels. The treatment groups did not differ in baseline biomarker levels. At baseline, IL-6 correlated with CRP (0.73, p<0.0001) and CTX-II (0.48, p=0.0004); VEGF with YKL-40 (0.46, p=0.001); CTX-II with CTX-I (0.40, p=0.004) and OC (0.45, p=0.0008), and OC with CTX-I (0.55,

p<0.0001). From baseline to week 12 significant correlations between the percentage changes in IL-6 and CRP (0.76 and 0.67, p<0.0002) and OC (−0.67 and −0.54, p≤0.005) were found in both treatment groups. In the placebo group only CRP and OC (−0.62, p=0.002) correlated and in the adalimumab group only CRP and MMP-3 (0.65, p=0.0004) and TA and YKL-40 (−0.55, p=0.004). From baseline to week 12, patients treated with adalimumab had larger percentage decreases in CRP (p=0.009), IL-6 (p<0.0001) and YKL-40 (p=0.04) compared to placebo treated patients. After 12 weeks of adalimumab treatment significant percentage decreases were seen in CRP (p=0.003), IL-6 (p=0.001), VEGF (p=0.006), YKL-40 (p=0.02) and MMP-3 (0.01). In the placebo group TA (p=0.01) increased. No significant changes were seen for VEGF, CTX-I, MMP-3, TA (adalimumab), DKK-1, sclerostin, CTX-I and OC after the first 12 weeks of treatment.

Conclusion: In patients with SpA treatment with adalimumab significantly reduced biomarkers of inflammation. No significant early changes were seen in sclerostin, DKK-1 and biomarkers of cartilage and bone turnover.

Examining a Role for Th17 Regulation and Toll-Like Receptor Signaling in Psoriatic Arthritis. Fatima Abji, Remy Pollock, Fawnda Pellett, Vinod Chandran and Dafna D. Gladman. Toronto Western Hospital and University of Toronto, Toronto, ON

Background/Purpose: Psoriatic arthritis (PsA) is a seronegative inflammatory arthritis that develops in 30% of patients with cutaneous psoriasis (PsC). Joint inflammation in PsA is mediated in part by natural killer (NK) cells which are an important arm of the innate immune system. We have previously shown that PsA is associated with activating ligands of NK cell receptors, including the killer cell immunoglobulin-like receptors (KIRs) and NKGD2. Toll-like receptors (TLRs) and Th17 cells are components of the innate immune response which have been implicated in other inflammatory arthridities such as rheumatoid arthritis and ankylosing spondylitis. We sought to determine whether a dysregulation in these pathways is also found in PsA.

Methods: Total RNA was isolated from peripheral blood of 20 PsA, 17 PsC, and 19 control subjects. Quantitative RT-PCR arrays (SABiosciences) were used to profile expression of 155 genes related to the Th17 regulatory network and toll-like receptor signaling. Expression was quantified using the ΔΔCt method and fold change differences between groups was determined by Student's t-test (p<0.05 cutoff).

Results: Out of 30 genes significantly dysregulated in psoriatic disease patients (PsA & PsC), two (TLR9 and IL13) were dysregulated greater than 1.5-fold (a 50% increase). 6 genes were significantly dysregulated less than 1.5-fold in PsC patients compared to controls, and one gene (IL23R) was increased 1.6-fold (p=0.049). In PsA patients compared to controls, 9 out of 45 significant genes were dysregulated greater than 1.5-fold: CLEC7A, CLEC4E, CXCL10, CXCL6, IL2, IL15, LY96, TBK1 and TLR9. Comparing PsA to PsC patients, 4 out of 50 significant genes were dysregulated greater than 1.4-fold (LY96, TBK1, CXCL10 and TLR4) and 13 of 50 significant genes were dysregulated less than 1.5-fold, including CD4, CD8A, CXCL5, NFATC2, SYK, TBX21, IRAK2 and RELA.

Conclusion: A majority of the changes observed in PsA were related to TLR signaling. LY96 dysregulation was previously identified in microarray analyses of PsA compared to PsC patients and controls. Over-expression of TLR3 and TLR4 in synovial tissue from patients with early RA has also been reported. Future studies will validate these results, examine the role of TLR signaling pathways in PsA, and determine whether they can serve as biomarkers of PsA susceptibility in patients with PsC.

Proteomic Analysis of Synovial Tissue: A Unique Tool to Predict Response to Anti-TNF Alpha Therapy in Patients with Inflammatory Arthritis. Opeyemi S. Ademowo[1], Emily S. Collins[1], Cathy Rooney[1], A. W. van Kuijk[2], Danielle M. Gerlag[2], Paul P. Tak[2], Oliver M. FitzGerald[3] and Stephen R. Pennington[1]. [1]UCD Conway Institute of Biomolecular and Biomedical Research, University College Dublin, Dublin 4, Ireland, [2]Academic Medical Centre/University of Amsterdam, Amsterdam, Netherlands, [3]St. Vincent's University Hospital, Dublin, Ireland

Background/Purpose: Inflammatory arthritis, which includes rheumatoid arthritis (RA) and psoriatic arthritis (PsA), is a leading cause of joint deformity, disability and reduced quality of life with a high economic cost [1]. A common target for therapeutic intervention is TNF-α, a key cytokine that drives the inflammatory and destructive processes of these diseases. However, due to common drug failure, diverse degree of response to therapy, cost of treatment as well as adverse drug events [2, 3] there is an urgent need for personalised medicine [4]. We hypothesized that there are distinct proteins or peptides within the synovial tissue that may predict the degree of response to anti TNF-α therapy in patients with inflammatory arthritis. Hence we aim to discover, develop and validate potential predictive biomarkers of treatment outcomes and map the protein changes to potential pathways.

Methods: Baseline protein expressions were investigated and compared in the synovium of 20 PsA patients with diverse responses to adalimumab (a monoclonal antibody against TNF-α) [5]. The EULAR response criteria were used to classify patients' treatment response categories at 3 months follow-up. Synovial proteins were extracted, subjected to digestion with trypsin and the resulting peptides were analysed by label free liquid chromatography-mass spectrometry (LC-MS) on an Agilent 6520 QTOF with HPLC chip cube source attached. Progenesis LC-MS software (version 2.6) was used for the differential protein expression analysis. The potential biomarkers discovered were targeted by multiple reaction monitoring (MRM) technique in a triple quadrupole mass spectrometer for quantitative measurement with the aid of skyline software for instrument method optimization.

Results: The protein profile of the different response categories varied. 313 proteins were differentially expressed between responders and non-responders; a cut off p-value<0.05 and fold change>2 were used to select the biomarker panel. The majority of these proteins have been found to be associated with inflammation. 54 proteins were successfully targeted with the MRM and quantified in synovial tissue. Of the 54 proteins, 25 were significantly over expressed in good responders and 30 were over expressed in non responders.

Conclusion: Label-free LC-MS of synovial tissue is a robust approach to the discovery of differentially expressed proteins that might predict response to anti-TNF-α therapy in PsA patients. These proteins are potential candidate synovial biomarkers of response to anti-TNF-α therapy and will be validated on a larger cohort of patients. The possibility of detecting and measuring these candidate markers in the serum will be explored.

Familial Aggregation and Heritability of Ankylosing Spondylitis in Taiwan: A Nationwide Population Study. Chang-Fu Kuo[1], Matthew J. Grainge[1], Lai-Chu See[2], Kuang-Hui Yu[3], Shue-Fen Luo[3], Ana M. Valdes[4], I-Jun Chou[3], Weiya Zhang[1] and Michael Doherty[1]. [1]University of Nottingham, Nottingham, United Kingdom, [2]Chang Gung University, Taoyuan, Taiwan, [3]Chang Gung Memorial Hospital, Taoyuan, Taiwan, [4]St. Thomas' Hospital, King's College London, London, United Kingdom

Background/Purpose: To estimate the risk of ankylosing spondylitis (AS) among individuals with affected first-degree relatives and to assess the magnitude of genetic contribution to the susceptibility of AS in the general population of Taiwan.

Methods: Using data from the National Health Insurance Research Database in Taiwan, we conducted a nationwide cross-sectional study in 11,770,921 men and 11,697,080 women in 2004. The case definition of AS was based on physician diagnosis. The relative risk (RR) was calculated as the prevalence of AS among individuals with affected first-degree relatives, divided by the prevalence of AS among individuals with no affected first-degree relatives. The identification of first-degree relatives of each individual was determined using the NIHRD registry for beneficiaries. The marginal Cox proportional hazard model with an equal follow-up time for all subjects was used to estimate RR and the 95% confidence interval (CI). This model was used to account for shared environment and case clustering within families with robust variance, and to adjust for age, sex, place of residence, income levels and occupation. Heritability was calculated based on multifactorial polygenic model.

Results: There were 82,618 men (0.70%) and 58,445 women (0.50%) who had AS diagnosis in 2004. The prevalence of AS was higher in individuals with affected first-degree relatives (3.28%) than those without (0.58%). The overall familial relative risk (RR) was 7.95 (95% CI, 7.68–8.24). The RRs (95% CIs) for an individual with an affected twin, sibling, parent and offspring were 21.70 (18.75–25.11), 15.07 (14.78–16.13), 6.98 (6.66–7.32) and 6.77 (6.50–7.06) respectively. The RR (95% CI) increased with the number of affected first-degree relatives, from 7.35 (7.10–7.62), 43.00 (38.77–47.70) and 141.85 (103.50–194.41) for one, two or three, or more affected relatives, respectively. The heritability of AS was 0.95 (95% CI, 0.92–0.98). Among individuals with AS, only 4.16% had a family history. The population attributable risk associated with familial aggregation in Taiwan was 3.73% (95% CI, 4.24%–4.59%).

Conclusion: The risk of AS is higher among individuals with affected first-degree relatives. In addition, the heritability of AS is very high in the general population in Taiwan, confirming that genetic predisposition plays a major role in AS susceptibility.

Association of Platelet Endothelial Cell Adhesion Molecule-1 and α1 Integrin Gene Polymorphisms with Uveitis Development in Ankylosing Spondylitis. Seung Cheol Shim, Donghyuk Sheen, Mi Kyoung Lim and Hyo Park. Eulji University Hospital, Daejeon, South Korea

Background/Purpose: Genetic factors provide over 90% of the susceptibility to ankylosing spondylitis (AS) and recent studies have focused on non-major histocompatibility complex genes. The etiology of uveitis in AS has been suggested to involve two adhesion molecules including intercellular adhesion molecule and leukocyte functional antigen.

Platelet-endothelial cell adhesion molecule 1 (PECAM1), a member of the immunoglobulin superfamily, may be an important regulator of antigen induced cell activation of lymphocytes. The β1 integrin (ITGB1) can associate with different membrane proteins and cause signal transduction by interactions in the extracellular and trans-membrane domain. Therefore, we examined the association of PECAM1 and ITGB1 gene polymorphisms with development of uveitis in patients with AS.

Methods: We conducted a case–control study where 223 AS patients who met the Modified New York criteria and 239 ethnically matched controls were genotyped for 9 single nucleotide polymorphisms (SNPs) in the PECAM-1 promoter and gene. Genomic DNA was isolated from peripheral blood leukocytes by a standard phenol–chloroform method and a GoldenGate assay (Illumina, http://www.illumina.com) was used for genotyping.

Results: Conditional logistic regression was used to evaluate the association between the PECAM1 or ITGB1 SNPs with susceptibility to AS, and no significant association was found on both genes. However, in the subgroup analyses between AS patients with uveitis and those without, seven SNPs in PECAM1 gene were associated with the presence of uveitis, including rs1050382 (dominant model (DM), p=0.022), rs2812 (recessive model (RM), p=0.013), rs4968721 (DM, p=0.016), rs6808

(DM, p=0.011), rs6809 (DM, p=0.013), rs9899806 (DM, p=0.013) and rs9913080 (DM, p=0.019) (Table 1). In addition, seven polymorphisms in ITGB1 gene including rs11009147 (DM, p=0.012; co-dominant model (CDM), p=0.034), rs17468 (DM, p=0.012; CDM, p= 0.019), rs2153875 (CDM, p= 0.030), rs2230396 (DM, p=0.012; CDM, p=0.034), rs2488330 (DM, p=0.004; CDM, p=0.017), rs3780871 (DM, p=0.031) and rs7079624 (RM, p=0.004; CDM, p=0.017) were associated with uveitis development (Table 2).

Conclusion: This is the first analysis of the PECAM1 and ITGB1 gene polymorphisms in AS, demonstrating a clear association with uveitis in AS. Given the functional role of PECAM-1 and ITGB1 variants in the immune system, larger studies are now warranted to elucidate the association of PECAM-1 and ITGB1 in the pathogenesis of uveitis in AS.

Relative Overexpression of Membrane-Bound Versus Soluble TNF in Human and Experimental Spondyloarthritis. Carmen Ambarus[1], Leonie M. van Duivenvoorde[1], Huriatul Masdar[1], Melissa N. van Tok[1], Paul P. Tak[1], Nataliya Yeremenko[1] and Dominique L. Baeten[2]. [1]Academic Medical Center/University of Amsterdam, Amsterdam, Netherlands, [2]Academic Medical Center/University of Amsterdam, Amsterdam, Netherlands

Background/Purpose: Macrophages and their pro-inflammatory cytokines, including TNF, are pivotal mediators of chronic synovitis in rheumatoid arthritis (RA) as well as spondyloarthritis (SpA). Despite similar levels of synovial macrophage infiltration and similar clinical responses to TNF blockade in both diseases, SpA is characterized by a more pronounced infiltration with alternatively activated CD163+ macrophages and ongoing osteoproliferation. This study aimed to investigate whether these differences were related to a differential expression and/or function of TNF between both diseases.

Methods: Healthy donor peripheral blood-derived monocytes were polarized in vitro by IFN-γ, IL-4 or IL-10 for 4 days. The expression of membrane-bound TNF (mTNF) and soluble TNF (sTNF) was measured by FACS and ELISA, respectively. Expression of TNF and its receptors was also measured by qPCR and ELISA in synovial fluid (SF) and synovial tissue biopsies (ST) of actively inflamed knee joints of SpA and RA patients. Mice transgenically overexpressing mTNF (TgA86) were evaluated clinically and histologically for spondylitis and peripheral arthritis.

Results: The expression of mTNF was increased in IL-10 and IL-4 polarized macrophages (alternatively activated macrophages) in comparison with IFN-γ polarized cells (classical activated macrophages). Moreover, the production of sTNF was clearly impaired in the IL-10 polarized CD163+ macrophages and IL-4 polarized macrophages (p<0.01 versus IFN-γ polarized macrophages), indicating a relative shift from sTNF to mTNF by alternative macrophage activation. In line with these in vitro data, the sTNF SF levels were significantly lower in SpA compared to RA (p=0.01) despite similar TNF mRNA levels in ST. This was not related to altered expression of TNF receptors as both TNF-R1 and TNF-R2 were similarly expressed in ST, both at protein and mRNA levels. The mRNA levels of TACE, the enzyme responsible for the cleavage of TNF, TNF receptors and other molecules from the cell membrane were also similar between SpA and RA ST. To investigate whether relative overexpression of mTNF could be relevant in SpA pathophysiology, we characterized mTNF transgenic mice. As previously described, these mice developed a moderate peripheral arthritis with 100% incidence, resulting in deformation of the paws and loss of grip strength. Histologically, the joints were characterized by moderate synovitis and appearance of lymphoid aggregates in the bone marrow, mostly in the absence of osteoclastic infiltration or extensive destruction. Besides arthritis, all transgenic animals spontaneously developed spondylitis as evidenced by a crinkled tail, a hunchback and histological inflammation in the connective tissue next to the intervertebral disc. Interestingly, also bone remodeling was observed both in axial and peripheral joints. None of the non-transgenic littermates developed signs of arthritis and/or spondylitis.

Conclusion: mTNF is relatively overexpressed by CD163+ alternatively polarized macrophages in SpA synovitis and leads to an axial and peripheral SpA phenotype in transgenic mice, including osteoproliferation.

High Prevalence of Anti-CD-74 Antibodies with Specificity for the Class II-Associated Invariant Chain Peptide in Patients with Axial Spondyloarthritis but Not in Controls. Xenofon Baraliakos[1], Niklas T. Baerlecken[2], Frank Heldmann[3], Torsten Witte[4] and Jügen Braun[1]. [1]Rheumazentrum Ruhrgebiet, Herne, Germany, [2]MD, Hannover, Germany, [3]Rheumazentrum Ruhrgebiet, Herne, Ghana, [4]Hannover Medical School, Hanover, Germany

Background/Purpose: The pathogenesis of axial spondyloarthritis (axSpA) is still unclear. Based on the strong association with HLA-B27 and ERAP-1, T cells are believed to play a major role but a role of B cells seems also possible. Autoantibodies have not been frequently found in axSpA but recently anti-CD74 antibodies with specificity to a class II-associated invariant chain peptide (CLIP) have been detected. We studied the prevalence of antibodies against CLIP (anti-CLIP-ABs) in patients with axSpA in comparison to controls and determine their sensitivity and specificity.

Methods: Sera of patients with axSpA and non-SpA were analyzed for IgG-antibodies against CD74 using an ELISA with specificity for CLIP, developed in cooperation with AESKU Diagnostics (Germany). A cut-off of ≥4 standard deviations of arbitrary units (AU) from the mean serum level was used to differentiate results. The laboratory workers were completely blinded for the clinical data.

Results: A total of 145 sera from 94 patients with axSpA and 51 with other diseases were analyzed. The patient demographics differed: axSpA patients were more often male and younger. The HLA-B27 status was available in 72 patients. Anti-CLIP-ABs were detected in 85.1% in axSpA but in only 7.8% in non-SpA patients (p£0.0001). Higher levels of anti-CLIP-ABs were found in axSpA vs. non-SpA: mean 14.5 vs. 0.8 AU (p£0.0001). The sensitivity of anti-CLIP-ABs for a diagnosis of axSpA was 85.1% and the specificity 92.2%, with a positive likelihood ratio (LR) of 10.8 and a negative LR of 0.08. The relative contribution of anti-CLIP-ABs and HLA-B27 was largely similar: 87.5% of the patients with axSpA were positive for both, but only 14.9% were anti-CLIP-negative while 23.6% were HLA-B27-negative.

Conclusion: Anti-CLIP antibodies were strongly associated with axSpA including AS. The LR for diagnosing AS was even higher than for HLA-B27. More studies using this promising new method in patients with non-radiographic axial SpA or peripheral SpA are needed to establish its usefulness in clinical practice.

Brain MRI and Psychophysics Analysis Demonstrate Neuropathic Pain to Be a Component of Back Pain in Ankylosing Spondylitis. Q. Wu[1], R. D. Inman[2] and Karen Davis[1]. [1]Toronto Western Research Institute, Toronto, ON, [2]Toronto Western Research Institute, University Health Network and University of Toronto, Toronto, ON

Background/Purpose: The mechanisms underlying pain in ankylosing spondylitis (AS) are unclear. The aim of this study was to investigate whether there is a neuropathic component in AS pain and to delineate gray matter brain abnormalities associated with AS.

Methods: Seventeen patients with back pain secondary to AS (12M/5F; 34.4 +/− 12.4yo) and age/sex-matched controls consented to the approved study. Mean BASDAI scores in the AS patients were 6.6 +/− 2.1, and none were on biologic agents at the time of the study. Patients were assessed with the PainDETECT (scores <12 indicate low probability of neuropathic pain) and McGill Pain Questionnaires. Mechanical and thermal pain thresholds were determined, 3T MRI scans obtained for all subjects. Brain gray matter was measured with cortical thickness analysis (Freesurfer) and voxel based morphology (FSL-VBM) for subcortical structures with age included as a covariate.

Results: The mean painDETECT score in AS patients was 15.1 ± 7.08 (eleven scored >12). Compared to controls, AS patients had significantly decreased mechanical and cold sensitivity on their dorsal feet but pain thresholds were not abnormal. The gray matter analysis identified that AS patients had significant cortical thinning in left primary sensory (S1), insular, and anterior mid-cingulate cortices (MCC), and right supplemental motor area and ACC. Furthermore, painDETECT scores correlated with cortical thinning in the left S1 and thickening in the left motor cortex, right anterior cingulate and prefrontal cortex. All cortical findings were significant at p< 0.05 image-wise, corrected for multiple comparisons.

Conclusion: Our psychophysical testing and self-reports identified signs of neuropathy. The imaging results of abnormal brain gray matter linked to neuropathic pain are concordant with the clinical picture of AS having sensorimotor and mood deficits as well as neuropathic pain. These data suggest that back pain in AS is a mixed pain condition that includes a neuropathic pain component.

Discovery of Two Public T Cell Receptor Clonotypes in B27+ Ankylosing Spondylitis by Deep Repertoire Sequence Analysis. Malek Faham[1], Victoria Carlton[1] and R. D. Inman[2]. [1]Sequenta, Inc., South San Francisco, CA, [2]Toronto Western Research Institute, University Health Network and University of Toronto, Toronto, ON

Background/Purpose: The strong association of AS with HLA-B27 implicates a T cell response restricted by this Class I MHC molecule, predicting that specific T Cell Receptor (TCR) sequences would be shared among AS patients.

Methods: We have developed a technology for large scale sequencing of TCR to assess the repertoire profile. All TCR sequences are amplified from peripheral blood and 1 million TCR sequences are obtained to generate a comprehensive profile of TCR repertoire. We applied this technology to profile B27+ AS (n=128), B27- AS (n=24), B27- mechanical back pain (n=24), healthy controls (n=25) and SLE patients (n=176).

Results: We used a TCR repertoire data from the controls (HC and SLE) to filter out clonotypes present in an appreciable number of these samples. After rigorous control of multiple testing using train and test data sets, two clonotypes were discovered to have significantly different frequencies in B27+ AS population and controls (41% vs 5% and 54% vs19%, p <0.0001). These clones were further tested in 24 patients with mechanical back pain and 24 B27- AS patients. The frequency of both clonotypes in the MBP population was similar to that in controls (4% vs 5% and 25% vs 19%). In B27- AS one clonotype had frequency similar to controls (8% vs 5%), and one had a higher frequency than controls (42% vs. 25% p =0.016). The table below shows the frequency of both clonotypes in the different populations.

Diagnosis	n	Clone 1: no. positive (%)	Clone 2: no. positive(%)
B27+ AS	128	54 (41%)	69 (54%)
B27− AS	24	2 (8%)	10 (42%)
MBP	24	1 (4%)	6 (25%)
Controls	201	11 (5%)	38 (19%)

Conclusion: We provide evidence that there is a distinctive set of shared clonotypes in the T cell repertoire in AS patients. This sheds light on the immunological role of HLA B27 in AS and demonstrates promising specificity for potential diagnostic utility.

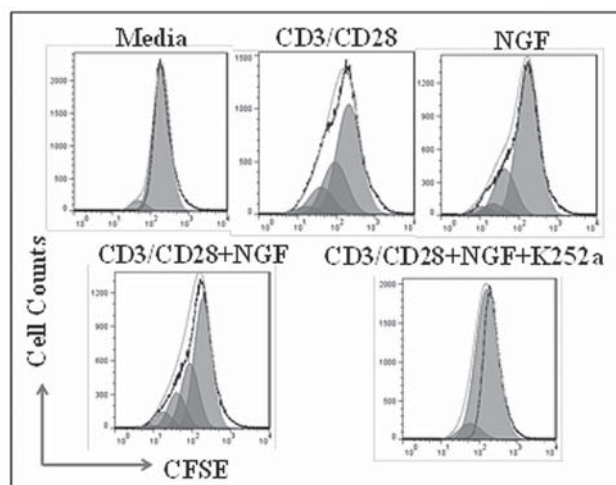
NGF and Trka: A Novel Therapeutic Target in Chronic Inflammation. Siba P. Raychaudhuri[1], Ananya Datta Mitra[2] and Smriti K. Raychaudhuri[2]. [1]VA Sacramento Medical Center/UC Davis School of Medicine, Mather, CA, [2]VA Sacramento Medical Center, Mather, CA

Background/Purpose: Outside the nervous system, several studies have established the regulatory role of nerve growth factor (NGF) and its high affinity receptor, TrkA. A clinical trial showed that NGF monoclonal antibody reduced osteoarthritic pain. We have reported regulatory role of NGF/TrkA in chronic inflammatory diseases, e.g., psoriasis, psoriatic arthritis (PsA) and rheumatoid arthritis (RA). These observations suggest the functional significance of NGF and its high affinity receptor, TrkA in pain and inflammation. We are reporting the role of NGF and TrkA on two key pathological events of inflammatory cascade: angiogenesis and T cell proliferation.

Methods: Human dermal microvascular endothelial cells (HDMEC) tubule formation (angiogenesis) was assessed using bovine type I collagen. HDMECs (40000 cells/ml) were incubated in presence or absence of NGF, K252a for 6 hours at 37°C. Tubule formation was checked under microscope (20x). Magnetically sorted CD3[+] T cells from psoriasis, PsA and RA were stimulated with CD3/CD28 cocktail and cultured in presence or absence of NGF, TrkA inhibitor K252a. Cell proliferation was measured by MTT and CFSE dilution assay.

Results: Angiogenesis was markedly increased with NGF (68.39±2.10%) compared to media (15.57±0.80%, p<0.001). K252a (20.42±0.98%) significantly inhibited NGF induced angiogenesis (68.39±2.10%, p<0.001) (Figure 1). CD3[+]T cells proliferation was significantly increased by NGF (OD: 1.2±0.09) compared to media (OD: 0.73±0.07, p<0.05). In presence of physiological stimulus (CD3/CD28), NGF induced more proliferation (OD: 2.17±0.23) of CD3[+]T cells compared to only physiological stimulus (1.62±0.23, p<0.01). Potent TrkA inhibitor, K252a significantly blocked the NGF induced CD3[+]T cells proliferation (1.33±0.16 vs. 2.17±0.23, p<0.01). Similar results were observed in CFSE assay too (Figure 2).


Conclusion: This study suggests the regulatory role of NGF/TrkA interaction on two major events of inflammatory cascade: angiogenesis and T cell proliferation. Thus inhibition of NGF/TrkA interaction either by NGF monoclonal antibody or TrkA inhibitor could be a new therapeutic approach for chronic inflammatory diseases.

590

The Association Between KIR3DL1 Alleles and Psoriatic Arthritis.
Remy Pollock, Jeffrey Berinstein, Arane Thavaneswaran, Fawnda Pellett, Dafna Gladman and Vinod Chandran. Toronto Western Hospital and University of Toronto, Toronto, ON

Background/Purpose: Killer-cell immunoglobulin-like receptors (KIRs) are activating and inhibitory receptors that regulate NK and NK-T cells, which have been found in psoriatic plaques and synovial fluid of patients with psoriatic disease (PsD). The inhibitory KIR3DL1 receptor binds to HLA-B alleles with the Bw4 motif. Binding of KIR3DL1 to HLA-Bw4 alleles with isoleucine at codon 80 (Bw4–80I) results in stronger inhibition than Bw4 alleles with threonine at codon 80 (Bw4–80T). KIR3DL1 alleles can be classified according to their expression levels on NK cells as High, Low, Null or KIR3DS1 (an activating allele of 3DL1). We examined the association of KIR3DL1 alleles and the Bw4 dimorphism with PsD.

Methods: Genomic DNA was available on 656 Caucasian patients with PsD (395 PsA patients: mean age 42 years, males 58%, age at psoriasis 28 years, age at PsA 36 years, PASI 5.6, active joint count 11, axial disease 33% who satisfied CASPAR criteria and 261 PsC patients: mean age 48 years, males 56%, age at psoriasis 30 years, PASI 5.4) and 377 Caucasian controls (mean age 41 years, males 48%). A nested quantitative PCR assay was designed to selectively amplify the KIR3DL1 locus and High, Low, Null, and KIR3DS1 alleles using custom Taqman SNP genotyping assays. DNA from the UCLA International KIR Exchange program was used for assay validation and optimization. Chi-squared test and tests for interaction were conducted and KIR3DL1 low and null allele categories were grouped together.

Results: The genotype frequencies across the 3 groups are given in Table 1. We observed statistically significant differences in the frequency of KIR3DL1 low/null alleles, and between Bw4–80I and –80T alleles. The frequencies of KIR3DL1 low/null alleles were lower in psoriatic disease and PsA compared to controls (Table 2). No significant differences between PsA and PsC could be demonstrated. We also investigated the interaction between KIR3DL1/3DS1 alleles and Bw4–80I and –80T and observed a trend towards significant interaction between KIR3DL1 low/null and Bw4–80T when comparing PsA to controls (p=0.1). The association between KIR3DL1 low/null was present only in the absence of Bw4–80T alleles (OR=0.86, 95% CI 0.78, 0.94, p=0.002).

Table 1. Differences in allele frequencies between the three groups.

Allele	Controls (n=377)	PsC (n=261)	PsA (n=395)	P value
KIR3DL1 low/null	225 (60%)	140 (54%)	199 (50%)	0.03
KIR3DLI High	194 (52%)	126 (48%)	199 (50%)	0.73
KIR3DS1	126 (33%)	98 (38%)	150 (38%)	0.37
HLA-B Bw4	233 (62%)	177 (68%)	292 (74%)	0.002
HLA-B Bw4- 80I	101 (27%)	93 (36%)	140 (35%)	0.02
HLA-B Bw4- 80T	151 (40%)	102 (39%)	191 (48%)	0.02

Table 2. Association between KIR3DL1 low/null alleles and disease groups.

Comparison	OR (95% CI)	P value
Psoriatic disease vs. controls	0.72 (0.56,0.93)	0.01
PsA vs. controls	0.69 (0.52,0.91)	0.01
PsC vs. controls	0.78 (0.57,1.08)	0.13
PsA vs. PsC	0.88 (0.64,1.20)	0.41

Conclusion: In PsA patients, there was a significantly decreased expression of the KIR3DL1 Low/Null alleles particularly in the absence of HLA-B Bw4–80T. The results support the role of KIR genes and their interaction with HLA-B alleles in susceptibility to PsA.

Structural Progression of Ankylosing Spondylitis Associated with Elevation in Two NOVEL, Inflammatory Biomarkers; Matrix Metalloproteinase and Cathepsin-Derived.
Anne C. Bay-Jensen[1], Morten Asser Karsdal[1], Stephanie Wichuk[2], Zheng Zhao[3], Robert GW Lambert[2], Per Qvist[4] and Walter P. Maksymowych[2]. [1]Nordic Bioscience A/S, Herlev, Denmark, [2]University of Alberta, Edmonton, AB, [3]Department of Rheumatology, University of Alberta and PLA General Hospital, Beijing, PR China, Beijing, China, [4]Nordic Bioscience, Herlev, Denmark

Background/Purpose: Current inflammatory biomarkers, such as CRP, have insufficient sensitivity and specificity to be broadly accepted for diagnosis and prognosis of AS. We hypothesized, that quantification of inflammation markers derived from the affected tissue might have improved clinical utility compared to the systemic markers. We developed two novel biomarker assays detecting MMP and cathepsin-derived CRP (MMP-CAT and CAT-CRP) and aimed to determine their diagnostic utility and association with radiological progression.

Methods: Serum samples (n=124) from AS patients, mean disease duration (SD) 18.0 (11.4) years were assessed. Within this cohort, samples from 16 AS patients with structural progression over two years and 29 without were selected for prognostic evaluation (sub-cohort 1A). A progressor was defined as having a baseline mSASSS of ' 10 units and progression of ≥5 units plus ≥ 1 new syndesmophyte over two years. Non-progressors were defined as disease duration at baseline of > 10 years, baseline mSASSS < 5 units, and no change in mSASSS over 2 years Sub-cohort 1B comprised samples from 53 AS patients pre- and post- anti-TNF treatment. We also included samples (n=39) from healthy controls.

Results: CRP-MMP and CRP-CAT were both elevated in AS compared to controls; mean (SD) 9.84 (4.40) ng/ml vs. 4.82 (1.49) ng/ml (p<0.05), respectively, for CRP-MMP, and 299.6 (137.6) ng/ml vs 178.6 (54.03) ng/ml (p<0.05), for CRP-CAT. AUC according to ROC analysis was 0.94 (p<0.0001) and 0.85 (p<0.0001) for CRP-MMP and CRP-CAT, respectively. In AS patients with progression CRP-MMP and CRP-CAT were significantly elevated compared to non-progressors. Both CRP-related markers decreased significantly after short term (2–3 months) anti-TNF treatment.

Conclusion: Both MMP and Cathepsin-derived fragments of CRP are significantly elevated in AS patients. These markers, but not CRP, were significantly elevated at baseline in patients having structural progression defined by a composite index including mSASSS and syndesmophyte quantification.

Two Novel Diagnostic Biomarkers of Cartilage Degradation and Connective Tissue Inflammation Are Predictive of Disease Progression in Ankylosing Spondylitis. Anne C. Bay-Jensen[1], Stephanie Wichuk[2], Inger Byrjalsen[3], Zheng Zhao[4], Robert GW Lambert[2], Morten Asser Karsdal[1] and Walter P. Maksymowych[2]. [1]Nordic Bioscience A/S, Herlev, Denmark, [2]University of Alberta, Edmonton, AB, [3]Nordic Bioscience, Herlev, Denmark, [4]Department of Rheumatology, University of Alberta and PLA General Hospital, Beijing, PR China, Beijing, China

Background/Purpose: Cartilage degradation and inflammation of synovial and connective tissue are key events in inflammatory arthropathies such as SpA. Presently there are no prognostic tools available for measuring these tissue related processes. Inflammation induces an increase in collagenases which lead to increased degradation of cartilage and synovial tissue. Type II collagen is the primary protein component of cartilage and type III collagen is one of the major proteins of synovial membrane. We aimed to investigate the diagnostic and prognostic utility of cartilage and synovial turnover biomarkers in AS.

Methods: Serum samples from patients with AS (n=124), RA (n = 47), and controls (n = 56) were assessed for type II and III collagen degradation using the C2M competitive ELISA and the C3M ELISA, respectively. Standard AS clinical outcome scores were collected: BASDAI (health questionnaire), hsCRP, and mSASSS. Progressors were defined as having new vertebral syndesmophytes over a two year period. Logistic regression and CART were used to analyze the prognostic value of the markers individually or in combination.

Results: Both cartilage and connective tissue degradation fragments, C2M and C3M, were significantly elevated in serum samples from AS patients compared to healthy controls (P<0.0001). The area under the curves of C2M and C3M, respectively, were 70% and 81% for AS. C2M and C3M were also significantly elevated in RA patients compared to controls (P<0.0001). Diagnostic utility analyzed by ROC and AUCs were 72% and 89% for C2M and C3M, respectively. C3M correlated significantly with AS score BASDAI and mSASSS (p<0.01). C2M did not show the same correlations. A combination of the two markers could identify 80% of those who were defined as progressors and 61% of the non-progressors.

Conclusion: This study is the first to show that the two novel biomarkers of cartilage and synovial tissue degradation add additional information to the understanding of the diagnosis and progression of SpA.

593

DKK1 Serum Level Is Increased in Recent Spondyloarthritis and Is Associated with Higher Prevalence of Syndesmophytes. Sclerostin Is Highly Correlated with Age. Data From the DESIR Cohort. Gaetane Nocturne[1], Stephan Pavy[2], Désirée van der Heijde[3], Philipe M. Goupille[4], Maxime Dougados[5], Christian Roux[6], Xavier Mariette[7] and Corinne Miceli-Richard[2]. [1]Université Paris Descartes, Paris, France, [2]Université Paris Sud, Le Kremlin Bicêtre, France, [3]Leiden University Medical Center, Leiden, Netherlands, [4]Hopital Trousseau, Tours, France, [5]Paris-Descartes University, APHP, Cochin Hospital, Paris, France, [6]Paris Descartes University, Paris, France, [7]Université Paris-Sud, Le Kremlin Bicetre, France

Background/Purpose: Dickkopf-1 (DKK-1) and sclerostin (SOST) are 2 inhibitory proteins of the Wnt signalling pathway that could rationally be involved either in AS osteoporosis or in the osteoblastogenesis associated with syndesmophyte construction. We aimed to investigate serum levels of DKK-1 among patients with recent inflammatory back pain fulfilling ASAS criteria for spondyloarthritis (SpA) and to investigate the parameters associated or correlated with DKK-1and SOST serum levels.

Methods: The DESIR cohort is a prospective, multicenter French cohort of patients with early IBP (Calin or Berlin criteria) (>3 months and <3 years of duration) suggestive of SpA, including 708 patients. DKK-1 and SOST serum levels were assessed at baseline on the whole cohort by sandwich ELISA (Biomedica, Vienna). DDK-1 and SOST serum levels were further analyzed in the subgroup of patients fulfilling ASAS criteria for SpA (N=479; 68.9%) and compared with serum levels from 71 controls (without autoimmune or chronic inflammatory disease). 461 SpA patients (94.8%) were treated with NSAIDs, 62

with corticosteroids (less than 10 mg per day) and 67 with DMARDs (35 SSZ and 32 MTX) at inclusion in the study. All SpA patients were naive of any TNF blocker at inclusion in the study. Univariate and multivariate analyses were performed in order to identify the main predictors of DKK-1 and SOST serum levels in SpA patients.

Results: Serum DKK-1 levels were available for 695 patients with IBP (472 of them fulfilling ASAS criteria for axial SpA) and were significantly increased in SpA patients (mean $\pm$ SEM 30.7 $\pm$ 0.7 pmol/L) compared with controls (10.8 $\pm$ 1.1 pmol/L) ($p<0.0001$). DKK-1 serum levels were significantly correlated with ESR (P=0.04; r=0.10), CRP (P=0.015; r=0.11), ASDAS-ESR (P=0.03; r=0.10), ASDAS-CRP (P=0.016; r=0.11). A significant positive correlation between DKK-1 serum levels and lumbar spine BMD was observed (P=0.04; r=0.13). DKK-1 serum levels were significantly higher among SpA patients with syndesmophytes (mSASSS>0; N=131) (mean $\pm$ SEM 35.4 $\pm$ 1.6 pmol/L) compared with patients with normal X-Rays (N=334) (mean $\pm$ SEM 28.6 $\pm$ 1.1 pmol/L) (P<0.0001). Multivariate analysis led to a significant association of DKK-1 serum levels with the presence of syndesmophytes at baseline. SOST was not significantly increased among SpA patients compared with controls. SOST serum levels were significantly correlated with US CRP (r=−0.20; P<0.0001), DKK-1(r=0.13; P<0.006), and age (r=0.31; P<0.0001). Neither axial structural lesions nor BMD measurements were associated or correlated with SOST serum levels. Multivariate analysis led to a significant association of SOST serum levels with age, DKK-1 and us-CRP.

Conclusion: This study conducted in a large cohort of patients presenting with early axial SpA clearly showed an increase in DKK-1 serum levels, such increase being even more important in the sub group of patients with axial structural lesions. SOST was mainly correlated with age and to a lesser extend with DKK-1 serum levels and us-CRP. Their respective role in SpA pathogenesis needs further investigation.

594

Evidence of Human Leucocyte Antigen-B27 in Healthy Individuals and Patients with Uveitis Is a Risk Factor for Alterations in Bone Metabolism. Sarah Schmidt[1], Stephanie Finzel[1], Jürgen Rech[1], Matthias Englbrecht[1], Silke Winkler[1], Isabel Schmidt[1], Roula Said-Nahal[2], Maxime A. Breban[2] and Georg A. Schett[3]. [1]University of Erlangen-Nuremberg, Erlangen, Germany, [2]Ambroise Paré Hospital (AP-HP), and Versailles Saint Quentin en Yvelines University, Boulogne-Billancourt, France, [3]Department of Internal Medicine III and Institute for Clinical Immunology, University of Erlangen-Nuremberg, Erlangen, Germany

Background/Purpose: To test whether positivity for HLA-B27 *per se* is associated with changes of biomarkers of the Wnt pathway.

HLA-B27 is strongly associated with the development of spondyloarthritis (SPA), a disease characterized by new bone formation and ankylosis of joints and intervertebral spaces. We have recently shown the role of the two Wnt antagonists, dickkopf 1 (DKK1) and sclerostin in new bone formation in SPA. We therefore hypothesized that HLA-B27 itself may be associated with alterations in expression of DKK1 and sclerostin.

Methods: 31 patients with HLA-B27 positive SPA, 30 patients with HLA-B27 positive uveitis as well as 30 healthy carriers of HLA-B27 were included. Furthermore, we assessed 32 HLA-B27 negative healthy controls comparable for age and gender. We evaluated total DKK1 and sclerostin levels in sera of all individuals by enzyme-linked immunosorbent assays (ELISA). Statistical analysis was done by t-tests using SPSS version 18.0.

Results: Healthy HLA-B27 positive individuals showed significant lower levels of DKK1 compared to negative controls (T (60)= −4.615, p< 0.001). Moreover, DKK1 levels were significant reduced in HLA-B27 positive SPA-patients (T (61)= −3.670, p=0.001) and in HLA-B27 positive uveitis patients (T(60)= −2.445, p=0.017). Lowest levels of DKK1 were found in HLA-B27 positive healthy carriers. Serum levels of sclerostin were significantly lower in HLA-B27 positive SPA-patients compared to HLA-B27 negative individuals (T (61)= −3.130, p=0.003). Additionally, serum levels of sclerostin were distinctly reduced in HLA-B27 positive uveitis patients and in HLA-B27 positive healthy carriers.

Conclusion: HLA-B27 positivity is associated with low levels of DKK1 and sclerostin independent from the presence of clinical symptoms of SPA. Both HLA-B27 healthy carriers as well as HLA-B27 associated uveitis without SPA

show lower levels of these two Wnt antagonists than normal HLA-B27 negative controls. These data suggest that alterations in bone metabolism even occur in the absence of clinical SPA and are associated with HLA-B27 carriage.

A Genomewide Association Study of Anterior Uveiti. Dorith Claushuis[1], Adrian Cortes[2], Linda A. Bradbury[1], Tammy M. Martin[3], James T. Rosenbaum[4], John D. Reveille[5], Paul Wordsworth[6], Jennifer Pointon[6], Australo-Anglo-American Spondyloarthritis Consortium[7], David Evans[8], Paul Leo[2], Pamela Mukhopadhyay[2] and Matthew A. Brown[2]. [1]The University of Queensland Diamantina Institute, Brisbane, Australia, [2]The University of Queensland Diamantina Insititue, Brisbane, Australia, [3]Oregon Health & Science Univ, Portland, OR, [4]Oregon Health & Science University, Portland, OR, [5]Univ of Texas Health Science Center at Houston, Houston, TX, [6]Nuffield Orthopaedic Centre, Oxford, United Kingdom, [7]Houston, TX, [8]Bristol University, Bristol, United Kingdom

Background/Purpose: Anterior uveitis (AU) is the most common extra-articular manifestation of ankylosing spondylitis (AS), occurring in up to 30–40% of AS cases. The aim of the current study was to investigate clinical associations of AS, and to identify genes associated with the risk of developing AU.

Methods: 972 AS cases with AU (AS+AU+) and 1404 AS cases without AU (AS+AU-) were available for study. All cases were of white European descent. A genomewide association study was performed using SNP data from the TASC and TASC-WTCCC2 AS studies, 291,537 SNPs being available in the merged dataset. Case-control analysis comparing the AS+AU+ and AS+AU- cohorts was performed using Eigenstrat to control for population stratification effects.

Results: Male and female AS cases were equally likely to develop AU. As expected, AU complicating AS was strongly associated with AS disease duration (beta=0.027, $P<10^{-6}$). No association was seen with age, independent of AS disease duration. Considering AS+AU+ cases in comparison with AS+AU- cases, no SNP achieved genomewide significance. Three loci showed suggestive association with AU. At chromosome 6q26, two SNPs in the *PARK2* gene achieved $P<10^{-5}$ (rs2849576, $p=7.6\times10^{-6}$; rs13205287, $p=2.0\times10^{-6}$). Five SNPs (rs379796, rs419519, rs445890, rs452186, rs45218) in an intergenic region on chromosome 4q33 achieved $P=9.0\times10^{-6}-9.5\times10^{-6}$. Association was noted with HLA-B27 (antigen carriage, odds ratio 2.58, $P=5.6\times10^{-8}$). There was a marginal association of B27-homozygosity in this analysis (odds ratio 2.1, $P=0.06$). No known AS locus was differentially associated in AS+AU+ cases in comparison with AS+AU- cases.

Conclusion: This analysis found that with the exception of HLA-B27, no differences were identified between AS+AU+ and AS+AU- cases. The study was adequately powered to identify moderately large genetic effects, but not small-moderate genetic effects for which larger studies will be required. Further, as all patients studied have AS, whether genetic associations of AS-AU+ cases are different to those of AS+AU+ remains unclear. Nonetheless, these findings suggest that AU has very similar genetic risk factors to AS, and therefore that they likely share similar aetiopathogenisis.

Evolution of Atherosclerosis in Psoriatic Arthritis: Is the Former an Independent Inflammatory Process? Roberta Ramonda[1], Massimo Puato[2], Valentina Modesti[1], Mariagrazia Lorenzin[1], Paola Frallonardo[1], Augusta Ortolan[1], Carla Campana[1], Alessandro Lo Nigro[1] and Leonardo Punzi[3]. [1]Unit of Rheumatology, University of Padova, Padova, Italy, [2]Department of Internal Medicine, University of Padova, Padova, Italy, [3]Rheumatology Unit - University of Padova, Padova, Italy

Background/Purpose: A non-invasive study focusing on the structural and functional properties of the carotid arteries was carried out in psoriatic arthritis (PsA) patients. Increased cardiovascular morbidity and mortality and accelerated atherosclerosis were observed in patients with several rheumatic diseases, including PsA. The impact of two years of Tumor Necrosis factor alpha (TNF-a) blockade treatment on vascular structure and function was assessed.

The aim of this study was to evaluate the presence of subclinical atherosclerosis in PsA patients before and after 24 months of TNF blockade therapy and to investigate the efficacy of treatment not only with regard to disease activity but also in improving atherosclerotic indexes.

Methods: Thirty-two PsA patients were studied before and after 24 months of TNF blockade therapy. Subclinical atherosclerosis was investigated on the basis of B-mode ultrasound measurements of the carotid intima-media thickness (IMT) expressed as the mean IMT value (the mean IMT measured bilaterally at 3 levels: the common carotid artery, the carotid artery bulb and the internal carotid artery,) and as the MMax (the mean maximum IMT). Post-occlusion flow mediated dilation (FMD) of the brachial artery was evaluated by high-sensitivity brachial ultrasonography and endothelial independent dilatation (GTN) using carotid duplex scanning. Response to therapy was studied by evaluating the tender and swollen joints (Tj and Sj), DAS 28, ESR and CRP. Patients' lipid profiles before and after the 24 month treatment period were also evaluated. Differences in parameters over the observation period were assessed using the Wilcoxon test.

Results: After a 24 month treatment period there was no improvement in ultrasonographic parameters with respect to baseline values. Indeed, there was a significant deterioration in both mean IMT and MMAX (respectively 0.75 ± 0.20 vs 0.96 ± 0.40 and 0.91 ± 0.25 vs 1.09 ± 0.44, $p<0.01$), while no alterations were observed in the FMD (5.81 ± 2.07 vs 5.29 ± 2.64, ns) or the GTN (7.76 ± 2.96 vs 7.84 ± 3.08, ns). There was instead a good response to therapy with significant reduction in the Tj (8.10 ± 5.56 vs 2.09 ± 2.32, $p<0.01$), the Sj (3.85 ± 3.84 vs 0.25 ± 0.72, $p<0.01$), the DAS 28 (4.16 ± 0.66 vs2.30 ± 0.82, $p<0.01$), the ESR (26.3 ± 16.4 vs 14.88 ± 13.99, $p<0.01$) and the CRP (11.25 ± 9.16 vs 2.91 ± 1.72, $p<0.01$). There were no significant alteration with regard to lipid profile after the two year treatment period.

Conclusion: PsA per se implies a pro-atherogenic remodelling of carotid arteries that did not seem to be affected by the 2 year anti-TNF blockade therapy despite clinical improvement. There was in fact a slight progression in subclinical atherosclerosis as assessed by ultrasonography. Both the mean IMT and the MMAX showed a slight worsening over the two year period, while FMD, which we expected to be improved, was instead stable. Other inflammatory mechanisms not related to TNF may be responsible for the progression in atherosclerotic disease and the possible role of a genetic predisposition should not be underestimated. PsA patients seem, in fact, to have a higher risk of atherosclerosis compared to subjects with other inflammatory rheumatic diseases.

Investigating the Genetic Association Between *ERAP1* and Spondyloarthritis. Amir Kadi[1], Brigitte Izac[1], Roula Said-Nahal[2], Ariane Leboime[2], Kurt L. de Vlam[3], Dirk Elewaut[4], Gilles Chiocchia[1] and Maxime A. Breban[2]. [1]Institut Cochin - INSERM U1016 - CNRS (UMR 8104), Paris, France, [2]Ambroise Paré Hospital (AP-HP), and Versailles Saint Quentin en Yvelines University, Boulogne-Billancourt, France, [3]University Hospitals Leuven, Leuven, Belgium, [4]Ghent University Hospital, Ghent, Belgium

Background/Purpose: A robust association was recently identified between polymorphisms in the non-major histocompatibility complex gene ERAP1 and ankylosing spondylitis (AS) in several populations. The aim of the current study was to determine the level of association of ERAP1 polymorphisms with spondyloarthritis (SpA) in French/Belgian population with a particular attention to genotype-phenotype correlations.

Methods: We studied 734 independent SpA cases and 632 controls from 2 European cohorts. Five single nucleotide polymorphisms (SNPs), rs27044, rs17482078, rs10050860, rs30187 and rs2287987 were genotyped and case-control association analyses were carried using PLINK. Linkage disequilibrium and haplotypes were estimated with Haploview. Analysis was first carried in SpA as a whole group, and then separately in AS and non-radiographic SpA (non-AS) patients.

Results: Consistent with previous studies conducted in AS, rs30187 was the most significantly associated SNP with SpA ($P=0.008$ in the French and $P=6.46\times10^{-4}$ in the Belgian cohorts). In the combined cohort, this SNP was associated with both AS and non-AS ($P_{Combined}=3.9\times10^{-5}$ and $P_{Combined}=0.005$, respectively). A similar trend was observed with other SNPs. The rs17482078/rs10050860/rs30187-CCT haplotype was significantly associated with increased risk of SpA in both cohorts

($P_{combined}=9.08\times10^{-4}$), including AS and non-AS ($P_{combined}=6.16\times10^{-4}$ and $P_{combined}=0.049$, respectively), whereas the -TTC haplotype was associated with reduced risk of SpA, including AS and non-AS ($P_{combined}=2.36\times10^{-7}$, $P_{combined}=5.69\times10^{-6}$ and $P_{combined}=2.13\times10^{-4}$, respectively).

Conclusion: This is the first study to show an association between several polymorphisms located in ERAP1 and SpA as a whole. Our findings demonstrate consistent association of the same SNPs and haplotypes with both AS and non-AS subtypes of SpA.

The Non-Synonymous Polymorphism *IL23R* Arg381Gln Is Associated with Ankylosis in Spondyloarthritis.
Amir Kadi[1], Félicie Costantino[1], Brigitte Izac[1], Ariane Leboime[2], Roula Said-Nahal[2], Gilles Chiocchia[1] and Maxime A. Breban[2]. [1]Institut Cochin - INSERM U1016 - CNRS (UMR 8104), Paris, France, [2]Ambroise Paré Hospital (AP-HP), and Versailles Saint Quentin en Yvelines University, Boulogne-Billancourt, France

Background/Purpose: Spondyloarthritis (SpA) is a group of articular disorders sharing genetic background. Single-nucleotide polymorphisms (SNP) of the interleukin 23 receptor (IL23R) gene have been reproducibly reported as associated with ankylosing spondylitis (AS) a subset of SpA, defined by advanced radiographic sacroiliitis. Here, we examined the association between several SNPs in the IL23R gene and SpA as a whole. A particular attention was devoted to genotype-phenotype correlations.

Methods: Eight single-nucleotide polymorphisms (SNPs) located in the IL23R gene were genotyped in a collection of 414 independent French SpA patients and 264 healthy controls. In addition, the most significantly associated polymorphism rs11209026 (Arg381Gln) was genotyped in 156 multiplex families of SpA and in 136 independent trios. Association analyses were carried using UNPHASED, in SpA as a whole group, and then separately in AS and non-radiographic SpA (non-AS) patients.

Results: Strong association with AS was observed in the 3 datasets (case/control, familial and trios) with the non-synonymous polymorphism rs11209026 Arg381Gln ($P=2.86 \times 10^{-3}$ $P=4.59 \times 10^{-3}$ and p=0.02, respectively). In contrast, such association was not detected with the non-AS group (P=0.878, p=0.65 and p=1). Furthermore, association with this polymorphism was significantly different between the AS and non-AS patients in both studies ($P=2.5 \times 10^{-3}$).

Conclusion: Our results confirm that IL23R polymorphisms are associated with SpA, either in sporadic or in familial cases. However, phenotypic analysis revealed that association with Arg381Gln polymorphism is restricted to the AS subtype, suggesting that IL23R could influence the phenotypic expression of SpA by promoting ankylosis.

LIGHT (TNFSF14), Cathepsin K, DKK-1 and Sclerostin in Ankylosing Spondylitis: Osteoclast/OSTEOBLAST Imbalance Unrelated to Disease Activity and Effect of ANTI-TNFα Treatment On the WNT/β Catenin Pathway.
Alberto Cauli, Grazia Dessole, Giovanni Porru, Matteo Piga, Alessandra Vacca, Valentina Ibba, Pietro Garau and Alessandro Mathieu. University of Cagliari, Cagliari, Italy

Background/Purpose: Ankylosing Spondylitis (AS) is an inflammatory arthritis characterized by erosions and new bone formation. These processes appear to be related by the fine balance of mediators involved in osteoclast activation, such as LIGHT (TNFSF14) protein and cathepsin K, and inhibition of osteoblast influenced by DKK-1 and sclerostin, although data available is still controversial. The aim of this study was to investigate in AS the main mediators involved in bone methabolism, and their relation to disease activity and anti-TNF-α treatment.

Methods: 63 patients with AS have been consecutively recruited as well as 19 healthy controls (HC). 15 patients underwent anti-TNF-α treament (Adalimumab), and were evaluated at baseline (w0) and 12 weeks after treatment (w12). Serum levels of DKK-1, Sclerostin, Cathepsin K and LIGHT were measured by ELISA assay (Biomedica, R&D System) and correlated with clinical scores (BASMI, BASFI e BASDAI) and inflammatory markers (ESR and CRP). Data were expressed as mean $+/-$SD.

Differences among groups and statistical correlation have been analyzed according to data distribution by means of paired t-test, unpaired t-test with Welch's correction and Spearman's test.

Results: Mediators of osteoclast activation were increased in AS patients compared to HC: LIGHT (115.1 pg/mL±74.8 vs 75.8 pg/mL ± 49.2; p= 0.009), cathepsin-k (21 pmol/L ± 35.9 vs 9.6 pmol/L ± 5.8; p= 0.03), as well as mediators involved in osteoblast function: DKK-1 (36.4 pmol/L ± 18.8 vs 23.5 pmol/L; ± 17.6; p=0.009), sclerostin (36.4 pmol/L ± 21.8 vs 25.1 pmol/L ± 9.1; p=0.001). The increase of these mediators resulted unrelated to disease activity, as evidenced by the lack of correlation of DKK-1, sclerostin, LIGHT and cathepsin-K with clinical scores; only LIGHT showed to correlate with ESR (p=0,01; r=0,4). It is also noteworthy the little modulation induced on these mediators by TNF-α antagonists, regardless the good clinical response according to EULAR criteria: DKK-1, LIGHT and cathepsin-k, w0 vs w12 p= ns, while increased sclerostin levels were observed at w12 compared with baseline (p=0.03).

Conclusion: AS patients showed an increased bone metabolism, characterised by an increase of both mediators responsible of osteoclast activation and erosions, and mediators of osteoblast activation and new bone formation. This increased bone turn-over appear not linked to the inflammatory process and to disease activity, as perceived by the patient. Furthermore it appear to be independent to TNF-α related mechanisms, as recently suggested by radiological progression in patients with disease in clinical remission following anti-TNF-α treatment.

Regulatory T Cells in Spondyloarthritis (SpA) Animal Model and Modulatory Role of Inducible Costimulator (ICOS).
Luiza Krause[1], Ingrid Fert[1], Karine Labroquère[2], Muriel Andrieu[2], Gilles Chiocchia[1] and Maxime A. Breban[3]. [1]Institut Cochin - INSERM U1016 - CNRS (UMR 8104)-Université Paris Descartes (UMR-S 1016), Paris, France, [2]Cochin Immunobiology Facility, Paris, France, [3]Ambroise Paré Hospital (AP-HP), and Versailles Saint Quentin en Yvelines University, Boulogne-Billancourt, France

Background/Purpose: HLA-B27/human β2m transgenic rats (B27-rats), a model of SpA develop spontaneous colitis and arthritis. It was recently shown in this model that IL-17 producing T cells are expanded both in mesenteric and popliteal lymph nodes (LN). Moreover, after *in vitro* stimulation, Th17 cells were preferentially induced and expanded by DCs from B27-rats (A&R 2012;64:110–20). Given that regulatory T cells (Treg) and Th17 cells have been described as two distinct subsets with opposing effects on inflammatory disorders, we hypothesized that the Th17 bias observed in B27-transgenic rats could be explained by a decreased frequency and/or a functional defect of Treg cells.

Methods: We examined the phenotype and function of Treg in the LN of B27- and control nontransgenic (NTG) rats, using the following methods: cell surface expression of Treg-associated markers; *in vitro* suppression assay; intra-cellular IL-17 and IL-10 production by flow cytometry and RT-PCR assay of *ex vivo*-sorted Treg cells; differentiation of naives T cells into Treg in Treg-polarizing conditions and transcription factor expression by RT-PCR.

Results: Based on the combination of Foxp3 and CD25 expression, two suitable markers for Treg in the rat, we distinguished two populations of CD4+ LN T cells, namely regulatory CD25+Foxp3+ T cells (Treg) and activated CD25+Foxp3- T cells (Teff). We observed that Teff cells were specifically enriched in the B27-rats. However, accumulation of Teff cells was not correlated with a defect in Treg differentiation, since we observed similar differentiation of naives Tcells to Treg in Treg-polarizing conditions, in both NTG and B27-rats. Despite a decreased proportion of Treg their suppressive activity was not compromised in the B27-rats. Indeed, Treg from NTG and B27-rats inhibited T cell proliferation to a similar extent. Cell surface expression of several Treg markers, i.e. GITR, CTLA-4 and LAG-3 was equivalent between NTG and B27-rats. In contrast, we observed an up-expression of ICOS marker in Treg cells from B27-rats, as compared to NTG-rats. High levels of ICOS expression usually define a population of Treg that present superior suppressive activity and expression of IL-10. Paradoxically, we observed that Treg from B27-rats down-expressed IL-10, as compared to those from NTG rats. Furthermore, Treg from B27-rats expressed higher levels of IL-17 than those from control rats. Interestingly, anti-ICOS mAb blocking assay resulted in a decrease of IL-17 expression and increase of IL-10 expression by naive or effector CD4+ T cells cocultured with DCs from B27-rats.

Conclusion: Our data suggest that an IL-10/IL-17 imbalance observed in Treg from B27-rats may contribute to disease development and reveal a critical role for ICOS signaling in the generation and maintenance of IL-17 producing T cells in this animal model of SpA.

Bath Ankylosing Spondylitis Functional Index (BASFI) Is a Better Indicator of Poor Quality of Life Than Bath Ankylosing Spondylitis Disease Activity Index (BASDAI) in Ankylosing Spondylitis: Results From SIRAS – the Scotland and Ireland Registry for Ankylosing Spondylitis. Gareth T. Jones[1], Linda E. Morton[1], Gary J. Macfarlane[1] and Scotland and Ireland Registry for Ankylosing Spondylitis[2]. [1]University of Aberdeen, Aberdeen, United Kingdom, [2]Aberdeen

Background/Purpose: Bath Ankylosing Spondylitis Disease Activity Index (BASDAI) and Functional Index (BASFI) are validated instruments used to determine disease activity and function amongst ankylosing spondylitis patients. BASDAI is more commonly collected in clinic due, in part, to its use as a clinical criterion for commencing biologic therapy, however the relationship between both BASDAI and BASFI, and quality of life (QoL), is not well established. The aim of this study was to investigate this relationship in the context of other QoL markers.

Methods: The Scotland and Ireland Registry for Ankylosing Spondylitis (SIRAS) collects data on clinically diagnosed ankylosing spondylitis patients in Scotland. Various clinical measures including BASDAI, BASFI are obtained from medical records, and postal questionnaires provide various demographic and patient-reported data, including pain, fatigue, extra spinal manifestations and QoL as determined by the Ankylosing Spondylitis Quality of Life (ASQoL) instrument. In addition, patient postcodes were used to determine a deprivation score from 1 (most affluent) to 20 (most deprived) using the Scottish Index of Multiple Deprivation scale. Factors associated with poor QoL (characterised by an ASQoL score ≥11) were examined using Poisson regression, and results are given as risk ratios with 95% confidence intervals.

Results: As of the 26th March 2012, 311 patients had been recruited and provided complete data on BASDAI, BASFI and QoL (75% male; median age 51yrs inter-quartile range: 42–61yrs; median ASQoL: 6.0,: 1–11). Poor QoL was associated with both high disease activity (BASDAI ≥4: risk ratio: 3.7, 95%CI 2.3–6.0) and poor function (BASFI ≥4: 6.1; 3.4–10.9). However, these were not independent of each other. After mutual adjustment only poor function (BASFI) remained an independent predictor of QoL (4.8; 2.4–9.6). The relationship with disease activity (BASDAI) was greatly reduced and no longer statistically significant (1.4; 0.8–2.4).

Other factors independently associated with poor QoL were: female gender (1.6; 1.1–2.4), reporting either chronic widespread body pain (2.7; 1.5–4.8) or moderate/severe fatigue (1.8; 1.2–2.8), ever receiving anti-TNF therapy (1.5; 1.0–2.2), and social deprivation (RR most versus least deprived): 2.0; 1.1–3.5). No other clinical measures, including markers of inflammation (CRP or ESR), any peripheral joint involvement, or co-morbid disease of the eyes, skin or gut, were associated with poor QoL.

Conclusion: As it is integral to anti-TNF prescribing guidelines, disease activity (BASDAI) is considered as the important clinical indicator in AS. However, clinicians should be aware that function (BASFI) is a stronger predictor of poor QoL. Patients with a high BASFI were almost five times more likely to report poor QoL than other patients. In addition, after adjusting for BASFI, few other clinical variables were independently associated with QoL.

Sexual and Reproductive Health Counseling Among Adolescents with Systemic Lupus Erythematosus. Xue Tian, Murray H. Passo, Janice D. Key, Thomas C. Hulsey and Natasha M. Ruth. The Medical University of South Carolina, Charleston, SC

Background/Purpose: Systemic Lupus Erythematosus (SLE) is an autoimmune disease that is known to target young adults, especially women of child-bearing age. Although it is well-accepted that teratogenic SLE medications can cause negative pregnancy outcomes, there has been little research conducted to examine sexual health and contraceptive counseling among young adults with SLE, specifically teens and adolescents. The purpose of this study is: 1) to determine how much female adolescents with SLE know about their disease, SLE medications, how SLE relates to their sexual health, and how SLE symptoms can be impacted by pregnancy, STDs and contraceptives containing estrogen. 2) to educate the same group of patients about sexual and reproductive health using a face-to-face counseling session. 3) to reassess their knowledge after the intervention.

Methods: Female adolescents with SLE were recruited from the MUSC Pediatric Rheumatology clinic. Information on age, race, gender, medications, previous pregnancies, and length of diagnosis with SLE was obtained. The questionnaire (31 items regarding SLE medications, contraceptives, and STD's) was completed by all subjects before and after the intervention, which was a face to face educational session. The resulting data was analyzed by using a paired t-test.

Results: 13 female SLE patients, ages 12–21, were studied (11 African Americans, 1 Caucasian, 1 other). The average percent correct on the pretest questions was 30.8% on questions regarding the effects of SLE medications on pregnancy, 38.8% on questions regarding contraceptives, and 78.8% on questions regarding sexual health and STD's. The average percent correct on post-tests for those 3 categories of questions were 88%, 77%, and 99% respectively. The average improvement between pre- and post-tests for the 3 categories were 57.7% with a p-value of 0.0001, 46.2% with p-value of 0.0001, and 20.2% with p-value of 0.0006 respectively.

Conclusion: The low scores on the initial baseline assessment show that SLE adolescents are under-educated about contraceptives and the effects of SLE medications on pregnancy. After the counseling session, the average percent correct scores on the post-test significantly improved in all 3 categories. The issues surrounding contraceptives and pregnancy are important for this population, and it is imperative to advise SLE adolescents and teens on effective contraceptives in order to avoid unplanned pregnancies with unfavorable outcomes. This study demonstrates the need to establish routine counseling on contraceptives and reproductive health for women with SLE.

Cell Bound Complement Activation Products Are Associated with Disease Activity in Systemic Lupus Erythematosus. Kenneth C. Kalunian[1], W. Winn Chatham[2], Elena M. Massarotti[3], Joyce Reyes-Thomas[4], Richard Furie[5], Jill Buyon[6], Emily C. Somers[7], Chaim Putterman[8], Rachel L. Gross[9], Kyriakos A. Kirou[10], Rosalind Ramsey-Goldman[11], Christine Hsieh[12], Thierry Dervieux[13] and A. Weinstein[14]. [1]UCSD School of Medicine, La Jolla, CA, [2]University of Alabama at Birmingham, Birmingham, AL, [3]Brigham and Women's Hospital, Harvard Medical School, Boston, MA, [4]Albert Einstein College of Med, Bronx, NY, [5]North Shore-LIJ Health System, Lake Success, NY, [6]New York University School of Medicine, New York, NY, [7]University of Michigan, Ann Arbor, MI, [8]Albert Einstein College of Medicine, Bronx, NY, [9]Albert Einstein College of Medicine, New York, NY, [10]Hospital for Special Surgery, New York, NY, [11]Northwestern University Feinberg School of Medicine, Chicago, IL, [12]University of Chicago, Chicago, IL, [13]Exagen Diagnostics, Albuquerque, NM, [14]Washington Hospital Center, Washington, DC

Background/Purpose: Elevated cell-bound complement activation products (CBCAPs) and decreased erythrocyte complement receptor 1 (ECR1) expression may correlate with disease activity in systemic lupus erythema-

tosus (SLE). We evaluated the relationship between CBCAPs, ECR1 and SLE disease activity as part the multicenter study of complement activation products in the assessment of lupus (CAPITAL).

Methods: The CAPITAL study was cross-sectional and enrolled SLE patients who met the ACR classification criteria. ECR1 as well as complement C4d levels on erythrocytes (EC4d), platelets (PC4d), and B cells (BC4d) were determined using flow cytometry. Disease activity was measured at the time of the study visit using the Safety of Estrogens in Lupus Erythematosus National Assessment (SELENA) version of the SLE Disease Activity Index (SLEDAI). Disease activity was dichotomously stratified by SELENA-SLEDAI scores <6 (low disease activity) or ≥6 (high disease activity). Statistical analyses utilized Wilcoxon rank-sum tests, area under receiver operating characteristic (ROC) curves, Fisher Exact tests and multivariate logistic regression.

Results: Among 209 SLE evaluable patients (90% females, mean age 41years), a total of 41 (19.6%) had high disease activity at the time of sample acquisition. As presented in Table I, high disease activity was associated with elevated levels of EC4d, BC4d, PC4d and reduced levels of ECR1 ($p<0.004$). ROC analyses indicated that EC4d above 14.8 units (ROC AUC=0.646) was associated with a 3.4-fold (95% CI: 1.6–7.4) higher likelihood of high disease activity. Similarly, BC4d above 71.5 units (ROC AUC=0.643) and PC4d above 6.3 units (ROC AUC=0.718) were associated with a 4.3-fold (95% CI:1.9–10.8) and 5.3-fold (95% CI:2.3–13.5) greater likelihood of high disease activity, respectively. Conversely, ECR1 levels below 10 net MFI (AUC=0.694) were associated with a 4.2-fold (95% CI:1.9–9.3) higher likelihood of high disease activity. By multivariate logistic regression analysis only elevated PC4d and low ECR1 were associated with high disease activity. Among patients presenting with both elevated PC4d (>6.3 net MFI) and reduced ECR1 (<10.2 net MFI), 45% had high disease activity compared to 5% of those having PC4d and ECR1 below 6.3 and above 10.2 net MFI respectively ($p<0.01$).

Table. CB-CAPS and ECR1 levels in SLE patients with low or high disease activity (MFI: mean fluorescence intensity)

	Low disease activity N=168	High disease activity N=41	P value
EC4d Net MFI	11.4 (7.4–19.5)	16.6 (11.3–26.0)	<0.004
Net MFI>14.8	33.9%	63.4%	<0.001
BC4d Net MFI	66.7 (35.1–130.0)	117.0 (75.2–188.6)	<0.005
Net MFI>71.5	45.2%	78.0%	<0.001
PC4d Net MFI	5.2 (2.4–10.8)	13.9 (7.3–43.4)	<0.001
Net MFI >6.3	39.9%	78.0%	<0.001
ECR1 Net MFI	13.5 (9.2–17.9)	9.3 (6.7–12.4)	<0.001
Net MFI>10.2	67.9%	34.1%	<0.001

Conclusions: These hypothesis generating data suggest that elevated EC4d, BC4d, PC4d and reduced ECR1 levels are associated with high disease activity. Prospective longitudinal studies will be essential to establish the predictive value of CBCAPs and ECR1 measurements for determining SLE disease flares.

604

Comparing the ACR and the SLICC Criteria for the Classification of SLE Patients Using Data from an Existing Multi-Ethnic Cohort. Graciela S. Alarcon[1], Gerald McGwin Jr.[1], Larry Madger[2] and Michelle Petri[3]. [1]University of Alabama at Birmingham, Birmingham, AL, [2]University of Maryland, Baltimore, MD, [3]Johns Hopkins University School of Medicine, Baltimore, MD

Background/Purpose: The SLICC group has proposed a modification of the revised/updated SLE ACR classification criteria; it has comparable metric properties but is felt to be clinically more relevant (Arthritis Rheum 2012, May 2, ePub ahead of print). We have now compared both sets of criteria in a well-characterized SLE cohort.

Methods: At cohort entry (V0), all patients had met 4 updated/revised ACR criteria. Using the data up to V0, we determined the dates at which the ACR and SLICC criteria were first met. Some SLICC criteria could not be applied (some acute and chronic forms of cutaneous lupus, non-scarring alopecia, mononeuritis multiplex and complement values). We compared

groups of patients based on whether the SLICC criteria were met before, at the same time or after the ACR were met.

Results: Of 640, using the SLICC criteria 319 (49.8%) were classified at the same time using either criteria set, 78 earlier (12.2%, mean 0.7 years) and 225 (35%) later (mean 4.4 years) compared to the ACR criteria; 18 patients (2.8%) did not meet the SLICC criteria despite a mean of 1.2 years from the time the ACR criteria were met and V0. Five of the 78 earlier patients (6.4%) met the SLICC rule of lupus nephritis (LN) plus 1 immunologic criterion. Of the patients diagnosed later, the majority did so because of the combination of malar rash and photosensitivity into the Acute Cutaneous Lupus criterion. There were no differences in terms of age, gender and disease activity between the groups, but African Americans and Texan-Hispanics were more likely to be in the no difference group and Caucasians and Puerto Rican-Hispanics in the later or in the no diagnosis groups. Tables 1 and 2 show the distribution of the ACR and SLICC criteria among all 4 groups; only those criteria which differ between the 2 sets are shown in Table 2.

Table 1. Patients who met ACR Criteria at V0

ACR criteria	N (positive)	SLICC criteria met earlier, % n=78	SLICC criteria met later, %, n=225	SLICC criteria not met, % n=18	SLICC criteria met at the same time, % n=319	p-value
Malar rash	316	30.8	57.3	88.9	46.1	<0.001
Discoid rash	76	9.0	11.1	11.1	13.2	0.757
Photosensitivity	332	48.7	64.9	100.0	40.8	<0.001
Oral ulcers	263	38.5	39.6	44.4	42.6	0.785
Synovitis	484	74.4	76.0	61.1	76.5	0.506
Serositis	265	28.2	35.1	5.6	51.1	<0.001
Neurologic	59	5.1	4.4	5.6	13.8	<0.001
Renal	202	29.5	24.4	5.6	38.6	<0.001
Hematologic	437	70.5	60.0	27.8	75.9	<0.001
Immunologic	451	65.4	59.1	5.6	83.4	<0.001
ANA	621	100.0	99.1	55.6	97.2	<0.001

Table 2. SLICC Criteria in SLE Patients at V0

Clinical	N (positive)	SLICC criteria met earlier, % n=78	SLICC Criteria met later, %, n=225	SLICC criteria not met, % n=18	SLICC criteria met at the same time, % n=319	p-value
Acute cutaneous lupus or SCLE	419	57.7	72.4	100.0	60.5	<0.001
Neurologic	76	11.5	4.9	11.1	16.9	<0.001
Hemolytic anemia	59	10.3	5.3	5.6	11.9	0.067
Leukopenia	464	85.9	62.2	27.8	79.0	<0.001
Thrombocytopenia	104	12.8	7.1	0	24.5	<0.001
Immunologic						
Anti-DNA	427	83.3	52.9	5.6	75.9	<0.001
Anti-Sm	290	73.1	24.0	0	56.1	<0.001
Anti-phospholipid	186	47.4	14.2	0	36.7	<0.001

Conclusion: Despite the lack of data for some of the items on the SLICC criteria, we have shown that some patients could be classified earlier with them than with the ACR criteria (major organ involvement or LN plus 1 immunologic criterion); however, a relatively high proportion of patients could not be classified until later (malar rash/photosensitivity combination in 1 criterion, main reason) or not at all. Longitudinally complete data collection is needed to better define the role of the SLICC criteria in the clinical and research settings.

605

Increased Incidence of Herpes Zoster Among Patients with Systemic Lupus Erythematosus. Eliza F. Chakravarty[1], Kaleb Michaud[2], Robert S. Katz[3] and Frederick Wolfe[4]. [1]Oklahoma Medical Research Foundation, Oklahoma City, CA, [2]National Data Bank for Rheumatic Diseases & University of Nebraska Medical Center, Omaha, NE, [3]Rush University Medical Center, Chicago, IL, [4]National Data Bank for Rheumatic Diseases, Wichita, KS

Background/Purpose: Herpes zoster (HZ) is the painful reactivation of latent varicella zoster virus infection. The incidence of HZ may be increased in some autoimmune diseases including systemic lupus erythematosus (SLE). We examined the incidence and risk factors for HZ in a prospective cohort of patients with physician-diagnosed SLE compared to those diagnosed with non-inflammatory musculoskeletal conditions (MSK).

Methods: Study subjects were participants in the National Data Bank for Rheumatic Diseases (NDB) longitudinal study of rheumatic disease outcomes. Participants are followed prospectively with semi-annual detailed questionnaires collecting data on medication use, comorbid conditions, infections (including specific questions on HZ), hospitalizations, and standard patient reported outcomes. After excluding 808 participants with a history of prior HZ at enrollment, we followed 1,485 SLE patients and 2,775 MSK for incident HZ between 2001 and 2010. Reports of HZ were validated by confirmation of a physician diagnosis. Age adjusted incidence rates were calculated for each group. Cox proportional hazard regression models were used to identify predictors of HZ for the entire cohort as well as for specific predictors for SLE patients. Zostavax vaccination rates for individuals ≥ 60 years old were compared between groups.

Results: SLE patients were younger than MSK (48.3 vs. 64.9 years), but had a similar disease duration of 13–14 years at enrollment. Health Assessment questionnaire at baseline was similar between groups (0.90 SLE vs. 0.87 MSK), although 25% of SLE patients were disabled from work compared to 9% of MSK. SLE patients had increased incidence of HZ at all ages, with an age-adjusted incidence of 12.0/1000 person-years compared to MSK (8.7/1000 person-years) and a hazard ratio of 1.7 (95% CI 1.08–2.71) for SLE (Figure). Increasing age (HR 1.01, 95%CI 1.00–1.02 per year) and increased HAQ (HR 1.26, 95% CI 1.10–1.44) were independent predictors of HZ. Among SLE patients, prednisone (HR 2.29, 95% CI 1.24–4.23) and mycophenolate mofetil (HR 5.00, 95% CI 1.40–17.6) conferred additional risk. SLE had the lowest HZ vaccination rates among age-eligible subjects; 7.1% SLE vs. 13% MSK, p<0.001.
Figure. Sex-adjusted relative incidence of incident herpes zoster by age for each diagnosis.

Conclusion: The incidence of HZ is increased in SLE at all ages when compared to MSK, while vaccination rates remain low. Prednisone and mycophenolate mofetil are associated with increased risk.

Risk Factors Associated with Cervical Human Papillomavirus Infection in Women with Systemic Lupus Erythematosus: The Role of Rituximab. Mario Garcia-Carrasco[1], Claudia Mendoza Pinto[1], Alejandro Taboada-Cole[1]. Verónica Vallejo-Ruiz[2], Julio Reyes-Leyva[2] and Aurelio Lopez-Colombo[3]. [1]HGR 36 CMN Manuel Ávila Camacho, Instituto Mexicano del Seguro Social, Puebla, Mexico, [2]Centro de Investigación Biomédica de Oriente, Instituto Mexicano del Seguro Social, Hospital General de Zona No. 5, Puebla, Mexico, [3]Delegación Estatal, Instituto Mexicano del Seguro Social, Puebla, Mexico

Background/Purpose: Systemic lupus erythematosus (SLE) is a chronic, autoimmune, multisystemic disease that affects women of reproductive age. Women with SLE have an increased risk of cervical abnormalities and cervical human papillomavirus (HPV) infection. Studies have investigated risk factors for cervical infection with HPV, with contradictory results. The role of biological therapy on the risk of HPV infection in women with SLE has not been explored. The objective of our

study was to identify the prevalence and factors associated with cervical infection by HPV in women with SLE.

Methods: In this cross-sectional study, we investigated 148 women with SLE. A structured questionnaire was administered to identify traditional and SLE-related disease risk factors. A gynecological evaluation and cervical cytology was made. Polymerase chain reaction for viral DNA was performed for HPV determination.

Results: The mean (± SD) age and disease duration of SLE patients were 42.5 ± 11.8 years and 9.7 ± 5.3 years, respectively. The prevalence of squamous intraepithelial lesions was 6.8%. The prevalence of HPV infection was 29%, with HVP 18 being the most frequent type (found in 25.5% of patients without multiple infections). HPV (+) patients were younger than HPV (−) patients (38.2 ± 11.2 vs. 44.2 ± 11.5; p = 0.05) and were receiving a higher daily dose of prednisone (12.8 ± 6.8 mg vs. 9.7 ± 6.7 mg; p = 0.01). In the multivariate logistic analysis, only age at the time of the study was associated negatively with HPV infection (B= 0.04, OR 0.95, 95% CI: 0.95–0.98). There was a non-significant trend to more-frequent administration of immunosuppressive and biologic therapy with rituximab in HPV (+) patients.

Table. Sociodemographic, clinical and treatment characteristics of systemic lupus erythematosus patients with and without cervical human papillomavirus infection

Variable	VPH + (n=43)	VPH − (n=105)	P
Age, mean ± SD DE years	38.2 ± 11.2	44.2 ± 11.5	0.05
Current smoker, n (%)	4 (9.3)	12 (11.4)	0.4
Age at first intercourse, mean ± SD	20.4 ± 3.4	20.5 ± 3.8	0.8
Number of sexual partners, mean ± SD	1.65 ± 1.0	1.42 ±0.8	0.16
Oral contraceptive use, n (%)	1 (2.3)	0 (0)	0.29
Disease duration, mean ± SD years	9.5 ± 6.2	9.8 ± 6.1	0.77
Current medication	36 (83.7)	81 (77.1)	0.5
Antimalarials, n (%)	12.8 ±6.8	9.7 ± 6.7	0.01
Prednisone (mg/d), mean ± SD	25 (58.1)	57 (54.1)	0.7
Immunosuppressive therapy, n (%)	16 (37.2)	30 (28.5)	0.33
Azathioprine, n (%)	5 (11.6)	25 (23.8)	0.17
Methotrexate, n (%)	5 (11.6)	6 (4.7)	0.28
Leflunomide, n (%)	4 (9.3)	1 (0.9)	0.02
Mycophenolic acid, n (%)	7 (16.2)	9 (8.5)	0.24
Rituximab			

Conclusion: Women with SLE, and especially younger patients, had an increased prevalence of cervical HPV infection. Conventional and biologic therapy with rituximab may not influence HPV infections. Screening for HPV infection is recommended in patients with SLE.

Activity Index After Renal Failure in a Cohort of 32 Patients with Lupus Nephritis. Cristina Gonzalez-Pulido[1], Sara Croca[2] and D.A. Isenberg[3]. [1]University Hospital Virgen del Rocio, Seville, Spain, [2]University College London, London, United Kingdom, [3]University College of London, London, United Kingdom

Background/Purpose: Most published studies that have measured activity in patients with lupus nephritis suggest the disease is relatively quiescent after renal failure.

Purpose: To analyze retrospectively the activity index of 32 patients in end-renal stage disease (ESRD) from a cohort of 182 patients with lupus nephritis during dialysis and/or post renal transplant.

Methods: We used the BILAG index, levels of complement C3 (n = 0.9–1.8 g/L) and anti-DNA antibodies (n = 0–50 IU/ml) to measure the lupus activity every 6 months after the beginning of dialysis and after renal transplant. Inactive disease was defined as no BILAG A/B both C3 and DNA level within the normal range. Mild-moderate disease was defined as at least 1 B in BILAG and/or mild serological involvement (C3 levels= 0.89–0.73 g/L and/or DNA levels= 51–149 IU/ml). We considered patients to be severely activity when at least 1 A or 2 B were present in BILAG and/or major serological abnormality (C3 levels< 0.73 g/L and/or DNA levels >149 IU/L).

Results: We followed up a cohort of 182 patients with lupus nephritis from January 1978 to February 2012. 32 patients went into ESRD defined as the need of haemodialysis (HD) or peritoneal dialysis (CAPD). Ethnically, 37,5% were

Afrocaribbean, 25% from the Indian subcontinent, 28% Caucasian and 9,4% others. The duration of follow up during ESRD dialysis ranged from 1 to 144 months (median 24, IQR 12–54). 14 of them had a renal transplant. We divided our cohort in two groups: 1) all patients in ESRD (n=32). 2) Transplant patient (n=14). **Group 1:** 15.1% of the measurements showed completely inactive disease and 84.9% had at least mild-moderate activity at some time (58.5% had both BILAG index and serological activity, 26.3% only serological involvement, 16.95% only activity by BILAG. Severely active disease only was present in 54.7% of them (34.2% BILAG and serological, 50% serological, 15.8% only BILAG activity). The BILAG involvement was haematological (29.6%), musculoskeletal (19.7%), mucocutaneous (15.5%), constitutional (11.3%), neurological (8.4%) and gastrointestinal (1.4%). 12 patients died. **Group 2:** 42.3% of the measurements showed inactive disease and 57.7% had at least one flare in this period (43.3% BILAG and serological, 23.3% serologically, 33,3% by BILAG). Severe activity markers were present in only 26.92% (50% BILAG and serological, 32,14% BILAG, 17.9% serologically). The BILAG involvement in this group was due to renal alteration (34%), haematological (30%), constitutional (10%), neurological and cardiovascular (8% each), mucocutaneous (6%), musculoskeletal and gastrointestinal (2%) each. 2 patients died.

Conclusion: We report a 34 years follow-up of a cohort of 32 patients with SLE nephritis in renal failure. The activity after ESRD was much lower in the group of transplant patients. Serological activity was the main finding in both groups.

608

Association of Discoid Lupus with Other Clinical Manifestations Among Patients with Systemic Lupus Erythematosus. Joseph F. Merola, Christina Iversen, Jose A. Gomez-Puerta, Tabatha Norton, Hsun Tsao, Peter H. Schur, Elena M. Massarotti, Bonnie L. Bermas and Karen H. Costenbader. Brigham and Women's Hospital, Harvard Medical School, Boston, MA

Background/Purpose: Prior studies suggest that cutaneous discoid lupus (DLE) is a marker for less severe disease with a low frequency of nephritis and end-stage renal disease among SLE patients. These past studies have not included diagnostic confirmation of DLE by expert dermatologists and did not adjust for medication use. We investigated associations of validated cases of DLE with other specific SLE manifestations in a large validated SLE Cohort.

Methods: Our academic hospital SLE registry contains data on 5,030 patients seen for potential SLE, 1970–2011. Inclusion criteria for this study were: definite SLE per treating rheumatologist and an SLE expert, 4/11 of 1997 ACR classification criteria for SLE, >2 visits and >3 months of follow-up, and a documented year of SLE diagnosis. The presence of DLE was validated by an expert dermatologist with review of multispecialty notes, pathology and digital images, when available. We collected SLE manifestations, medication and serologic data from review of electronic medical records. We tested for associations between DLE and each of the ACR SLE criteria, as well as end-stage renal disease (ESRD), using multivariable-adjusted logistic regression analyses.

Results: Of 1,043 SLE patients included, 92% were female and 51% White, 100% were ANA positive, 66% were anti-dsDNA positive. Mean age at diagnosis was 32 years ($\pm$ 13) and mean duration of follow-up was 10 years ($\pm$ 6.5). DLE (n=117) was significantly associated with the presence of photosensitivity, leukopenia and anti-Smith antibodies (**Table**). DLE was inversely associated with both arthritis and pleuritis. We found no significant associations between DLE and nephritis or ESRD.

Table. Associations between Discoid Lupus (n=117) and other ACR Criteria for SLE and End-Stage Renal Disease

SLE Manifestation	Number with DLE	Number without DLE	OR* (95% CI)	p-value
Anti-Smith (n=246)	45	201	2.41 (1.58–3.69)	<0.01
Photosensitivity (n=434)	60	374	1.63 (1.09–2.44)	0.02
Leukopenia (n=351)	50	301	1.55 (1.03–2.32)	0.04
Pleuritis (n=380)	31	349	0.56 (0.36–0.87)	0.01
Arthritis n=817)	79	738	0.49 (0.31–0.76)	<0.01

No significant associations between discoid lupus and the following were found: malar rash, oral ulcers, pericarditis, proteinuria, casts, lupus nephritis, seizure, psychosis, anemia, lymphopenia, thrombocytopenia, anti-dsDNA, antiphospholipid antibodies, end-stage renal disease
* OR= odds ratio, adjusted: Multivariable logistic regression analyses modeling the odds ratio of DLE associated with each SLE manifestation or laboratory finding separately, adjusted for age at diagnosis, sex, race/ethnicity, disease duration, ever medication use (azathioprine, cyclophosphamide, hydroxychloroquine, methotrexate, mycophenolate mofetil, systemic corticosteroids)

Conclusion: In this large cohort of SLE patients, we have found an increased frequency of photosensitivity, leukopenia and anti-Smith antibodies among SLE patients with DLE and an inverse association of DLE with both pleuritis and arthritis. We did not observe the inverse associations of DLE with anti-dsDNA antibodies, lupus nephritis, or ESRD that have been noted in other studies. These findings have important implications for prognosis among patients with DLE and possibly for different underlying pathophysiologies of SLE subtypes.

Peripheral Neuropathy in Systemic Lupus Erythematosus. Amin Oomatia[1], Hong Fang[2], Michelle Petri[2] and Julius Birnbaum[3]. [1]University of Cambridge, Cambridge, United Kingdom, [2]Johns Hopkins University School of Medicine, Baltimore, MD, [3]Johns Hopkins University, Baltimore, MD

Background/Purpose: Whilst Neurological disorders are a common manifestation of systemic lupus erythematosus (SLE), peripheral neuropathies have received little attention. The literature consists mostly of small case series with very few studies investigating larger samples. Consequently, various features of SLE-associated peripheral neuropathies such as prevalence, symptoms, severity, chronicity, clinical and serological associations, and electrophysiological and biopsy findings, are poorly described. Small fibre neuropathies are almost entirely un-reported. The aim of this study is to determine the prevalence, clinical features, electrophysiological and biopsy findings of peripheral neuropathies in systemic lupus erythematosus and to identify clinical and laboratory correlations.

Methods: We performed a retrospective study of 2,097 SLE patients seen at a single Center since 1987, and ascertained for the presence of neuropathy according to diagnostic criteria laid down by the American Academy of Neurology. We categorized subtypes of peripheral neuropathies on the basis of symptoms, examination, electrophysiological studies, and punch skin biopsy features. We excluded patients with co-morbid features associated with neuropathies. We evaluated for an association of demographic, SLE-related clinical features, antibodies, and other immunological data in SLE patients with neuropathies versus without neuropathies by student's t-test or chi-squared test, with p-values <0.05 considered statistically significant.

Results: The prevalence of neuropathies was 4.4%, present in 82 of 2097 patients. Of these 82 patients, the most common neuropathy was a large fiber neuropathy (68.3%): including neurophysiological assessment demonstrating 36 (44%) symmetric axonal neuropathies and 42 (51%) patients with a pure axonal loss, 18 patients had small-fiber neuropathies, characterized by decreased intra-epidermal nerve fiber density and/or morphological changes of unmyelinated fibers on skin biopsy. Altogether, patients with neuropathies were older at time of SLE diagnosis (39.16 versus 32.05, p<0.0001), had an increased risk of Zoster infection, but otherwise had similar profile of SLE-related clinical and laboratory features).

Conclusion: Our characterization of small-fiber neuropathy in patients, has never been systematically evaluated and reported in unselected SLE cohorts, and suggests that this neuropathy may be an unrecognized cause of morbidity in SLE patients. SLE patients with neuropathies versus without neuropathies shared similar clinical and immunological features. Given the tropism of VZV for peripheral neuronal structures, prospective studies are warranted to evaluate whether re-activation of VZV is a risk factor for SLE neuropathies.

B Lymphocyte Stimulator Levels Are Higher in Caucasian SLE patients Earlier in Disease Course and Predict Damage Accumulation. Eoghan M. McCarthy[1], Ruth Lee[1], Joan Ni Gabhann[2], Siobhan Smith[2], Michele Doran[3], Gaye Cunnane[3], Donough G. Howard[1], Paul G. O'Connell[1], Grainne M. Kearns[1] and Caroline Jefferies[2]. [1]Beaumont Hospital, Dublin 9, Ireland, [2]Royal College of Surgeons in Ireland, Dublin, Ireland, [3]St. James Hospital, Dublin, Ireland

Background/Purpose: B Lymphocyte Stimulator(BLyS) plays an important role in the pathogenesis of Systemic Lupus Erythematosus(SLE). Whilst trials of anti BLyS-targeted therapy have shown promise, the optimal timing and benefits of anti BLyS therapy remain undetermined. We sought to assess the relationship

between BLyS levels, disease activity, damage scores and clinical profiles in Caucasian SLE patients.

Methods: BLyS levels were determined by ELISA. Elevated BLyS levels were defined as values above the 95% percentile in a cohort of healthy controls. Patients were enrolled only if they could confirm three generations of their family were of Irish descent. Patients with SLE were divided into two groups: those with elevated BLyS levels(Group 1) or normal BLyS levels(Group 2).Demographic data, disease activity as per SLEDAI and damage scores(SLICC) at 5 year follow-up were recorded. Categorical variables were analyzed using Fisher's exact test and continuous variables by unpaired *t*-tests. The Mann-Whitney test was used in instances of non-normality.

Results: 45 patients were recruited.In this homogenous Caucasian population BLyS levels were higher in those with malar rash (920pg/ml v 594pg/ml, p<.05), musculoskeletal involvement (930pg/ml v 591pg/ml, p<.04), immunologic activity(1041pg/ml v 646pg/ml, p <.005) and renal disease (1127 pg/ml v 748pg/ml, p<.009).

In keeping with previous reports BLyS levels showed significant correlation with disease activity as measured by SLEDAI (r =.682, p<0.001). Twenty three SLE patients (51%) fell above the defined cutoff in healthy controls and were therefore classified as having "elevated" BLyS levels with the remaining twenty two patients having "normal" BLyS levels, the difference between groups being significant(1173 pg/ml v 558pg/ml, p<.001).

Patients with elevated BLyS levels at time of enrolment were found to be significantly younger at time of study visit (32.97 v 44.32 years, p<0.0019) with a shorter disease duration (4.96 v 9.23 years, p <0.0125). They also accrued significantly more damage over the subsequent five year period with a mean increase in damage score of 0.53 compared to 0.13 for patients with normal BLyS levels (p< 0.012). The odds ratio (OR) was 5.8 (p=0.023 by Fishers exact test). The change in SDI correlated significantly with plasma BLyS levels (r =.399,p<0.007). There was no difference in BLyS levels between those requiring steroid therapy to control their disease versus those steroid free. However, BLyS levels were higher in those patients requiring additional immunosuppression (Azathioprine or greater) to control their disease (926pg/ml v 642 pg/ml, p<0.005).

Sm antibody (OR 13.4, p=0.049), low C4 (OR 8, p=.016) and dsDNA positivity (OR 6.1, p=0.007) predicted BLyS elevation.

Conclusion: BLyS levels are higher in younger patients and those with a shorter disease duration. Although further validation of these clinical and immunological associations are warranted in larger cohorts of genetically homogenous populations our study suggests BLyS blockade may be most beneficial if introduced early in disease in young patients in an effort to prevent damage. BLyS levels remain elevated despite the use of additional conventional immunosuppressive agents.

611

Impaired Diffusion Tensor Imaging Findings in the Corpus Callosum and Cingulum May Underlie Impaired Learning and Memory Abilities in Systemic Lupus Erythematosus. Daphna Paran[1], Elissa Ash[1], Ira Litinsky[1], Valerie Aloush[1], Marina Anouk[1], Dan Caspi[2], Talma Hendler[3] and Irit Shapira-Lichter[3]. [1]Tel Aviv Sourasky Medical Ctr, Tel-Aviv University, Tel Aviv, Israel, [2]Tel Aviv, Israel, [3]Tel-Aviv Sourasky Medical Ctr, Tel-Aviv University, Tel Aviv, Israel

Background/Purpose: Memory impairment is prevalent in systemic lupus erythematosus (SLE), however the pathogenesis is unknown. In a previous functional Magnetic Resonance Imaging (MRI) study we demonstrated altered brain activity dynamics and less brain deactivation in patients with SLE without overt neuropsychiatric manifestations as compared to healthy controls, when performing a learning and memory task. Our findings localized this impairment to the anterior medial prefrontal cortex of the default mode network (DMN). In addition altered networking of the hippocampal subsystem of the DMN was seen in patients with SLE when performing this task. These findings may reflect compensatory mechanisms to overcome memory impairment. The purpose of the present study is to search for a structural substrate for the abnormal recruitment pattern observed in the functional MRI studies using Diffusion Tensor Imaging (DTI).

Methods: Using a DTI sequence in a 3.0T MRI scan, we characterized brain diffusivity in ten SLE patients and nine healthy controls. We examined two tracts associated with the DMN: the corpus callosum and the cingulum.

Results: In the left cingulum fibers higher apparent diffusion coefficient

(ADC, $F_{(1,16)}$ = 4.9, p<0.05) and radial diffusivity (Dr, $F_{(1,16)}$=4.6, p<0.05) values were seen in SLE patients as compared to controls. Similarly, in the corpus callosum, higher ADC values ($F_{(1,16)}$=13, p<0.005), radial diffusivity (Dr)($F_{(1,16)}$=7.4, p<0.05) and longitudinal diffusivity (Da) ($F_{(1,16)}$=14.4, p<0.005) were evident in SLE patients.

Conclusion: Higher diffusion coefficients in the corpus callosum and the left cingulum may indicate impaired organization/reduced integrity of these tracts which may underlie the abnormal pattern of brain activity recruitment of the DMN observed during a verbal learning and memory task. The abnormal findings in the left cingulum are in line with the central role of the left hippocampus in verbal memory and suggests that these findings may contribute to the impairment seen in patients with SLE on performance of a verbal memory task.

Thrombosis Recurrence in Systemic Lupus Erythematosus Patients with and without Antiphospholipid Antibodies. Ibrahim AlHomood, D. D. Gladman, Dominique Ibanez and Murray B. Urowitz. Toronto Western Hospital and University of Toronto, Toronto, ON

Background/Purpose: To determine the outcome of thrombotic events in the presence and absence of antiphospholipid antibodies (aPL) in patients with systemic lupus erythematosus (SLE).

Methods: Patients with SLE and thrombotic events followed prospectively at the Lupus clinic were divided into two groups: 1) those with one event (no recurrence) and 2) those with recurrent events.

Demographic and clinical data collected at time of thrombosis included age, race, gender, aPL status (anticardiolipin antibodies &/or lupus anticoagulant), disease duration, disease activity (SLEDAI-2K), hypertension, diabetes mellitus (DM), hypercholesterolemia, smoking and use of aspirin (ASA). Thrombotic events (TE) were divided into arterial TE(ATE) and venous TE (VTE).ATE was defined as angina, myocardial infarction, stroke, or peripheral arterial thrombosis, and VTE was defined as deep vein thrombosis or pulmonary emboli. Comparison between patients with and without recurrence was done using descriptive statistics. Time to recurrence was compared using Kaplan-Meier curves and stepwise Proportional hazard models.

Results: 613 TE were identified in 400 patients. 213 recurrences were observed in 132 patients. The aPL status is known in 367 patients of whom118 (32.2%) have had a recurrence. The mean time to recurrence in these 118 patients is 5.0 ± 5.1 years.

Serum Level of Syndecan-1 Is Associated with Disease Activity in Patients with Systemic Lupus Erythematosus. In-Woon Baek[1], Ki-Jo Kim[2], Ji-Young Kim[3], Su-Jung Park[3], Chong-Hyeun Yoon[4], Wan-Uk Kim[5] and Chul Soo Cho[6]. [1]Internal medicine, Catholic University of Korea, Callege of Medicine, Seoul, South Korea, [2]College of Medicine, Catholic University of Korea, Seoul, South Korea, [3]Research Institute of Bone & Joint Diseases, Catholic University of Korea, Seoul, South Korea, [4]College of Medicine, The Catholic University of Korea, Seoul, South Korea, [5]College of Medicine, The Catholic University of Korea, Suwon, South Korea, [6]St Marys Hospital, Seoul, South Korea

Background/Purpose: Syndecan-1(SDC1), a transmemebrane heparansulfate glycoprotein, is predominantly expressed by plasma cells and is a receptor for a proliferation-inducing ligand (APRIL). SDC-1 is readily shed and release into plasma under certain pathologic conditions and remains biologically active to affect cellular behaviour of plasma cells. Plasma cells are effector cells producing pathogenic autoantibodies in systemic lupus erythematosus (SLE). The purpose of this study are to evaluate serum SDC1 concentration and to determine association between its levels and certain clinical manifestation in patients with SLE.

Methods: Serum samples from 127 patients with SLE and 24 normal healthy controls were assayed for SDC1 and APRIL by enzyme linked immunosorbent assay. Medical records were thoroughly reviewed for clinical features and serologic values. Disease activity was assessed using the Systemic Lupus Erythematosus Disease Activity Index (SLEDAI).

Results: Serum SDC1 levels were significantly elevated in patients with SLE compared to controls (61.2 ± 6.5 versus 31.4 ± 4.5 ng/ml, $P<0.001$). The level was correlated positively with anti-double stranded DNA (dsDNA) antibody titer and SLEDAI score ($r=0.263$, $P=0.004$, and $g=0.231$, $P=0.012$, respectively), but negatively with C3 and CH50 levels associated with the presence of active proteinuria (>0.5 gm/day) in SLE patients with lupus nephritis. Moreover, serum SDC1 levels had significant correlation with level of APRIL, which was known as surrogate marker of disease activity ($r=0.507$, $P=0.001$).

Conclusion: Serum SDC1 levels are elevated and correlated with markers of disease activity in patients with SLE, suggesting that serum SDC1 could be used as a potential marker of disease activity in patients with SLE.

Predictors of Systemic Lupus Erythematosus Flares: Baseline Disease Activity and Demographic Characteristics From the Combined Placebo Groups in the Phase 3 Belimumab Trials. Ronald F. van Vollenhoven[1], Michelle A. Petri[2], Roger A. Levy[3], Sandra V. Navarra[4], Jill P. Buyon[5], Z. John Zhong[6], William W. Freimuth[6] and Ricard Cervera[7]. [1]Karolinska University Hospital, Stockholm, Sweden, [2]Johns Hopkins University School of Medicine, Baltimore, MD, [3]Univ Estado Do Rio De Janeiro, Rio de Janeiro, Brazil, [4]University of Santo Tomas Hospital, Manila, Philippines, [5]New York University School of Medicine, New York, NY, [6]Human Genome Sciences, Inc., Rockville, MD, [7]Hospital Clínic of Barcelona, Barcelona, Spain

Background/Purpose: Predicting which SLE patients are at increased risk for clinically meaningful flares may be useful in making management decisions. The purpose of this analysis was to identify demographic and disease-related predictors of flares.

Methods: Baseline demographic and SLE-related disease activity characteristics were evaluated for their ability to predict new SLE flares by treatment wk 52 in the combined dataset of 562 patients receiving placebo + standard SLE therapy from the phase 3 belimumab BLISS-52 (NCT00424476) and BLISS-76 (NCT00410384) trials. Flare was defined as the development of 1 new British Isles Lupus Assessment Group (BILAG) A or 2 new B organ domain scores; any BILAG A score; or according to the modified severe SLE Flare Index (SFI). Baseline variables included race, age, gender, BMI, SELENA-SLEDAI (mean score, range, and 24 items with ≥30/group), PGA, BILAG A–E scores, ACR diagnostic criteria, Systemic Lupus International Collaborating Clinics Damage Index, SLE duration, and concurrent medications. Baseline disease characteristics associated with a $\geq10\%$ absolute difference (% flare - % no flare) or $\geq50\%$ increase ([% flare - % no flare]/% no flare) in flare rate were considered predictors of flare.

Results: By wk 52, 180 patients (32%) receiving placebo had 1 new BILAG A or 2 new B scores; 130 (23%) had a BILAG A score; and 133 (24%) had a severe SFI flare. By all 3 flare indices, SELENA-SLEDAI ≥12, and moderate–severe disease activity involving renal and hematologic domains were predictors of flare (see table). Serologic markers were predictors of severe SFI flare and 1 BILAG A or 2 B scores. Use of corticosteroids, immunosuppressives, antimalarials, and other concomitant medications did not predict flare.

Predictors of Flare

Characteristic	% 1 New BILAG A or 2 New B Scores		% Any BILAG A Score		% Severe SFI Flare	
	With (n = 180)	Without (n = 382)	With (n = 130)	Without (n = 432)	With (n = 133)	Without (n = 429)
SS ≥12	38.9#	24.1	39.2+	25.7	41.4#	24.9
SS proteinuria	20.0+	11.3	20.8*	12.0	21.1+	11.9
SS vasculitis	10.0*	5.0	10.0	5.6	9.0	5.8
SS low complement	70.0+	56.8	67.7	59.0	72.2+	57.6
SS DNA binding	75.0+	64.1	73.1	66.0	77.4+	64.6
BILAG renal (A8722'2dC)	53.3#	31.7	56.9#	33.1	54.9#	33.6
BILAG vasculitis (A/B)	14.4*	6.8	14.6*	7.6	15.0*	7.5
BILAG hematologic (A/B)	22.8+	12.3	27.7#	12.0	25.6+	12.6

Nominal p values for pairwise comparison (likelihood ratio test). SS, SELENA-SLEDAI. #$p<0.001$; +$p<0.01$; *$p<0.05$.

Conclusion: SLE patients on standard therapy alone with moderate–severe renal, vasculitic, hematologic, or serologic disease activity, or SELENA-SLEDAI ≥12 were at increased risk of having a clinically meaningful flare over 52 wk.

Baseline Laboratory Characteristics From the Combined Placebo Groups in the Phase 3 Belimumab Trials Are Predictive of Severe Flare At 52 Weeks. Michelle A. Petri[1], Ronald F. van Vollenhoven[2], Roger A. Levy Sr.[3], Sandra V. Navarra[4], Ricard Cervera[5], Z. John Zhong[6], William W. Freimuth[6] and Jill P. Buyon[7]. [1]Johns Hopkins University School of Medicine, Baltimore, MD, [2]Karolinska University Hospital, Stockholm, Sweden, [3]Hospital Universitário Pedro Ernesto, Rio de Janeiro, Brazil, [4]University of Santo Tomas Hospital, Manila, Philippines, [5]Hospital Clinic, Barcelona, Spain, [6]Human Genome Sciences, Inc., Rockville, MD, [7]New York University School of Medicine, New York, NY

Background/Purpose: Identification and validation of potential serologic biomarkers of clinically meaningful SLE flare are major unmet medical needs

in clinical practice and trials. The purpose of this analysis was to examine biomarker predictors of SLE flares at baseline in the combined placebo groups from the phase 3 belimumab BLISS-52 (NCT00424476) and BLISS-76 (NCT00410384) trials.

Methods: The BLISS trials enrolled patients with active SLE (SELENA-SLEDAI ≥6) who were autoantibody positive (antinuclear antibody or anti-double-stranded DNA [anti-dsDNA]), on stable standard SLE therapy for 30 d, and without severe active lupus nephritis or CNS SLE. Patients were randomized to placebo, or belimumab 1 or 10 mg/kg, plus standard therapy. Changes in prednisone were allowed early in the trials, but had to be within 25% or 5 mg of baseline dose. Flare was defined as the development of 1 new British Isles Lupus Assessment Group (BILAG) A or 2 new B organ domain scores; any new BILAG A score; or according to the modified severe SLE Flare Index (SFI). Laboratory biomarkers evaluated included antinuclear antibody, anti-dsDNA, anti-Smith, complement (C) 3 and 4, C-reactive protein (CRP), proteinuria >0.5 g/24 h, immunoglobulin, B- and T-cell subsets, and B-lymphocyte stimulator (BLyS) quartile levels. The proportion of placebo patients with abnormal laboratory values who developed a new flare was compared with the proportion without a flare. Meaningful difference was defined as: a ≥10% absolute difference (% flare - % no flare) or nominal p value for pairwise comparison (likelihood ratio test); or a ≥50% increase ([% flare - % no flare]/% no flare). Study limitations: laboratory tests were defined as categorical variables (present/absent at baseline), and the time-varying nature of the characteristics over the 52 wk was not examined.

Results: By wk 52 in the placebo group (n = 562), 32% of patients (n = 180) had 1 new BILAG A or 2 new B scores; 23% (n = 130) had a BILAG A score; and 24% (n = 133) had a severe SFI flare. Predictors of wk-52 flare (% with vs without flare) are shown in the table.

Univariate Analysis of Predictors of 52-Wk Flare

Baseline Laboratory Value	% 1 New BILAG A or 2 New B Scores		% Any BILAG A Score		% Severe SFI Flare	
	With (n = 180)	Without (n = 382)	With (n = 130)	Without (n = 432)	With (n = 133)	Without (n = 429)
Low C3 <90mg/dL	52.8#	40.1	51.5	41.9	59.4#	39.4
Low C4 <16mg/dL	61.1+	50.5	60.8	51.9	63.2*	51.0
CRP >3mg/L	43.4+	34.9	46.0*	35.2	44.6*	35.5
Proteinuria ≥0.5g/24 h	29.5+	17.3	32.3#	17.8	32.3#	17.7
Positive anti-dsDNA (>200 IU/mL)	44.4#	28.0	46.2#	29.4	49.6#	28.2
Serum BLyS ≥2 ng/mL	35.8#	20.1	37.8#	21.3	41.7#	19.9

# p <0.001; + p <0.01; * p <0.05.

Conclusion: SLE patients on standard therapy with low C3 or C4, elevated CRP, proteinuria >0.5 g/24 h, positive anti-dsDNA, or serum BLyS ≥2 ng/mL were at increased risk for SLE flare over 52 wk. The 3 flare definitions had high concordance regarding predictors; univariate risk factors, with the exception of C3/C4, were the same for all flare definitions at 52 wk. The data suggest serologic tests predict clinically meaningful flare over 52 wk of standard SLE therapy, and may be useful in the identification of patients at greater risk for flares in clinical practice and trials.

Bioavailability, Pharmacokinetics, and Safety of Belimumab Administered Subcutaneously in Healthy Subjects. Wendy Cai[1], Cecil Chen[1], Z. John Zhong[1], William W. Freimuth[1], William Lewis[2] and David Subich[3]. [1]Human Genome Sciences, Inc., Rockville, MD, [2]Covance Clinical Research Unit, Inc., Dallas, TX, [3]Covance Clinical Research Unit, Inc., Daytona Beach, FL

Background/Purpose: Belimumab is a recombinant, human Ig-G1λ monoclonal antibody that binds and antagonizes the biological activity of soluble B-lymphocyte stimulator protein, a member of the tumor necrosis factor ligand superfamily that promotes the survival of B lymphocytes. This study (NCT#01583530) evaluated the absolute bioavailability, PK, tolerability, and safety of belimumab (200 mg/mL) administered SC to healthy subjects as a single dose and as multiple doses up to 240 mg.

Methods: In all, 118 healthy subjects (aged 18−55 y; body weight 51−115 kg) were enrolled. Seventy-eight subjects received a single dose of belimumab 240 mg IV, or 2 × 120, 1 × 240, or 1 × 200 mg SC. Forty subjects received 4 weekly injections of belimumab 2 × 120 or 1 × 200 mg

SC. Randomization was stratified by weight (< vs ≥ 75 kg) and, for SC administration, by injection site (abdomen vs thigh), with a target enrollment of 50% women/treatment group. Serial blood samples were collected and the serum belimumab concentrations measured by a validated electrochemiluminescence-based assay. Belimumab PK parameters were derived by noncompartmental or compartmental analysis.

Results: The bioavailability and PK parameters of belimumab following single IV and SC administration are summarized in the table. Following 4 weekly SC belimumab doses, bioavailability values (90% CI) were 75% (63%−89%) and 78% (67%–91%) for the 2 × 120- and 1 × 200-mg SC groups, respectively. Four subjects had persistent positive immune responses; neutralizing antibodies in these subjects were not detected and there was no apparent impact on PK. Single and multiple dosing of belimumab was generally safe and well tolerated, with no severe/serious injection-site reactions, eg, rash, edema, erythema, and pruritus.

PK and Bioavailability of Belimumab

Parameter	Belimumab			
	240 mg IV	2 × 120 mg SC	1 × 240 mg SC	1 × 200 mg SC
No. of subjects	19	19	18	18
t_{max}, d[a]	0.09 (0.05–0.30)	3.9 (0.9–9.8)	4.9 (2.9–13.9)	5.9 (1.9–13.9)
C_{max}, μg/mL[b]	86.2 (20.2)	32.7 (29.0)	31.6 (27.9)	24.3 (40.3)
$AUC_{0-\infty}$, μ·d/mL[b]	1030 (32.1)	788 (36.1)	812 (36.2)	612 (37.9)
$t_{1/2\cdot term}$, d[c]	18.2 ± 6.3	15.9 ± 5.3	18.2 ± 6.0	16.0 ± 5.1
F, %[d]	–	76 (64–90)	82 (70–95)	74 (60–91)

[a] Median (range); [b]geometric mean (coefficient of variance); [c]mean ± SD; [d]absolute bioavailability (F) and 90% CI.
$AUC_{0-\infty}$, area under plasma concentration-time curve from time 0 to ∞; C_{max}, maximum plasma drug concentration; t_{max}, time to reach maximum plasma concentration; $t_{1/2\cdot term}$, terminal half-life.

Conclusion: Following single belimumab SC doses, bioavailability was 74%−82%, indicating that belimumab SC was well absorbed, and bioavailability was similar among the 3 SC groups. Bioavailability after 4 weekly SC doses was similar to that following single SC administration. Belimumab was generally safe and well tolerated after single and multiple SC dosing.

Soluble Urokinase Plasminogen Activator Receptor (suPAR) Levels Reflect Organ Damage in Systemic Lupus Erythematosus. Helena Enocsson[1], Jonas Wetterö[2], Thomas Skogh[2] and Christopher Sjöwall[1]. [1]Linkoping University, Linkoping, Sweden, [2]Linköping University, Linköping, Sweden

Background/Purpose: Disease activity assessment in systemic lupus erythematosus (SLE) remains a challenge due to lack of reliable biomarkers and disease heterogeneity. Ongoing tissue inflammation can be difficult to distinguish from irreversible damage caused by previous flares or side-effects of medication. Soluble urokinase plasminogen activator receptor (suPAR) is a part of the plasminogen activation system and is involved in inflammation, tissue remodelling and cancer metastasis. Cell-surface expression of uPAR on endothelial cells, megakaryocytes, monocytes, neutrophils and activated T cells is up-regulated upon stimulation with growth factors and cytokines, such as IL-1β and TNF. suPAR is released by protease-mediated shedding of cell-bound uPAR, and has emerged as a useful biomarker in disparate conditions (*e.g.* sepsis, malignancies, and focal segmental glomerulosclerosis). Herein, we evaluated suPAR as a marker of disease activity and organ damage in lupus.

Methods: Cross-sectional sera from 100 healthy blood donors and 198 SLE patients fulfilling the 1982 American College of Rheumatology (ACR) classification criteria (81%) and/or the 'Fries criteria' (a clinical SLE diagnosis based upon a history of abnormal ANA titre and ≥2 typical organ manifestations) were analyzed for suPAR by enzyme immunoassay. Patients were recruited consecutively; most were prevalent cases (91%), but a few (9%) had recent-onset disease at the time of sampling. Disease activity was assessed by SLE disease activity index-2K (SLEDAI) and the physician's global assessment (PGA). Organ damage was evaluated by SLE international collaborating clinics (SLICC)/ACR damage index (DI). Routine analyses included blood cell counts, erythrocyte sedimentation rate, C-reactive protein (CRP), C3, C4, creatinine, creatine kinase, urinalysis and anti-dsDNA (*Crithidia luciliae* IF test, CLIFT). Informed consent was obtained from all subjects and the research protocol was approved by the Regional Ethics Committee in Linköping (M75-08).

Results: No significant difference was found comparing suPAR in healthy controls and patients. In SLE, suPAR levels were highly associated with leukocyte count; and thus, this was adjusted for, as well as for age, sex and glucocorticoid dose in further analyses. Yet, no associations were recorded between suPAR levels and disease activity reflected by SLEDAI or PGA. However, a highly significant association was observed between suPAR and global SLICC/ACR DI (p<0.0005), and a borderline significant association was found between CRP and SLICC/ACR DI (p=0.05). Dissecting SLICC/ACR DI into organ systems in a multiple regression analysis, we found renal, ocular, neuropsychiatric, skin and peripheral vascular damage to have a significant positive impact on suPAR levels, whereas no separate organ system had significant impact on CRP.

Conclusion: This study demonstrates a strong association between suPAR and organ damage, but not with disease activity, in lupus. The high association between suPAR and leukocyte count could possibly explain why no difference in suPAR was found between patients and healthy blood donors. Analysis of suPAR may be a valuable clinical tool to assess disease outcome in SLE.

BAFF/BLyS Gene Expression Predicts Disease Activity in Systemic Lupus Erythematosis Over One Year. Eric Zollars[1], Hong Fang[1], Jadwiga Bienkowska[2], Norm Allaire[2], Susan Kalled[2] and Michelle Petri[1]. [1]Johns Hopkins University School of Medicine, Baltimore, MD, [2]Biogen Idec Inc., Cambridge, MA

Background/Purpose: The search for a marker of SLE disease activity has included inflammatory markers, chemokines and gene signatures. We explored the ability of the BAFF gene expression to predict SLE disease activity in the subsequent year after measurement.

Methods: 292 patients (59% Caucasian, 34% African-American, 92% female, mean age 46 ± 12 years) were enrolled in a prospective observational study. At baseline, BAFF gene expression level was determined in peripheral blood RNA using Affymetrix chips. Clinical associations, based on the same-day visit disease activity (using the Physician Global Assessment and SELENA SLEDAI) as well as activity over the ensuing year were then determined. **Results** were determined with a generalized estimating equation to account for the repeated observations among the same patients.

Results: The number of visits within a year after the measurement of BAFF gene expression varied from 1–9. Six patients had 1 visit, 46 patients had 2–3 visits, 159 patients had 4 visits, and 81 patients had more than 4 visits.

Table 1. Percentage of visits with disease activity by BAFF gene expression

Variable	Low BAFF (<10.7) (%, N=387)	Med BAFF (10.7–11.4) (%, N=476)	High BAFF (>11.4) (%, N=347)	P-value	Adjusted P-value for Race
Physician global assessment >1	8%	21%	24%	.0003	.0041
SLEDAI ≥2	36%	57%	71%	<.0001	<.0001
Urine Protein/ Creatinine Ratio (≥0.5)	3%	13%	13%	.0004	.0096
Anti-dsDNA ≥ 10	9%	21%	35%	<.0001	<.0001
C3 <79 mg/dL	4%	11%	21%	.0002	.0004
C4 <12 mg/dL	4%	11%	19%	.0004	.0005
ESR >20	35%	55%	63%	<.0001	.0005

We controlled for race, sex, baseline low complement and baseline anti-dsDNA.

Table 2. Average disease activity over a year of follow-up.

Variable	BAFF gene expression	Unadjusted Activity	Adjusted Mean Differences	P-values
PGA	Low (<10.7)	0.48	0 (Ref.Group)	
	Med (10.7–11.4)	0.70	0.14	.044
	High (>11.4)	0.74	0.15	.045
SLEDAI	Low (<10.7)	1.08	0 (Ref.Group)	
	Med (10.7–11.4)	2.10	0.39	.031
	High (>11.4)	2.98	0.72	.0029

Conclusion: We have previously shown that the BAFF gene expression correlates with same-day disease activity. We now can prove that BAFF gene expression predicts disease activity over the ensuing year. This supports BAFF/BLyS as a target for clinical intervention.

619

Elevated Plasma Levels of CXCL2 and CXCL10 Have Distinct Predictive Value in Systemic Lupus Erythematosus. Felipe Andrade[1], Ehtisham Akhter[2], Hong Fang[2] and Michelle Petri[2]. [1]The Johns Hopkins University School of Medicine, Baltimore, MD, [2]Johns Hopkins University School of Medicine, Baltimore, MD

Background/Purpose: Serum levels of chemokines have been previously used as downstream markers of the interferon (IFN) pathway in SLE. CXCL2 (GROB) and CXCL10 (IP-10) have been found to be elevated in SLE (over controls) and in SLE with high type I IFN gene signature over controls (Bauer et al, 2006). CXCL2, however, may be an IFN-independent marker, in contrast to previous reports. We compared CXCL2 with CXCL10 (which is IFN-induced) over time in SLE, and determined the relationship with disease activity.

Methods: 25 SLE patients (84% female, 72% Caucasian, 28% African-American, mean age at baseline 48 + 10 yrs) had CXCL10 and CXCL2 levels measured in plasma by ELISA at baseline and at follow-up visit 0.72 years (mean) later. Chemokine levels were defined as low (<150 ng/ml for CXCL10 and <100 ng/ml for CXCL2) or high (>150 ng/ml for CXCL10 and >100 ng/ml for CXCL2).

Results: Baseline high CXCL2 levels were associated with a history of proteinuria. High CXCL10 was associated with low C3 (p=0.007), low C4 (p<0.0001) and anti-dsDNA (p=0.0094). The high CXCL10 group had a significant increase in SLEDAI at the second visit (2.4 to 4.5, p=0.021). The high CXCL2 group had an increase in activity by both PGA (p=0.02) and SLEDAI (p=0.011), as well as lower C3 (p=0.023) and lower C4 (p=0.096) at the second visit. Urine pr/cr went up (0.3 to 0.7), but was not statistically significant.

Changes in Measures of Disease Activity by Chemokine High/Low

CXCL10	Mean at baseline	p–value for baseline between groups	Mean at followup	Mean Change between baseline and followup	p–value for change within group	p–value for change between groups
PGA						
Low CXCL10(n=12)	0.6	0.47	0.7	0.1	0.57	0.73
High CXCL10(n=13)	0.8		0.8	0.0	0.98	
SLEDAI						
Low CXCL10(n=12)	0.8	0.061	1.3	0.5	0.54	0.16
High CXCL10(n=13)	2.4		4.5	2.2	0.021	
C3						
Low CXCL10(n=12)	118.5	0.0007	119.8	1.3	0.85	0.97
High CXCL10(n=13)	79.0		80.5	1.5	0.74	
C4						
Low CXCL10(n=12)	25.7	<0.0001	25.9	0.3	0.88	0.63
High CXCL10(n=13)	12.2		13.4	1.2	0.31	

CXCL2	Mean at baseline	p–value for baseline between groups	Mean at followup	Mean Change between baseline and followup	p–value for change within group	p–value for change between groups
PGA						
Low CXCL2(n=18)	0.8	0.48	0.6	−0.2	0.49	0.052
High CXCL2(n=7)	0.5		1.1	0.6	0.022	
SLEDAI						
Low CXCL2(n=18)	1.8	0.47	2.5	0.7	0.33	0.058
High CXCL2(n=7)	1.1		4.3	3.1	0.011	
C3						
Low CXCL2(n=18)	96.9	0.81	103.4	6.4	0.19	0.033
High CXCL2(n=7)	100.6		89.0	−11.6	0.023	
C4						
Low CXCL2(n=18)	18.1	0.66	20.2	2.1	0.080	0.026
High CXCL2(n=7)	20.0		17.3	−2.7	0.096	

Conclusion: The lack of correlation between levels of CXCL2 and CXCL10 strongly supports that these chemokines are driven by distinct mechanistic pathways in SLE. Although the IFN pathway is likely to be responsible of changes in CXCL10 levels in SLE, the mechanism(s) that regulate CXCL2 in SLE is unclear. High CXCL2 is predictive of increasing disease activity over a mean of 0.7 marks, by both PGA and SLEDAI, and reduction in C3 and C4. Neither chemokine, however, significantly changed from baseline to second visit.

Development of A Quantitative PCR Method to Determine Interferon Signature Metric Status in SLE Patients: Distribution and Clinical & Serological Associations in Two Lupus Clinical Trials. Bruce C. Richardson[1], William P. Kennedy[2], John C. Davis Jr.[2], R. Maciuca[2], A. Morimoto[2], J. M. McBride[2], Alexander R. Abbas[2], Timothy W. Behrens[2] and Michael J. Townsend[2]. [1]University of Michigan, Ann Arbor, MI, [2]Genentech, Inc, South San Francisco, CA

Background/Purpose: Elevated and coordinated expression of multiple Interferon-regulated genes (IRGs) in peripheral blood cells is present in most systemic lupus erythematosus (SLE) patients. Here we describe the development of a validated quantitative PCR (qPCR) test to accurately measure relative levels of IRGs in SLE blood at baseline and over the course of clinical trials.

Methods: A cross sectional SLE cohort (n=150) and a healthy cohort (n=70) were used for qPCR development. Subject samples from two clinical trials with rontalizumab (anti-IFN alpha), Phase 1 with mild to moderate lupus (n=60) and Phase 2 with moderate to severe lupus (ROSE, n=238) were used for validation. Expression of type I IRGs was determined by expression microarray and qPCR analysis of peripheral blood RNA. Relationships between IRGs were assessed using Spearman's rank correlation. Exploratory hypothesis testing between patient subsets was performed using Wilcoxon rank sum or Fisher's exact tests.

Results: Unsupervised hierarchical clustering revealed a region comprised of a high density of IRGs and a representative 3-gene combination (r >0.98) was chosen for measurement by qPCR. An Interferon Signature Metric (ISM) score was derived from the average normalized expression of these 3 genes. ISM scores in the Rontalizumab trials followed a bimodal distribution compared with controls. Determination of threshold cutoff for ISM high vs. low designation was based upon the 95th percentile of the ISM scores of healthy controls, allowing discrimination of the two modes of distribution in SLE. In the ROSE trial there were no differences in disease activity as measured by BILAG and SELENA-SLEDAI between identified ISM high and ISM low subjects. Further, longitudinal assessment of subjects in the placebo arm of the ROSE trial followed over 36 weeks showed that the probability of maintaining either ISM low or high status was 94% (95% CI 91%–97%).

IFN signature metric (ISM) distribution in normal and SLE populations
Conclusion: The ISM test accurately quantifies the bimodal blood Interferon Signature in SLE subjects. ISM high status was not associated with increased BILAG and SELENA-SLEDAI-defined disease activity. ISM status was observed to be stable over 36 weeks of longitudinal assessment. The ISM test may provide useful information in clinical trials of targeted therapies and in the understanding of disease heterogeneity in SLE.

Prolonged Improvement of Systemic Lupus Erythematosus Following Systematic Administration of Rituximab and Cyclophosphamide. Thomas J. A. Lehman[1], Emily Baird[2], Anusha Ramanathan[3], Risa Alperin[3], Emma J. MacDermott[3], Alexa B. Adams[3], Laura V. Barinstein[4] and Lakshmi N. Moorthy[5]. [1]Hosp for Special Surgery, New York, NY, [2]Hospital for Special Surgery, NY, [3]Hospital for Special Surgery, New York, NY, [4]Maimonides Medical Center, Brooklyn, NY, [5]Robert Wood Johnson-UMDNJ, New Brunswick, NJ

Background/Purpose: We report sustained improvement in 15 patients with corticosteroid dependent SLE who received a systematic regimen of rituximab and cyclophosphamide administered at months 0, 6, and 18. All patients had active SLE despite prior therapy. Five patients were male and 10 were female. Seven patients had biopsy proven DPGN. Three patients were Hispanic, 5 were Asian, 1 African American, and 6 Caucasian. All experienced a marked and sustained reduction in their corticosteroid dose with improvement in C3, C4, Hb, ESR, Cr, serum albumin and SLEDAI which persisted at 60 months following initiation of therapy (42 months following the last dose of these medications).

Methods: All patients received rituximab 750 mg/m^2 (max 1 gram) on day 1 and cyclophosphamide 750 mg/m^2 on day 2. This regimen was repeated on days 15 and 16. All patients received a further two doses of rituximab and cyclophosphamide at month 6 and two doses at month 18. Patients with active DPGN received additional doses of cyclophosphamide (750 mg/m^2) at 6, 10, 14, and 18 weeks. The prednisone dosage was gradually decreased at the discretion of the treating physician. Because the data were nonparametric Wilcoxon signed rank tests were used for all statistical comparisons.

Results: Significant improvement occurred in prednisone dose, C3, C4, Hb, ESR, Cr, serum albumin and SLEDAI which persisted (see chart). No patient experienced a disease flare requiring hospitalization. The mean SLEDAI score decreased from 8.929 to 1.917 after the first six months of therapy and remained low thereafter. Four patients are known to be ANA negative at month 36 following the initiation of treatment.

	N = 15 Month 0	N = 15 Month 12	N = 15 Month 24	N = 13 Month 36	N = 9 Month 60
Prednisone dose (mg daily)	29.10 ± 21.88	14.74*** ± 7.35	10.43*** ± 3.518	8.409** ± 2.567	8.5** ± 4.802

Headache in Systemic Lupus Erythematosus (SLE): Results From a Prospective, International, Inception Cohort Study. John G. Hanly[1] and Systemic Lupus International Collaborating Clincs[2]. [1]Dalhousie University and Capital Health, Halifax, NS, [2](SLICC)

Background/Purpose: Headache is common in SLE patients and in the general population. We examined the frequency, characteristics and attribution of headaches in a large, prospective, inception cohort of SLE patients and determined the association with global disease activity and health related quality of life.

Methods: An international network of 31 academic medical centers enrolled patients within 15 months of SLE diagnosis. Assessments occurred annually for up to 10 years for headache (5 types) and other neuropsychiatric (NP) events as per the ACR case definitions for 19 NP syndromes. Additional data were demographic and clinical variables, SLE global disease activity (SLEDAI-2K), SLICC/ACR damage index (SDI) and self-report mental (MCS) and physical (PCS) component summary scores of the SF-36. Statistical analyses of time to first headache (all headaches and migraine only) were based on Cox's proportional hazards model. SF-36 scores were examined by linear regression models with generalized estimating equations to account for within patient correlation.

Results: Of the 1732 enrolled patients 89% were female with the following racial/ethnic distribution: Caucasian (48%), African (16%), Asian (16%), Hispanic (16%) and other (4%). At enrollment the mean ($\pm$ SD) age was 34.6 ± 13.4 years, disease duration was 5.6 ± 4.8 months and followup was 3.8 ± 3.1 years. Mean SLEDAI-2K at enrollment was 4.0 ± 5.3 and SDI was 0.32 ± 0.78. Within the enrollment window (6 months pre-diagnosis up to the enrollment visit) the proportion of patients with headache was 17.8% subdivided into: migraine (55.2%), tension (35.1%), intractable non-specific (6.5%), cluster (2.4%) and intracranial hypertension (0.9%). The estimated proportion of patients ever reporting a headache increased to 57% after 10 years (Kaplan-Meier estimate) with similar subset distribution. Only 2% of patients in 0.6% of assessments had "lupus headache" in SLEDAI-2K scores over the study. Headache was associated with other NP events as indicated by Hazard Ratio (HR) estimates (95% CI) for: aseptic meningitis 3.8 (1.2, 12.0), autonomic disorder 13.3 (3.3, 53.6), cerebrovascular disease 2.3 (1.5, 3.6), anxiety disorder 2.2 (1.5, 3.2) and mood disorder 2.1 (1.6, 2.7). Headache increased with rising SLEDAI-2K (excluding "lupus headache" variable). The estimated risk for any 5 unit increase in SLEDAI-2K corresponded to an HR (CI) of 1.13 (1.03, 1.23). The mean (SD) SF-36 MCS scores were lower in patients with headache compared to patients without headache (mean $\pm$ SD: 42.5 ± 12.2 vs 47.8 ± 11.3; $p < 0.001$) as were PCS scores (38.0 ± 11.0 vs 42.6 ± 11.4; $p < 0.001$). Comparable results were found in all analyses when migraine was examined separately. All associations with headache and migraine alone remained significant after adjustment for gender, race/ethnicity, geographic location and age at diagnosis.

Conclusion: Headaches, particularly migraine and tension types, occur frequently among SLE patients and are associated with other types of NP events. Although the majority of headaches are not attributable to active lupus, they are associated with higher global SLE disease activity and lower self-reported health-related quality of life.

Endothelial Microparticles As a Biomarker for Endothelial Dysfunction in Active Systemic Lupus Erythematosus. Ben Parker[1], Awal Zaki[2], M. Yvonne Alexander[3] and Ian N. Bruce[4]. [1]Arthritis Research UK Epidemiology Unit, Manchester, United Kingdom, [2]Arthritis Research UK Epidemiology Unit, Manchester, United Kingdom, [3]The University of Manchester, Manchester, United Kingdom, [4]Arthritis Research UK Epidemiology Unit and NIHR Manchester Musculoskeletal Biomedical Research Unit, Manchester, United Kingdom

Background/Purpose: Systemic Lupus Erythematosus (SLE) is associated with an increased risk of clinical and subclinical cardiovascular disease (CVD) including endothelial dysfunction, in part due to systemic inflammatory disease activity. Endothelial microparticles (EMPs) are membrane-bound subcellular particles produced by endothelial cells in response to a variety of activation triggers, including inflammatory cytokines and classic CVD risk factors. EMPs reflect endothelial damage and may correlate with measures of endothelial function, such as flow-mediated dilatation (FMD) of the brachial artery. EMPs may therefore serve as a biomarker for endothelial dysfunction in SLE. We aimed to: 1) compare EMP levels and FMD in patients with active SLE compared to controls; 2) assess change over time in EMP and FMD following improved disease control and 3) assess the correlation between EMPs and FMD.

Methods: Patients with active SLE ($\geq$4 ACR criteria) were recruited and assessed at baseline and 4 months after a change in therapy. Disease activity (BILAG 2004 and SLEDAI 2K) and clinical features were recorded at each visit. Healthy age-matched controls were assessed once. FMD (%) of the brachial artery was measured using 2D ultrasound and automated edge-tracking software. EMPs were quantified (number/ml) using flow cytometry after incubating platelet-poor-plasma with the cell surface markers CD31, CD42b and Annexin-V. Events positive for annexin-V and CD31, and negative for CD42b, were classified as EMPs. Continuous data were compared using Mann-Whitney test, and Spearman's Rank was used to correlate EMP levels with %FMD.

Results: 27 patients with SLE (mean (SD) age 41.5 (14.1) yrs) and 22 controls (mean age (SD) 38.5 (9.3) yrs) underwent assessment of endothelial function. In SLE patients the mean (SD) SLEDAI-2K and total BILAG scores were 8.2 (5.5) and 16.9 (10.6) respectively. Endothelial-dependent FMD was significantly reduced in the SLE group compared to controls at baseline (median (IQR) FMD 1.63% (-1.22, 5.32) vs. 5.40% (3.02, 8.57); p = 0.05). EMPs (n/ml) were significantly elevated in the SLE cohort compared to controls at baseline (median (IQR) 157,548/ml (59,906, 272,643) vs. 41,025 (30,179, 98,082); p = 0.003). In patients with paired results, disease activity significantly improved 4 months after a change in therapy (SLEDAI-2K 3.8 (3.4); BILAG 2004 score 6.9 (5.4) (p= 0.001 and 0.001 vs. baseline respectively). The median (IQR) FMD improved over time (0.33% (-2.31, 4.1) vs. 3.19% (0.98, 5.09); p = 0.1), as did median (IQR) EMP levels (166,982/ml (59906, 278,775 vs. 55655 (29475, 188,659; p = 0.02). In the whole cohort, EMPs demonstrated a significant negative correlation with %FMD (correlation coefficient -0.42; p =0.008). In SLE patients with paired data the correlation coefficient was -0.51 (p = 0.005).

Conclusion: Endothelial function is significantly impaired and EMPs are significantly elevated in young patients with active SLE compared to healthy controls. Both EMPs and FMD improve over time, following a reduction in disease activity. EMPs also correlate with FMD, and may serve as a useful biomarker of endothelial damage/dysfunction and CVD risk in SLE.

Excess Health Care Utilization Prior to Diagnosis of Systemic Lupus Erythematosus in England. Amy Steffey[1], Trung N. Tran[1], Jie Li[1] and Herve Caspard[2]. [1]MedImmune, Gaithersburg, MD, [2]MedImmune LLC, Gaithersburg, MD

Background/Purpose: Systemic Lupus Erythematosus (SLE) is a chronic auto-immune disease resulting in significant excess morbidity and health care utilization. Since time of disease onset is often unknown, we hypothesized that there is an excess of health care utilization prior to diagnosis of SLE cases (but after disease onset).

Methods: We identified a cohort of incident cases of SLE among individuals documented in the Clinical Practice Research Datalink (CPRD) and linked with Hospital Episode Statistics (HES). CPRD is a database of anonymized longitudinal medical records from primary care from over 600 practices in the United Kingdom. HES is a database documenting all admissions to the National Health System hospitals in England that can be linked with CPRD since 1997. All individuals documented in GPRD and HES prior to October 1st, 2010 and aged 18 years or older were retained in the analysis.

Patients with SLE were identified as individuals with at least one relevant diagnosis code in CPRD or HES (list of codes available upon request).

Incident cases were defined as patients with at least 12 months of registration in CPRD prior to the date of first diagnosis. All incident SLE cases were matched with up to 5 controls registered in CPRD and linked with HES at the time of and during the one year prior to first diagnosis of the SLE case, and matched by age, gender, and practice. The index date for the controls is the index date (or date of first diagnosis) of the matched case.

Results: The proportions of individuals in the controls group who were hospitalized at least once, had an encounter with a health care practitioner (HCP) or were treated with corticosteroids during each 6 month period over the 3 years prior to the index date remained relatively stable (Table 1).

Table 1. Health care utilization three years prior to diagnosis of SLE or prior to index date of the matched controls

Matched Controls	M.–36/M.–31 n=3,954	M.–30/M.–25 n=4,344	M.–24/M.–19 n=4,752	M.–18/M.–13 n=5,139	M.–12/M.–7 n=5,557	M.6–to D.0 n=5,687
Hospitalization	7%	8%	9%	8%	9%	9%
Treatment with cortico steroids	10%	10%	11%	10%	10%	11%
Encounter with HCP	75%	74%	75%	75%	75%	74%

SLE Cases	M.–36/M.–31 n=973	M.–30/M.–25 n=1,024	M.–24/M.–19 n=1,096	M.–18/M.–13 n=1,126	M.–12/M.–7 n=1,159	M.6–to D.0 n=1,159
Hospitalization	14%	16%	16%	17%	20%	26%
Treatment with cortico steroids	20%	20%	21%	23%	27%	33%
Encounter with HCP	73%	73%	73%	75%	76%	81%

The proportions of SLE cases who were hospitalized at least once or were treated with corticosteroids per 6 month period grew from 14% to 26% and from 20% to 33%, respectively, over the 3 years prior to the date of incident diagnosis. The proportion of patients who had at least one encounter with a HCP grew also from 73% to 81%.

There is a significant excess of health care utilization in SLE cases versus matched controls during the 3 years prior to the date of incident diagnosis. The excess was still significant between M.-36 and M.-31, when the proportions of individuals hospitalized at least once and treated with corticosteroids were twice as high among SLE cases than in matched controls: 14% versus 7% and 20% versus 10%, respectively.

Conclusion: Excess health care utilization prior to incident diagnosis of SLE should be taken into account to assess the total burden of disease. This analysis suggests that there is an excess health care utilization for at least 3 years prior to diagnosis.

625

Control of Hypertension and Hypercholesterolemia Is Not Associated with a Decreased Rate of Atherosclerotic Vascular Events in Patients with Systemic Lupus Erythematosus. Joanna Ueng, D. D. Gladman, Dominique Ibanez and Murray B. Urowitz. Toronto Western Hospital and University of Toronto, Toronto, ON

Background/Purpose: Systemic lupus erythematosus (SLE) is a chronic autoimmune disease of unknown etiology. It has been shown that patients with SLE are at a higher risk for premature atherosclerosis because of their disease and its treatment. Hypertension and hypercholesterolemia are treatable risk factors for the prevention of coronary artery disease in these patients. The purpose of this study was to determine if controlling hypertension and hypercholesterolemia is associated with a decreased rate of atherosclerotic vascular disease in patients with SLE who have been followed prospectively in a long term study.

Methods: SLE patients registered in the Lupus Clinic within 1 year of diagnosis between 1985 and 2002 were studied. Thirty-one patients with atherosclerotic vascular events (AVEs), defined as myocardial infarction, angina, pacemaker insertion, coronary artery bypass surgery, transient ischemic attack, stroke, or peripheral vascular disease, were identified from the computerized database. AVEs were subsequently confirmed by a detailed chart review. Controls, defined as having no history of AVEs, were matched to cases based on age at SLE diagnosis, gender, decade of clinic entry, disease duration at clinic entry, Adjusted Mean SLE Disease Activity Index-2K (AMS) at time of AVE and SLE Disease Activity Index-2K (SLEDAI-2K). Successful control of blood pressure and cholesterol (total and LDL) was determined for patients with AVEs and for those without AVEs. Successful control was defined as normal levels in 90% of follow-up visits (ie. systolic BP ≤140 mmHg, diastolic BP ≤90 mmHg, serum total cholesterol ≤5.2 mmol/L, serum LDL ≤3.2 mmol/L). P-values were calculated based on the chi-square test.

Results: 30 patients with AVEs and 60 matched controls without a history of AVEs were included. Average disease duration at time of AVE for cases was 6.9 ± 4.8 years, and matched disease duration for controls was 6.1 ± 4.2 years (p=0.45). Successful control of hypertension and hypercholesterolemia are shown in Table 1, according to risk factor profile.

Table 1. Number of patients with successful control of hypertension and hypercholesterolemia

Risk factor profile	Cases (n=30)	Controls (n=60)	p–value
Hypertension and hypercholesterolemia	17	23	
Both success	2 (12%)	2 (9%)	
BP only success	6 (35%)	3 (13%)	0.08*
Cholesterol only success	3 (18%)	2 (9%)	
Neither success	6 (35%)	16 (69%)	
Hypertension only	8	12	
BP success	2 (25%)	1 (8%)	0.54
Unsuccessful	6 (75%)	11 (92%)	
Hypercholesterolemia only	2	12	
Cholesterol success	1 (50%)	3 (25%)	0.51
Unsuccessful	1 (50%)	9 (75%)	
Neither hypertension nor hypercholesterolemia	3 (10%)	13 (22%)	

*Mantel-Haenszel chi-square test where "BP only success" was combined with "Cholesterol only success"

Conclusion: Hypertension and hypercholesterolemia are infrequently controlled in patients with SLE. Inadequate control of these risk factors is seen in both patients who have had an AVE and those who have not, suggesting that other risk factors or protective factors must play a role in the development of AVEs.

626

The Interferon Alpha Gene Signature Is Not Associated with Nor Does It Predict Progression of Coronary Artery Calcium (CAC) or Carotid Intima-Media Thickness (IMT) in Systemic Lupus Erythematosus (SLE). Adnan Kiani, Hong Fang, Jie Xu, Ehtisham Akhter and Michelle Petri. Johns Hopkins University School of Medicine, Baltimore, MD

Background/Purpose: Accelerated atherosclerosis is the major cause of late mortality in SLE. Interferon alpha plays a role in atherosclerosis by deleting endothelial progenitor cells and causing endothelial dysfunction. NZM and Apo E −/− mice exposed to IFN-alpha develop platelet activation and thrombosis. Loss of Type I interferon receptor signaling improves endothelium dependent vasorelaxation, endogenous progenitor cell numbers and function and neoangiogenesis. We investigated whether the interferon alpha gene signature would predict changes in subclinical measures of atherosclerosis in human SLE over 2 years.

Methods: 70 SLE patients, 91% female, 60% Caucasian, 34% African-American, 6% others, mean age 43±10 yrs had coronary artery calcium (CAC) measured by helical CT and carotid intima-media thickness by carotid duplex. The IFN gene signature was determined in peripheral blood RNA using Affymetrix chips.

Results: At baseline, there was no difference in coronary calcium or IMT progression with low vs. high interferon gene signature. Patients with high interferon signature had lower CAC scores at baseline and 2 years but the difference between the 2 groups was not statistically different.

Table 1. Changes in coronary artery calcium (CAC) and carotid intima-media thickness (IMT)

Measure	Mean at baseline	Mean after 2 years	Mean Change	p-value for baseline between groups*	p-value for change within group	p-value for change between groups*
Log_e(CAC score+1)						
Low IFN	1.48	1.69	0.21	0.38	0.22	0.24
High IFN	0.90	0.81	–0.09		0.68	
Carotid IMT						
Low IFN	0.58	0.67	0.10	0.52	0.0008	0.54
High IFN	0.56	0.63	0.07		<0.0001	

* P-value when age, gender, and ethnicity are controlled

Conclusion: In contrast to in vitro and murine studies which clearly show a role of interferon alpha in atherosclerosis, our study failed to find any difference in coronary calcium progression or carotid IMT progression over 2 years, comparing low vs. high signature patients. In fact, the high interferon gene signature group had no progression in coronary calcium over 2 years. Although interferon could still be acting locally at the level of the coronary artery, our study suggests that we must look elsewhere to identify a genetic biomarker of atherosclerosis in SLE.

Zostavax Vaccine Is Safe in Lupus Patients with Low Disease Activity.
Eliza F. Chakravarty[1], Joel M. Guthridge[2], Joan T. Merrill[2], Abigail Cogman[2], Tiny Powe[1], Virginia C. Roberts[3] and Judith A. James[4]. [1]Oklahoma Medical Research Foundation, Oklahoma City, CA, [2]Oklahoma Medical Research Foundation, Oklahoma City, OK, [3]OMRF, Oklahoma City, OK, [4]Oklahoma Medical Research Foundation and Oklahoma University Health Sciences Center, Oklahoma City, OK

Background/Purpose: The Zostavax vaccine was FDA approved in 2006 for the prevention of herpes zoster in healthy adults over age 50. Because it is a live-attenuated vaccine, concerns exist regarding the safety of vaccination in individuals with autoimmune diseases and those on immunosuppressive therapies. We sought to evaluate the safety and immunogenicity of Zostavax vaccination in a group of SLE patients compared to healthy control subjects.

Methods: Ten SLE patients and ten healthy control subjects, all older than 50 years, were recruited to receive Zostavax vaccination followed by 12 weeks of follow-up for safety and immunogenicity. All study subjects had serologic confirmation of primary varicella infection before vaccination. SLE patients had mild, stable disease, with SLEDAI ≤ 4 at enrollment. SLE medications were restricted to azathioprine, methotrexate, anti-malarials, and ≤ 10 mg prednisone daily. Exclusion criteria included history of any varicella vaccination, herpes zoster within 5 years, and use of mycophenolate mofetil, cyclophosphamide or biologic therapies within 6 months of enrollment.

Each subject received Zostavax subcutaneously in the deltoid region during the baseline visit. Follow-up visits were scheduled at 2, 6, and 12 weeks following vaccination for safety and efficacy assessments. The primary safety endpoint was development of herpetiform or bullous lesions at the injection site at any time. Secondary safety endpoints were SLE flare by SLEDAI flare index, any injection site reaction, and any treatment-related adverse events. Primary immunogenicity endpoint was change in VZV-specific cell mediated immunity at 6 weeks compared to baseline between groups. Secondary endpoints included changes in WBC subsets by FACs analysis at each time point.

Results: All study participants were women. Baseline demographics are outlined in Table 1. Among SLE patients, mean baseline SLEDAI was 1.1 (range 0–2). Four patients were receiving prednisone (range 2.5–10 mg daily), two, methotrexate, and seven hydroxychloroquine. All subjects received Zostavax vaccination and have completed at least 6 weeks of follow-up, and 13 have completed the 12 week study. No episodes of herpes zoster, bulliform lesions at the injection site, serious AEs, or SLE flares occurred during the study. Three subjects in each group experienced injection site reactions of erythema or tenderness. All were mild and transient. Mean change in SLEDAI score at six weeks was 0.2. Proportions of leukocyte subsets or plasmacytoid dendritic cells were not significantly changed following vaccination in either group. Functional varicella response cellular assays will be performed on batched samples once all 12-week visits have been completed.

Table 1. Demographic and Safety Outcomes

	SLE	Healthy

Urinary Heparanase Activity Is Elevated in Patients with Lupus Nephritis and Correlate with Protein Excretion.
Ki-Jo Kim[1], In-Woon Baek[2], Chong-Hyeun Yoon[1], Wan-Uk Kim[3] and Chul-Soo Cho[1]. [1]College of Medicine, The Catholic University of Korea, Seoul, South Korea, [2]Callege of Medicine, The Catholic University of Korea, Seoul, South Korea, [3]College of Medicine, The Catholic University of Korea, Suwon, South Korea

Background/Purpose: The heparin sulphate proteoglycans (HSPGs) in the glomerular basement membrane (GBM) play an important role in the charge-selective permeability of the glomerular filter. The b-D-endoglycosidase heparanase has been proposed to be important in the pathogenesis of proteinuria by selectively degrading the negatively charged side chains of HSPGs within the GBM in various forms of glomerulonephritis. We evaluated plasma and urinary activity of heparanase and determined association between its levels and proteinuria in patients with lupus nephritis.

Methods: Plasma from 86 patients with systemic lupus erythematosus (SLE) and 24 normal healthy subjects were collected. The clinical and laboratory data of the patients were obtained at the time of sampling. Forty six patients had a history of lupus nephritis and their urine was also collected. Proteinuria was defined as more than 500 mg/24h or spot urine protein/creatinine ratio > 0.5. Heparanase activity of plasma and urine was determined by a commercially available kit.

Results: Plasma heparanase activity was significantly elevated in SLE patients compared to healthy controls (734.9 ± 91.1 vs. 203.6 ± 87.1 mIU/ml, $p = 0.038$), but its activity was not different between patients with lupus nephritis and those without (743.3 ± 105.5 vs. 722.3 ± 166.1 mIU/ml, $p = 0.915$). However, urinary heparanase activity was significantly elevated in SLE patients with lupus nephritis compared to those without lupus nephritis and healthy controls (1299.7 ± 200.5 vs. 337.5 ± 35.2 and 203.6 ± 87.1 mIU/ml, $p = 0.046$ and 0.026, respectively). Thirty six of patients with lupus nephritis showed significant proteinuria and urinary heparanase activity of them was significantly elevated compared with those of patients without proteinuria (997.0 ± 245.3 vs. 194.6 ± 122.0 mIU/ml, $p = 0.006$). Importantly, urinary heparanase activity was positively correlated with protein excretion (r = 0.381, $p = 0.003$). Moreover, urinary heparanase activity showed an inverse correlation with C3 complement level and complement haemolytic activity (CH50) (r = −0.495, $p = 0.002$ and r = −0.565, $p < 0.001$) and had a tendency to associate negatively with C4 complement levels (r = −0.299, $p = 0.072$).

Conclusion: Urinary heparanase activity was elevated in patients with lupus nephritis and reflect the urinary protein excretion, suggesting a potential role in the pathogenesis of proteinuria in lupus nephritis.

Inflammatory Biomarkers of Atherosclerosis and Oxidative Stress Are Associated with Disease Flare in SLE.
Maureen A. McMahon[1], Jennifer M. Grossman[1], Brian Skaggs[1], Elaine Lourenco[1], Cheryl Lee[1], Lori Sahakian[1], John D. FitzGerald[1], Christina Charles-Schoeman[1], Alan H. Gorn[1], George A. Karpouzas[2], Michael H. Weisman[3], Daniel J. Wallace[3], Weiling Chen[1] and Bevra H. Hahn[1]. [1]UCLA David Geffen School of Medicine, Los Angeles, CA, [2]Harbor-UCLA Medical Center, Torrance, CA, [3]Cedars-Sinai Medical Center, Los Angeles, CA

Background/Purpose: Although our current serologic measures of disease activity are useful for predicting flare in some patients, other patients experience disease flare in the absence of fluctuations in complement or antibody titers. We previously reported that novel inflammatory biomarkers of oxidative stress and endothelial activation, including pro-inflammatory HDL (piHDL), elevated leptin, and soluble tumor necrosis factor-like weak inducer of apoptosis (sTWEAK), independently confer increased risk for carotid artery plaque (ATH). We hypothesized that biomarkers of ATH are reflective of alternate pathways driving inflammation and disease activity in SLE, and will also be associated with increased non-ATH disease flares.

Methods: We retrospectively calculated longitudinal disease activity and flare measurements for 204 SLE women from our "Biomarkers of Atherosclerosis in SLE" cohort. SELENA-SLEDAI disease activity measures were calculated for each patient visit in the 12 month period following their baseline ATH biomarker assessment. Mild/moderate and severe flares were categorized at each visit using the SELENA flare tool.

Antioxidant function of HDL was measured as the change in fluorescence intensity caused by oxidation of DCFH by LDL in the presence or absence of test HDL. Plasma leptin, sTWEAK, and Lp(a) were measured in the baseline blood samples using ELISA (R&D Biosystems). Homocysteine was measured in the UCLA clinical labs by Fluorescence Polarization Immunoassay.

Results: 57.4% of SLE subjects experienced a mild to moderate flare and 22.5% experienced a severe flare in the 12 months following study entry. In univariate analysis, high sTWEAK and Lp(a) were positively associated and C3 levels were inversely associated with mild to moderate SLE flares. High leptin and high homocysteine were positively associated with severe SLE flares. In multivariate analysis controlling for lupus medications and other potential confounders, high levels of sTWEAK were associated with 2.3 fold increased odds ratio (OR) for mild to moderate disease flare (p=0.02), and high leptin (OR 5.4, p=0.04), homocysteine (OR 5.8, p=0.02), and baseline prednisone dose (OR 1.1, p<0.001) were associated with severe flare (TWEAK trended towards association, OR 2.3, p=0.08). When we substituted our *combined ATH biomarker* variable for individual biomarkers, patients with baseline High risk scores had 6.7 fold increased odds for experiencing a severe flare in the subsequent year, and a shorter time to severe flare (Hazard ratio for high PREDICTS score 3.1, p=0.01).

Conclusion: In conclusion, many of our biomarkers of interest for the progression of ATH in SLE may also have implications for overall progression of disease flares. A panel of atherosclerosis biomarkers may help identify SLE patients at risk for both cardiovascular and lupus disease related flares.

Risk Factors Associated with Early Central Nervous System Damage Detected Through Diffusion Tensor Imaging (DTI) in Patients with Systemic Lupus Erythematosus. Paola Tomietto[1], Federica Casagrande[2], Maja Ukmar[3], Luca Weis[2], Pia Morassi[4], Rita Moretti[2], Gianni Biolo[2], Carlo Giansante[2] and Maria Assunta Cova[2]. [1]AOU Ospedali Riuniti, Trieste, Italy, [2]University of Trieste, Trieste, Italy, [3]University of Trieste, Trieste, [4]AOU Ospedali Riuniti di Trieste, Trieste, Italy

Background/Purpose: Antiphosholipid antibodies, SLICC-DI and some cardiovascular risk factors have been identified as risk factors for neuropsychiatric lupus (NPSLE). Diffusion tensor imaging (DTI) is an advanced MRI technique with an increased accuracy compared to conventional MRI (cMRI) in evaluating white matter microstructure. Our purpose was to assess the main factors affecting early SNC damage detected through DTI in SLE.

Methods: 20 consecutive SLE patients underwent a clinical evaluation to characterize CNS involvement (NPSLE) including: clinical hystory, a neuropsychological battery and pychiatric tests (HADS). All the patients and 14 healthy controls underwent MRI examination on a 1.5T magnet with a standard protocol for cMRI and DTI sequences. Region of interest (ROI) were placed symmetrically on normal appearing white matter (NAWM) in 12 areas (frontal and parietal WM, amygdala, corpus callosum, middle cerebellar peduncles). Mean diffusivity (MD) and fractional anisotropy (FA) were calculated bilaterally. ROI relevant to distinguish patients with NPSLE vs patients without and controls were selected on the basis of the receiver operating characteristic (ROC) curve analysis. SLEDAI, SLICC-DI, generic cardiovascular risk factors, positivity for Raynaud's phenomenon, livaedo reticularis, cutaneous vasculitis, aPL, anti-RNP and anti-DNA were determined for all the patients and included as independent variables in several stepwise regression analysis to determine which of them affected changes in FA/MD in NAWM in an independent way.

Results: Measures of MD at the level of frontal right WM, corpus callosum and right middle cerebellar peduncle and of FA in left middle cerebellar peduncle showed moderate accuracy (AUC>0,71) in distinguishing SLE patients and healthy controls, while MD and FA of right corpus callosum and FA in right amygdala in differentiating patients with and without NPSLE, according to the clinical classification (AUC>0.73). Among cardiovascular risk factors, diabetes, smoking and hypertension resulted as independent factors affecting MD and FA in corpo callosum bilaterally; hypertension was associated also to changes in FA and MD of amygdala. Among SLE-related factors, aPL, anti-DNA and SLEDAI were independent factors affecting FA of corpus callosum; aPL were associated also to changing in FA of fronto-parietal WM while SLICC-DI to modifications of FA in amygdala. Finally cutaneous vasculitis resulted as an independent factor affecting MD in corpus callosum.

Conclusion: This preliminary analysis showed as some cardiovascular risk factors (smoking, hypertension, diabetes), and some SLE-related factors (aPL, anti-DNA, SLEDAI, SLICC-DI, cutaneous vasculitis), previously reported as related to NPSLE, are associated to changes of FA and MD in normal appearing white matter of fronto-parietal lobes, corpus callosum and amygdala. These data, if confirmed, suggest a probable multifactorial pathogenesis of white matter abnormalities in SLE and underlie the possible role of DTI in detecting early SNC damage

Peripheral Neuropathy Due to Systemic Lupus Erythematosus (SLE) Itself: Incidence, Disease Risk Factors and Outcome. Simone Fargetti[1], Samuel K. Shinjo[2], Sandra G. Pasoto[1], Ana L. Calich[1], Eloisa Bonfa[3] and Eduardo F. Borba[1]. [1]University of Sao Paulo, Sao Paulo, Brazil, [2]Faculdade de Medicina da Universidade de São Paulo, Sao Paulo, Brazil, [3]University of São Paulo, São Paulo, Brazil

Background/Purpose: Peripheral neuropathy (PN) solely attributable to SLE itself is difficult to define since most of these patients are exposed to several other conditions that may cause this manifestation. The aim is to determine characteristics and outcome of PN attributed exclusively to SLE and its possible association with clinical/laboratorial features in a large cohort.

Methods: SLE patients (ACR 1997) with PN were identified from our Lupus Outpatient Clinic computerized database of 1038 patients. Only patients with definitive PN proved by electroneuromyography were included. Exclusion criteria were conditions related to PN: diabetes mellitus, alcohol consumption, use of any drug related to neuropathy (thalidomide, statins, etc.), thyroid disease, infection, cancer, vitamin B12 deficiency, renal or hepatic failure, and other autoimmune disease (antiphospholipid syndrome, Sjogren's syndrome, etc.). Medical records were extensively reviewed and included clinical/laboratorial data, treatment, and evolution. Each SLE patient with PN [n=22] was compared with 2 SLE patients without PN (controls) [n=44] that were age- and sex-matched and had similar disease duration.

Results: PN exclusively attributed to SLE was identified in 22 patients (2.1%). The mean age (34.4±11.6 vs. 33.9±9.6 years, p=0.85) and disease duration (9.2±7.7 vs. 9.9±6.8 years, p=0.73) of PN were similar to controls. The interval between SLE onset and PN diagnosis was 4.9±5.7 years and the mean SLEDAI scores was higher in PN patients (5.4±7.6 vs. 1.8±2.9,p=0.001). The most common pattern on electroneuromyography was sensorimotor polyneuropathy of lower limbs (50%), followed by mononeuropathy (26.9%), and polyradiculoneuropathy (15.3%). PN was associated to hematological involvement (72.7% vs. 43.2%,p=0.036), leukopenia (50% vs. 20.5%,p=0.022), lymphopenia (68.2% vs. 29.5%,p=0.004), cutaneous vasculitis (54.5% vs. 22.7%,p=0.014), and anti-Sm (50% vs. 15.9%,p=0.007). Multivariate analysis revealed that PN was related to anti-Sm (OR=5.36; 95%CI 1.37–20.99) and cutaneous vasculitis (OR=4.97; 95%CI 1.23–20.08). All SLE patients received corticosteroids, most of them associated with immunosuppressive drug (59% cyclophosphamide; 31.8% azathioprine). After immunosuppressive therapy, 63.6% improved of neurological symptoms and 31.8% remained stable.

Conclusion: Our study suggested that PN attributed to SLE itself is rare in the absence of other conditions and seems to be strongly associated to anti-Sm antibodies and cutaneous vasculitis. A favorable outcome with immunosuppressive therapy is observed in most of SLE patients with this neurological manifestation.

The Effects of Co-Existing Proliferative Histopathology On Membranous Lupus Nephritis. Jennifer L. Graybill, Catarina Vila-Inda, Chaim Putterman and Irene Blanco. Albert Einstein College of Medicine, Bronx, NY

Background/Purpose: Lupus nephritis (LN) affects up to 60% of SLE patients and is worse in minority communities. Traditionally membranous LN confers a better prognosis than proliferative, but a significant number of patients do develop renal failure. Moreover, mixed membranous and proliferative histology is not uncommon. To determine if co-existing proliferative lesions worsen the prognosis of membranous disease, we studied SLE patients who underwent renal biopsy at a large tertiary center.

Methods: We analyzed all biopsies with classes: III±V, IV±V and V from January 1997-December 2011, and confirmed that all patients met ≥4/11 ACR SLE criteria. We collected baseline demographic and laboratory information at the time of biopsy as well as medications given. Our composite endpoint was the development of end stage renal disease (ESRD) requiring dialysis and/or death.

Results: Of the 202 patients included, 81.3% were female and the median age was 30.5y. The predominant race was black (54.5%), followed by Hispanic (37.1%) and 8.4% were another race/ethnicity. There was no significant difference between the groups in age, gender or disease duration.

123 patients had proliferative LN (Class III or IV, P), 55 had membranous LN (Class V, M), and 24 had mixed disease (P+M). Black patients were more likely to have class V (p=0.02). Creatinine was higher in P (p<0.01) but there was no difference between M or P+M (p=0.12). There was no difference in median protein to creatinine ratios, serum albumin, and BP between groups.

62/202 (31%) patients reached the composite end point: 41.5% P, 14.6% M, and 12.5% P+M (p<0.01). Survival was significantly worse for P compared to M (p<0.01) and P+M (p=0.05), but no difference was seen between M and P+M (p=0.74). As previously reported, on univariate analyses, urine protein to creatinine ratio (p<0.01), creatinine (p<0.01), systolic BP (p=0.02), and age (p=0.05) were associated with the end point. There was no association with cyclophosphamide (p=0.07) or mycophenolate induction (p=0.2), ACEI/ARB use (p=0.85), or treatment with antimalarials (p=0.2).

Unadjusted Kaplan-Meier Survival Curves For Composite Score By Class

Log-Rank P v M : p<0.01
Log-Rank P v P+M: p=0.05
Log-Rank M v P+M: p=0.74
In multivariate models, M as compared to P had improved survival (HR=0.31, p=0.02) but there was no longer a significant difference between P and P+M (p=0.18) As in the univariate analysis, age (p=0.03), protein to creatinine ratio (p=0.03), and creatinine at biopsy (p<0.01) were all associated with a decreased risk of survival.

Conclusion: At first glance membranous with or without proliferative lesions on histology have a similar prognosis. However, in multivariate models the difference between proliferative and mixed disease was no longer seen when adjusted for age, protein to creatinine ratio and creatinine at biopsy. Therefore proliferative lesions alone on biopsy do not confer a worse prognosis for membranous disease rather it is likely disease severity itself that drives prognosis.

Missed Work Days in Systemic Lupus Erythematosus. Jie Xu, Hong Fang and Michelle Petri. Johns Hopkins University School of Medicine, Baltimore, MD

Background/Purpose: Indirect costs are part of the medical and financial burden of SLE. These costs are easy to undervalue because a significant portion of this economic loss results from lost productivity in the workforce (Clarke A, et al. Am J Manag Care, 2001; 7(16):S496-S501.). This effect is magnified by the population typically affected by SLE, young women, who may suffer disabilities that affect the most productive years of life (Panopalis P, et al. Arthritis & Rheumatism, 2008; 59(12):1788–1795.). We attempted to identify both demographic and disease variables that may serve as predictors of this loss in work-related activities.

Methods: The medical resource use questionnaire was distributed to SLE patients in the Hopkins Lupus Cohort that covered the last 3 months before the baseline visit and then at the following two quarterly clinic visits. 199 SLE patients (89% female, 58% Caucasian, 31% African-American, 11% other ethnicities, mean age at baseline 44±11 years) were included in the analysis. Exclusion criteria were diagnosis with lupus less than 6 months ago, age younger than 18 or older than 75, pregnant at baseline, and active HIV patients. Those who were unemployed were also excluded.

Results: The mean number of missed work days over 6 months was 2.6 days (range 0 to 39). Predictors of missed work days are shown in Table 1. The two significant predictors were low family income (p=0.019) and a history of missed work days in the 3 months before the study year (p<0.0001). A multivariate linear regression model for number of missed work days was then constructed (Table 2). In the multivariate model, disease activity (mean SLEDAI) was not associated with the number of missed work days. Renal activity (urine protein/cr ratio) had a borderline association. Family income was not predictive.

Table 1. Predictors of missed work days (any vs none) - univariate analysis.

		Number (%) missed work days during followup	P–value
Age at baseline (years)	≤ 40 (n=86)	36 (41.9)	0.68
	> 40 (n=113)	44 (38.9)	
Gender	Female (n=177)	71 (40.1)	0.94
	Male (n=22)	9 (40.9)	
Ethnicity	African–American (n=61)	29 (47.5)	0.16
	Caucasian (n=115)	42 (36.5)	
Family income ($)	≤ 50K (n=75)	38 (50.7)	0.019
	> 50K (n=124)	42 (33.9)	
Education (years)	< 12 (n=7)	4 (57.1)	0.44
	≥ 12 (n=192)	76 (39.6)	
Use of prednisone at baseline	No (n=126)	46 (36.5)	0.16
	Yes (n=73)	34 (46.6)	
PGA[1] at baseline	≤1 (n=176)	67 (38.1)	0.090
	>1 (n=23)	13 (56.5)	
Mean PGA over year	≤1 (n=170)	65 (38.2)	0.17
	>1 (n=29)	15 (51.7)	
SLEDAI at baseline	≤2 (n=154)	59 (38.3)	0.31
	>2 (n=45)	21 (46.7)	
Mean SLEDAI over year	≤2 (n=140)	54 (38.6)	0.47
	>2 (n=59)	26 (44.1)	
Anti–dsDNA at baseline	Negative (n=148)	58 (39.2)	0.65
	Positive (n=49)	21 (42.9)	
C3 or C4 at baseline	Low (n=40)	15 (37.5)	0.74
	Normal (n=156)	63 (40.4)	
Increased ESR at baseline	No (n=117)	46 (39.3)	0.72
	Yes (n=74)	31 (41.9)	
Urine Pr:Cr ratio at baseline	≤0.5 (n=178)	70 (39.3)	0.23
	>0.5 (n=12)	7 (58.3)	
Diabetes	No (n=187)	72 (38.5)	0.070
	Yes (n=12)	8 (66.7)	
BMI at baseline	≤30 (n=143)	52 (36.4)	0.10
	>30 (n=55)	27 (49.1)	
Vitamin D	<32 (n=57)	26 (45.6)	0.32
	≥32 (n=137)	52 (38.0)	
Baseline history of missed work days	No (n=108)	22 (20.4)	<0.0001
	Yes (n=75)	52 (69.3)	

[1]PGA: Physician's global assessment (0–3 scale)

Table 2. Multivariate Linear Regression Model

	Effect on number of missed work days	P–value
Age at baseline (per 10 years)	0.03 ± 0.04	0.39
Ethnicity (African–American)	0.19 ± 0.91	0.83
Family income (>50K)	0.29 ± 0.85	0.73
Mean SLEDAI (per unit)	0.05 ± 0.20	0.79
Urine Pr:Cr ratio at baseline (per unit)	1.23 ± 0.66	0.063
Diabetes	2.81 ± 1.88	0.13
Vitamin D at baseline	–0.04 ± 0.03	0.19
Number of missed work days at baseline	0.67 ± 0.11	<0.0001

Conclusion: This study found that disease activity (either by physician's global assessment or SLEDAI) is not predictive of missed work days. However, renal lupus had a borderline association. Demographic factors (sex, ethnicity, income) were not significant in the multivariate model. The most important factor remains a pattern of past history of missed work days.

634

Adherence to Adult Treatment Panel III Guidelines for Systemic Lupus Patients. Matthew Basiaga and Lisabeth Scalzi. Penn State Univ/Hershey, Hershey, PA

Background/Purpose: The National Cholesterol Education Program (NCEP) Adult Treatment Panel III (ATP III) has provided education and guidance for decades on the management of hypercholesterolemia. Systemic lupus erythematosus (SLE) patients are in an intermediate risk category for cardiovascular disease. We examined a SLE cohort to examine whether patients were being treated according to ATP III guidelines.

Methods: Data from 133 patients with SLE was examined to see whether ATP III guidelines were being adhered to. All patients were free of any known clinical heart disease. Available information that was used included traditional CVD risk factors (a history (or present use) of cigarettes, hypertension (HTN) (BP ≥ 140/90 mmHg or on an antihypertensive agent for the purpose of lowering blood pressure), HDL cholesterol < 40 mg/dL, family history of premature CVD, diabetes (self reported history or a fasting blood glucose of >126 mg/dL), fasting cholesterol profiles, and age (men ≥ 45 years; women ≥ 55 years). We then compared the proportion of SLE patients who met ATP III criteria for initiation of lipid therapy and who reported ever having been/or were presently on therapy to those who had never been on a lipid lowering medication. We evaluated group differences between those patients who have been treated versus those who have not using t-tests and chi-square analyses.

Results: The mean age of the cohort was 50.7 ± 8.8 years, 96% were female, and 78% were Caucasian. Thirty-four of the 133 (26%) participants met ATP III criteria for the initiation of lipid lowering therapy. Only 9 (26%) in this group had ever been on any lipid lowering medication and only 4 (12%) were currently being treated. Significant variables associated with lipid lowering therapy versus no therapy included, the mean number of ATP III risk factors (4.8 versus 4.0; p=0.03), body mass index (35.4 versus 27.8; p=0.001), age (50.2 vs. 57.3 years; p=0.02), cholesterol level (249 versus 187 mg/dL; p<0.0001), LDL (163 vs. 109 mg/dL; p<0.0001), and HTN (78% vs. 40%; p=0.03). Race, SLICC scores, diabetes, HDL, family history, and smoking were not significant variables as to whether a patient was treated.

Conclusion: ATP III guidelines are standard guidelines for assessing whether patients should have interventions, including drug therapy, to treat hyperlipidemia and decrease CVD risk. More than a quarter of our SLE participants met ATP III guidelines for lipid lowering therapy and only 12% of those who fulfilled ATP III criteria were being treated. Younger patients who met criteria were not treated, while older, obese, and those with a higher number of ATP III risk factors were treated. Given that SLE patients are already at an intermediate CVD risk, similar to diabetes, more awareness is needed in addressing the needs of this at-risk population. This is an excellent area for quality improvement for rheumatologists and highlights the need for communication between rheumatologists and primary physicians regarding treatment and/or referral to cardiology for primary preventative care. Future studies addressing obstacles in initiation and maintenance of therapy are needed in SLE patients.

635

Elevated Transglutaminase Levels On Microparticles From Systemic Lupus Erythematosus Patients. Leslie Harris, Ratnesh Chopra, Ann K. Rosenthal and Mary E. Cronin. Medical College of Wisconsin, Milwaukee, WI

Background/Purpose: Systemic Lupus Erythematosus (SLE) is characterized by the formation of autoantibodies, and over-exuberant antigen presentation may account for some of this pathology. Circulating microparticles (MP) are membrane-bound 100–1000 nM sized vesicles derived from platelets, leukocytes, endothelial cells and red cells. They are immunomodulatory and participate in antigen presentation. The protein crosslinking enzymes, transglutaminases (Tgases), are involved in antigen presentation. Evidence from mouse studies supports a potential role for excess Tgase activity in SLE and TGase inhibitors have been shows to ameliorate murine lupus. Interestingly, we also noted a single report of Tgase inhibition with hydroxychloroquine (HCQ), a commonly used drug for SLE. Previous studies have shown increased numbers of circulating MPs in SLE patients. We sought to characterize the cell sources of MPs and determine protein levels of the Tgase enzymes (type II Tgase and factor XIIIA) on MPs from SLE patients and controls. We also measured Tgase activity on MPs from several normal donors and investigated the effect of HCQ on MP-associated Tgase activity.

Methods: We obtained 12 ml of blood from 25 SLE patients and 25 age and sex-matched normal controls after IRB approval. SLE patients satisfied ACR criteria for SLE and were excluded if they had anti-phospholipid antibody syndrome. MPs were isolated from platelet rich plasma according to published protocols. Flow cytometry was used to enumerate MPs and determine the percent of MPs from each cell source. Cell markers included CD45 for leukocytes, CD41 (GPIIb) + CD42 (GPIX+GPIb) for platelets, CD144 (VEcadherin) for endothelial cells, CD235a (glycophorin A) for red cells, as well as the Tgase enzymes, type II Tgase and factor XIIIA. Tgase activity was measured with a standard radiometric assay detecting crosslinking activity in the presence and absence of 10 mM HCQ. The Mann-Whitney test was used to determine statistically significant differences between groups.

Results: Numbers of MPs were similar in SLE patients and controls. SLE patients had higher numbers of MPs derived from red cells 1448 (CI 908–2640) positive particles (PP)/μl compared to 2570 (CI 1069–9035) PP/μl in SLE patients (p=0.027). Type II Tgase enzyme levels were significantly higher in the SLE cohort, which had 1531 (CI 854–4097) PP/μl, compared to the control group with 895 (CI 402–1526) PP/μl (p=0.007). Factor XIIIA levels were slightly higher in the SLE group, but did not reach statistical significance (p=0.068). Tgase activity on a random sample of MPs from controls demonstrated an average Tgase activity level of 163 ± 75 mU/mg protein (n=3). Activity levels fell to 112.8± 14.9 mU/mg protein with HCQ (p<0.05).

Conclusion: Type II Tgase enzyme levels are significantly higher on MPs from SLE patients than controls, and activity is inhibited with HCQ. Because Tgase enzymes may have active roles in antigen presentation as well as platelet aggregation, the ability of HCQ to suppress Tgase activity may be an additional mechanism of action for this effective SLE drug. Further studies of the role of Tgase in SLE and on MPs are warranted.

Retrospective Study of Allogenic Mesenchymal Stem Cells Transplantation in Active and Refractory Lupus Nephritis for Induction Therapy. Lingyun Sun, Dandan Wang, Xia Li and Huayong Zhang. Department of Rheumatology and Immunology, the Affiliated Drum Tower Hospital of Nanjing University Medical School, Nanjing, China

Background/Purpose: Allogenic mesenchymal stem cells (MSCs) transplantation demonstrated significant clinical efficacy on various autoimmune diseases. Here we retrospectively analyzed the role of allogenic MSCs transplantation in renal remission in patients with active and refractory lupus nephritis (LN).

Methods: Eighty-one patients with active and refractory lupus nephritis in China from 2007 to 2010 were enrolled in the study. Allogenic bone marrow or umbilical cord derived MSCs were administered intravenously at the dose of one million cells per kilogram of bodyweight. Then all the patients were followed up for 12 months to evaluate renal remission as well as possible adverse events. The primary outcomes were renal complete remis-

sion (CR) and partial remission (PR) at each visit times, as well as renal flares. The secondary outcomes included renal activity score, total disease activity score, renal function and serologic index. Rates of overall survival, renal remission, as well as relapse at different visit times were calculated by using the Kaplan-Meier method and were statistically tested with the log-rank test. We calculated the HR and their 95% CIs using the univariate *Cox* proportional hazards model.

Results: The overall survival rate during 12 months follow-up was 95% (77/81). The probability of renal remission was 41% (18% CR and 23% PR) at 3 months, 45% (18% CR and 27% PR) at 6 months and 44% (23% CR and 21% PR) at 12 months after allogenic MSCs transplantation. Renal remission was not correlated with age, disease duration, MSCs source and baseline SLEDAI score, but was significantly correlated with baseline proteinuria (P=0.003, 95%CI 0.336–0.794) and serum creatinine levels (P=0.047, 95%CI 0.224–0.990) by *COX* regression analysis. Eleven in 81 (14%) patients underwent renal flare in 12 months follow up after a prior complete or partial remission. Renal activity evaluated by BILAG score significantly declined after MSCT, in parallel with the obvious amelioration of renal function. Total disease activity evaluation by SLEDAI score also decreased after treatment. Additionally, the doses of concomitant prednisone and immunosuppressive drugs were tapered. Four of 81 patients died of uncontrolled lupus nephritis unrelated to MSCT.

Conclusion: Allogenic MSCs transplantation resulted in renal remission within 12 months visit, which could be used early as a potential induction therapy for active and refractory lupus nephritis.

Anti-Mullerian Hormone and Ovarian Reserve in Systemic Lupus Erythematosus. Chi Chiu Mok[1], Pak To Chan[2] and Chi Hung To[2]. [1]Tuen Mun Hospital, Hong Kong, Hong Kong, [2]Hong Kong, Hong Kong

Background/Purpose: To study the level of anti-mullerian hormone (AMH) and its relationship with age and previous cyclophosphamide (CYC) exposure in patients with systemic lupus erythematosus (SLE).

Methods: Consecutive female patients aged 18–52 years who had menstruation in the preceding 12 months and fulfilled [3]4 ACR criteria for SLE were recruited. AMH was assayed by an ELISA kit (Beckman Coulter, Inc., USA). Serum AMH level was compared between patients with and without previous use of immunosuppressive agents. The relationship of AMH level to age and CYC exposure was studied by linear regression.

Results: 216 female SLE patients were studied. The mean age of patients at the time of venepuncture was 35.1 ± 10.1 years and the mean SLE duration was 7.6 ± 5.9 years. Immunosuppressive drugs ever received by these patients were: prednisolone (90%), AZA (69%), MMF (30%), tacrolimus (21%), cyclosporin A (17%), CYC (22%) and HCQ (67%). Prednisolone was exclusively used in combination with one or more of the other immunosuppressive drugs. Of the 48 CYC users, 29 (40%) received daily oral treatment and 19 (40%) received monthly intravenous pulse therapy. The median total duration of CYC exposure was 20 weeks (inter-quartile range [IQR] 12.3–32.8). Fifty-four (25%) patients had undetectable AMH level (78% aged >40 years). These patients were significantly older than those with measurable AMH level (median age 47 [IQR 42–51] vs 31 [IQR 25–38.3] years; p<0.001). Significantly lower levels of AMH were observed for past users of CYC than non-users, after adjustment for age (1.58 ± 2.92 vs 1.73 ± 2.11 ng/mL; p=0.04 by ANCOVA). The mean time interval between AMH assay and last dose of CYC administered was 6.28 ± 3.8 years. AMH levels were not statistically different between users and non-users of other immunosuppressive agents that included prednisolone, mycophenolate mofetil, azathioprine and the calcineurin inhibitors. Linear regression revealed age (Beta -0.32; p=0.02) and each 5g of CYC exposure (Beta -0.28; p=0.047) were independently associated with lower AMH level. The route of CYC administration, duration of CYC treatment, disease activity score and duration of SLE was not significantly associated with AMH level on univariate regression analyses.

Conclusion: AMH is a sensitive marker for ovarian damage due to previous CYC treatment in SLE patients.

The Progression of Brain MRI Biomarker of Cognitive Impairment (White Matter Hyperintensity) in Systemic Lupus: A Clinical and Imaging Longitudinal Study. Jamal Mikdashi and Umran Ashruf. University of Maryland School of Medicine, Baltimore, MD

Background/Purpose: SLE patients are at high risk for accumulation of white matter hyperintensity (WMH) on brain MRI which has been correlated with cognitive impairment. Our goal is to determine whether the progression of WMH in newly diagnosed SLE patients predicts increased risk of cognitive impairment.

Methods: Brain MR T2 weighted images were compared at baseline and annually for 5 years among newly diagnosed SLE patients, presenting with neuropsychiatric SLE (NPSLE), {(n= 30), [mean age 37.6 years, 73 % African American, and 90 % women]}, and age- and gender- matched non NPSLE patients (n= 25), and healthy controls (n=20) to assess WMH burden (mild, moderate or severe). Standard cognitive tests were examined at enrollment and at end of study. Demographic and clinical manifestations were compared among the groups. Significant variables in the analyses, depression, cardiovascular risk factors and worsening of WMH grade using dichotomous measures were entered into multivariable and Cox proportional hazard analyses to determine their contribution to cognitive impairment.

Results: At baseline, 59 MRI were normal and16 had WMH lesions (NPSLE = 9, non NPSLE= 4 and controls = 3). The WMH burden was higher among NPSLE patients compared to non NPSLE patients (OR= 3.1, 95 % CI: 0.7– 13.2, p value =0.09). At baseline, frontal and parieto -occipital lesions were more frequent among NPSLE patients, whereas periventricular lesions were more frequent among non NPSLE patients or controls. At end of study, 24 patients had normal MRI findings and 21 had new and increased WMH lesions (NPSLE =13, non NPSLE =6, control= 2). The rate of WMH burden progression was variable across the groups. NP SLE patients had a faster rate of accumulation of WMH lesions, as compared to non NPSLE (OR =3.5, 95 % CI: 1.1–10.7; p value= 0.03). The median number of impaired cognitive domains increased, regardless of the presence of baseline WMH lesions particularly among NPSLE compared to non NPSLE or controls.

Ischemic strokes and MRI -defined incident infarcts (OR = 5.8; 95% CI = 1.2–29.4; p value = 0.04), and worsened WMH grade (OR = 4.3; 95% CI = 2.1–16.3; p value = 0.03), were associated with increased risk of cognitive impairment in the areas of attention, processing speed and executive function. Hydroxychloroquine use was associated with reduced risk for WMH progression (OR= 0.3, 95 % CI: 0.1– 0.7; p value= 0.02), but not cognitive impairment.

Conclusion: The progression of WMH has prognostic relevance for long-term cognitive outcome in newly diagnosed SLE. Strategic preventive measures are needed to optimally target individuals at highest risk of cognitive decline.

Safety and Efficacy of Epratuzumab in an Open-Label Extension Study (SL0006). K. Hobbs[1], D.J. Wallace[2], V. Strand[3], K. Kalunian[4], B. Kilgallen[5], S. Bongardt[6], W.A. Wegener[7] and D.M. Goldenberg[7]. [1]Denver Arthritis Clinic, Denver, CO, [2]Cedars-Sinai Medical Center, Los Angeles, CA, [3]Stanford University, Palo Alto, CA, [4]UCSD School of Medicine, La Jolla, CA, [5]UCB Pharma, Smyrna, GA, [6]UCB Pharma, Brussels, Belgium, [7]Immunomedics Inc, Morris Plains, NJ

Background/Purpose: Epratuzumab, a monoclonal antibody targeting CD22, is in development for the treatment of systemic lupus erythematosus (SLE). Two randomized, double-blind trials (ALLEVIATE 1 and 2) were prematurely terminated due to interruption of drug supply. SL0006 was an open-label extension study in which patients previously enrolled in the ALLEVIATE trials received epratuzumab. This abstract reports final long-term safety and efficacy data from SL0006 in patients with moderately-to-severely active SLE.

Methods: Patients (*n*=29) in SL0006 received 12-week cycles of epratuzumab 360 mg/m² (2 infusions, at days 1 and 8 of each cycle). Ten were from ALLEVIATE-1 and had severe (BILAG A) SLE activity in ≥ 1 body/organ system, while 19 were from ALLEVIATE-2 with moderate (BILAG B) activity in ≥ 2 body/organ systems. All patients were eligible for enrollment in SL0006, subject to investigator's judgment of treatment benefit. There was a median delay in epratuzumab dosing of 165 days (range 1–400)

between premature termination of the ALLEVIATE studies and entry into SL0006. Assessments were every 4 weeks from screening (Visit 1; V1).

Results: Patients were aged 22–61 years; almost 90% were women, and 72% were of European descent (79% Caucasian). Median study duration was 4.0 years (0.3–5.3). Median corticosteroid dose (range) at the start of ALLEVIATE (baseline) was 21 mg/day (10–80), and by the start of SL0006 (V1) dose reduced to 7.5 mg/day (0–30). Lower levels of corticosteroid were maintained to the last visit (0–105). Median (range) total BILAG scores decreased throughout the study from baseline of 17 (12–30) (last visit 12 [1–34]). BILAG improvement from baseline was maintained from SL0006 V1 to end of study, with most V1 BILAG A/B grades improving to C/D at least once during the study (Table). Median (range) total SLEDAI scores also decreased throughout the study from baseline of 10 (4–26) (last visit 8 [0–16]). SLEDAI improvement from baseline was also maintained from V1 to end of study. Median patient and physician global assessments of disease activity each improved from 3.0 and 2.8, respectively, at baseline by a median of 1.0 categories. Median reductions in absolute B-cell (CD19+) counts were observed throughout the study, from screening (34.0% reduction) until the last visit (45.0% reduction). All patients reported at least 1 AE, with 14 patients (48.3%) experiencing at least one SAE. Four patients (13.8%) discontinued because of AEs. The most frequent AEs, occurring in at least 5% of subjects, were infections and infestations (upper respiratory tract infections 58.6%, and sinusitis, nasopharyngitis, urinary tract infections [all 37.9%], anxiety, and nausea [both 34.5%]).

Table.

BILAG organ system (Total n = 29)	Baseline* A/B grades n	Baseline* A/B grades New C/D grade during study	Visit 1† A/B grades n	Visit 1† A/B grades New C/D grade during study	Baseline* C/D/E grades n	Baseline* C/D/E grades New A/B grade during study	Visit 1† C/D/E grades n	Visit 1† C/D/E grades New A/B grade during study
General	14	14 (100%)	8	8 (100%)	15	6 (40%)	21	7 (33.4%)
Mucocutaneous	24	22 (91.7%)	17	15 (88.2%)	5	2 (40%)	12	9 (75%)
Neurological	4	4 (100%)	2	2 (100%)	25	7 (28%)	27	8 (29.6%)

CV and Respiratory	4	4 (100%)	2	2 (100%)	25	8 (32%)	27	9 (33.3%)
Vasculitis	4	4 (100%)	1	1 (100%)	25	2 (8%)	28	4 (14.3%)
Renal	1	1 (100%)	0	0	28	9 (32.1%)	29	10 (34.5%)
Hematology	1	1 (100%)	2	1 (50%)	28	8 (28.6%)	27	7 (25.9%)

*Baseline of ALLEVIATE study.
†Visit 1 = Baseline of SL0006 study.

Conclusion: With continued administration, epratuzumab maintained improvements in SLE disease activity over approximately 4 years, with a tolerable safety profile. No new safety concerns were identified.

640

Association of Body Weight with Cardiovascular Events in Systemic Lupus Erythematosus. George Stojan[1], Homa Timlin[2], Hong Fang[1], Laurence S. Magder[3] and Michelle Petri[1]. [1]Johns Hopkins University School of Medicine, Baltimore, MD, [2]West Drayton, United Kingdom, [3]University of Maryland, Baltimore, MD

Background/Purpose: Excessive body mass among healthy subjects carries an increased risk of subsequent cardiovascular (CV) events. In healthy subjects, the relationship between body mass index (BMI) and total and CV mortality follows a U-shaped curve, with the lowest mortality in overweight (BMI $25.0-29.9$ kg/m²) and mildly obese (BMI $30.0-34.9$ kg/m²) individuals. Despite a high burden of CV disease in systemic lupus erythematosus (SLE), the relationship between BMI and CV outcomes in SLE has not been studied.

Methods: We estimated the effect of BMI on CV events in a cohort of 2000 patients with SLE. We analyzed the rate of CV events during cohort participation, for five predetermined body weight groups: low (BMI<20 kg/m²), normal weight (reference, BMI 20–24.9 kg/m²), overweight (25–29.9 kg/m²), obese (BMI 30–34.9 kg/m²), and severely obese (BMI>35 kg/m²). CV events were defined as either stroke, myocardial infarction, incident angina, a coronary procedure (CABG or PCI), or claudication. Those with a CV event prior to cohort entry were excluded. We adjusted for various confounding factors (age, sex, race, complement, hematocrit, anti-dsDNA, immunosuppressant use), including related CV risk factors: hypertension, hypercholesterolemia, diabetes and smoking.

Results: There were 140 CV events observed over 11,374 person-years of follow-up. The rate of CV events per 1000 patient years of follow up was 6.0 for low weight, 9.3 for normal weight, 14.5 for overweight, 17 for obese, and 13.2 for severely obese. The rate of CV events in obese patients was statistically significantly higher compared to patients with normal weight (p=0.015) in a non adjusted model. After adjusting for confounding factors the p-value approached statistical significance (p=0.062).

BMI (kg/m²)	Person–years	CV events	Rate[1]	Unadjusted model RR (95% CI)	Unadjusted model P–value	Adjusted model RR (95% CI)	Adjusted model P–value
<20	1006	6	6.0	0.6 (0.3, 1.5)	0.31	0.5 (0.2,1.3)	0.14
20–24.9	3644	34	9.3	1.0 (REF.GP)		1.0 (Ref.Gp)	
25–29.9	3095	45	14.5	1.6 (1.0, 2.4)	0.051	1.2 (0.7,1.9)	0.52
30–34.9	1884	32	17.0	1.8 (1.1, 3.0)	0.015	1.6 (0.9,2.7)	0.078
>35	1744	23	13.2	1.4 (0.8, 2.4)	0.20	1.1 (0.6,2.0)	0.73

[1]Per 1000 person years

Conclusion: Obesity (BMI 30–34.9 kg/m²) is associated with the highest rate of adverse cardiovascular events in SLE. Interestingly, the CV event rate in severe obesity (BMI>35 kg/m²) was lower than in overweight and obese patients, suggesting the presence of a unique obesity paradox in SLE that differs from the one described in the general population.

641

Study of Anti-Müllerian Hormone and Probability of Pregnancy in 112 Systemic Lupus Erythematosus Patients Exposed or Not to Cyclophosphamide. Nathalie Morel[1], Anne Bachelot[1], Zeina Chakhtoura[1], Zahir Amoura[1], Olivier Aumaitre[2], Jean-Emmanuel Kahn[3], Du Boutin[1], Pierre Duhaut[4], Dominique Farge[5], Camille Francès[1], Lionel Galicier[6], Gaëlle Guettrot-Imbert[2], Jean-Robert Harlé[7], Olivier Lambotte[8], Véronique Le Guern[9], Jean-Charles Piette[1], Jacques Pourrat[7], Karim Sacre[10], Damien Sene[11], Salim Trad[12], Elisabeth Vidal[13], Lamiae Grimaldi[14], Christiane Coussieu[1], Nathalie Costedoat-Chalumeau[1] and PLUS[15]. [1]Groupe Hospitalier Pitié-Salpétrière, Paris, France, [2]Centre Hospitalier de Clermont-Ferrand, Clermont-Ferrand, France, [3]Internal Medicine, Foch Hospital, Suresnes, France, [4]CHU Nord, Amiens, France, [5]EBMT, Paris, France, [6]Hopital Saint Louis, Paris, France, [7]CHU Toulouse, Toulouse, France, [8]Hopital Kremlin Bicêtre, Kremlin Bicêtre, France, [9]Cochin Hospital, Paris, France, [10]Bichat Hospital, University Paris-7, APHP, Paris, France, [11]Hopital Lariboisière, Paris, France, [12]Hopital Ambroise Paré, Paris, France, [13]Hopital de Limoges, Limoges, France, [14]Société Laser, Paris, France, [15]Paris, France

Background/Purpose: Cyclophosphamide (CYC), a drug commonly used in systemic lupus erythematosus (SLE), is associated with a risk of ovarian failure resulting in infertility. In the general population, anti-Müllerian hormone (AMH) level is correlated with ovarian reserve in adult women. We compared AMH serum levels in SLE patients with and without previous cyclophosphamide treatment (exposed and unexposed group). For the first time, we analyzed their subsequent probability of pregnancy.

Methods: This ancillary study was done on serum bank collected during the PLUS study between 07/2007 and 11/2009 (ClinicalTrials.gov: NCT00413361). SLE women included in the PLUS study, below 40 years and who had been exposed to CYC were compared to SLE patients unexposed to CYC and matched for age at 6 months. AMH concentration was determined by Elisa using Immunotech kit (Beckman-Coulter). All patients were contacted by phone in May 2012, and provided information regarding their pregnancies following the date of sample.

Results: 112 patients (56 exposed and 56 not exposed patients) were included. Mean age was 31.6 ± 5.8 years.

The mean AMH serum level was 1.21 ± 1.01 ng/ml. 82% of the patients had AMH < 2 ng/ml and 50 % had AMH ≤1 ng/ml. The mean AMH serum level was significantly lower in patients exposed to CYC than in unexposed (1.02 ± 0.97 vs 1.41 ± 1.01 ng/ml, p = 0.03) and in patients older than 30 years-old (1.02 ± 0.97 versus 1.43 ± 1.02 ng/ml, p = 0.02).

Mean follow-up (interval between sample and phone interview) was 3.9 ± 0.6 years. During this follow-up, 36 of the 112 patients willed to become pregnant, and 30 succeed (83.3%). In univariate analysis, the risk of failure was associated with exposure to CYC (5 failure in 15 versus 1 failure in 21, p=0.023), older age (35.5 ± 4.8 years old at sample in failure versus 30 ± 4.3 years old in success, p = 0.024) and lower AMH serum level (0.64 ± 0.68 ng/ml in failure versus 1.6 ± 1.15 ng/ml in success, p=0.052).

Interestingly, pregnancy occurred in 6 out of 10 women who had very low AMH serum level (≤ 0.05 ng/ml), and in 10 out of 14 who had AMH serum level ≤ 1 ng/ml.

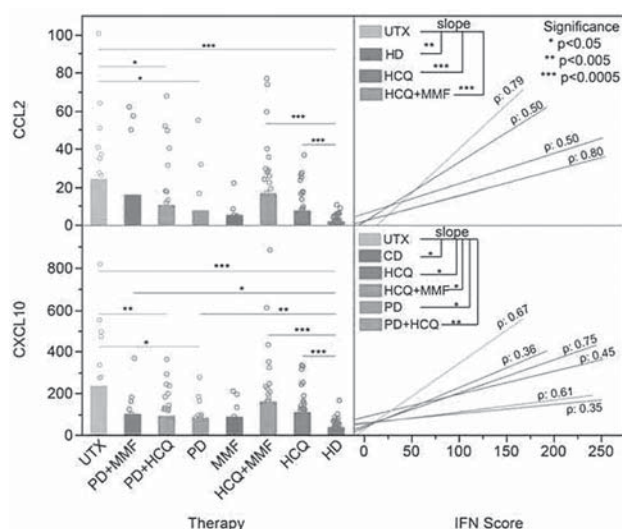
Conclusion: As previously reported, we confirm that the AMH level is low in many SLE patients, and that this level decreases significantly with age and with exposition to CYC. However, and despite this, we show for the first time that the risk of failure to become pregnant was low with pregnancy obtained in 83.3% of the patients who were willing to become pregnant. Successes were observed even in the patients with the lowest level of AMH. Preliminary results show that failure was associated with older age and CYC exposition. Additional analyses (multivariate analyses) are ongoing.

642

Effects of Treatment On the Expression of CCL2 and CXCL10 in Systemic Lupus Erythematosus Patients. Paul R. Dominguez-Gutierrez, Angela Ceribelli, Minoru Satoh, Eric S. Sobel, Westley H. Reeves and Edward K.L. Chan. University of Florida, Gainesville, FL

Background/Purpose: Several candidate biomarkers for Systemic Lupus Erythematosus (SLE) have been reported including STAT1, ADAR, CCL2, CXCL10, and miR-146a. This study examines the effects of treatment on their levels.

Methods: Leukocytes were collected from 103 SLE patients (59 had 2 or more visits) fulfilling ACR criteria and 65 healthy donors (HD). Gene expression of type I- interferon (I-IFN) signature genes (ISGs) and chemokines was analyzed by Taqman qPCR and determined by $\Delta\Delta C_T$ method. IFN score was calculated from Mx1, OAS1, and Ly6e. Biomarkers expression, multiple comparisons of therapies, linear correlations, and slope comparisons were analysed by Wilcoxon/Kruskal-Wallis Test, Steel method with control, Spearman Rho constant (ρ), and ANCOVA respectively.

Results: STAT1, ADAR, CCL2, and CXCL10, but not miR-146a, were significantly elevated (p< 0.0001) in SLE patients. STAT1, ADAR, CCL2, and CXCL10 showed significant correlations (p<0.003) to IFN score in both HD and SLE. Next, therapies were analyzed for significant effects on the biomarkers. The effects of interest would be those that reduce the biomarkers levels below untreated (UTX) SLE and that are not significantly elevated above HD. As a further measurement, the slopes of biomarkers that significantly correlated to IFN score were compared to determine if the therapy was capable of reducing (directly or indirectly) the biomarkers response to I-IFN. A lack of correlation and/or decreased slope may indicate disruption of the relationship between biomarkers and I-IFN by the therapy. Alone or in combination, prednisone (PD), hydroxychloroquine (HCQ), and mycophenolate mofetil (MMF) did not have significant effects on IFN score, STAT1, or miR-146a. Both CCL2 and CXCL10 were affected by the therapy (see figure). CCL2 was significantly higher (p<0.0009) in UTX SLE and in HCQ- and HCQ+MMF-treated SLE and CXCL10 was significantly higher (p<0.009) in UTX SLE, SLE treated with HCQ, HCQ+MMF, PD, and PD+MMF compared to HD. CCL2 and CXCL10 maintained a significant correlation (p<0.009; ρ> 0.35) with IFN score in UTX SLE, HCQ, and HCQ+MMF SLE. Furthermore, comparing CCL2 and CXCL10 vs IFN score, UTX SLE patients display a significantly higher slope (p<0.009) than HD, HCQ, and HCQ+MMF. CCL2 in HCQ, PD-, and PD+HCQ- treated SLE was significantly lower (p<0.038) than UTX SLE, nor significantly correlated with IFN score, except for HCQ. But only PD and PD+HCQ had significantly lower CXCL10 than UTX SLE. When comparing CXCL10 vs IFN score, UTX SLE display a significantly higher (p<0.02) slope than PD-, PD+MMF-, and PD+HCQ-treated SLE patients.


Conclusion: CCL2 and CXCL10 levels were significantly lower for several treatments compared to UTX. Therapies appear to attenuate the response of CCL2 and CXCL10 to I-IFN. Overall, CCL2 and CXCL10 are candidate markers of response to treatment for SLE.

643

Clinical Characteristics for Future Development of Systemic Lupus Erythematosus in Korean Patients with Idiopathic Thrombocytopenic Purpura. Yeon-Ah Lee[1], Somi Kim[1], Ran Song[2] and Sang-Hoon Lee[2]. [1]Kyung Hee University, Seoul, South Korea, [2]Hospital at GANGDONG, Kyung Hee University, Seoul, South Korea

Background/Purpose: Systemic lupus erythematosus (SLE), a chronic inflammatory autoimmune disease capable of exhibiting virtually any clinical symptoms, occasionally presents itself with thrombocytopenic purpura as an initial manifestation. Some patients with initial diagnosis of idiopathic thrombocytopenic purpura (ITP) develop symptoms of SLE as time goes by. Our aim was to investigate the prevalence of SLE in patients with the initial diagnosis of ITP and recognize the salient characteristics of these patients, thereby identifying early diagnostic clues.

Methods: We retrospectively analyzed the clinical and laboratory features of 337 (203 females, 134 males) patients initially diagnosed with ITP between January 1993 and April 2012 at a single center, Kyung Hee University Hospital. At the time of diagnosis of ITP, patients with autoimmune diseases were excluded and ITP was classified into chronic, acute, and recurrent acute types. The following data were obtained for every patient: age at diagnosis, sex, presence of ANA and anti-platelet antibody, bone marrow findings, and bleeding manifestations. The patients were followed-up for development of symptoms indicative of SLE and clinical events including immune hemolytic anemia, splenectomy, infections and thrombosis.

Results: Fifteen of the 337 patients (4.5%) developed SLE; 14 were females while all 15 showed ANA positivity. The patients who eventually developed SLE were more likely to have chronic type ITP, higher ESR, and speckled type ANA, irrespective of its titer (p< 0.05, respectively). The mean incubation period turned out to have SLE was 33.3 months (range: 2–159). For these patients, the mean age at initial diagnosis of ITP was 26.6 years (range: 13–65), and the mean age at diagnosis of SLE was 29.4 years (range: 15–66). Splenectomy was performed in 4 patients, and 3 of them suffered from at least one event of infection. Six of the 15 ITP patients with later development of SLE had been diagnosed as having Evan's syndrome (ITP with immune hemolytic anemia). The most notable SLE manifestations were thrombotic complications such as deep vein thrombosis or cerebral infarction (40%), and accordingly, high positivity of anti-phospholipid antibody (6/13, 46.2%). Contrary to previous reports, renal involvement appeared to be quite frequent (7/15, 46.6%).

Conclusion: SLE was developed in 4.5% of patients with initial diagnosis of ITP during follow-up. ITP patients with later development of SLE are associated with adverse clinical course, therefore early recognition and accurate interventions are imperative. The presence of speckled type ANA,

elevated ESR or immune hemolytic anemia in ITP patients warrant careful monitoring, as they are prone to develop other manifestations of SLE or thrombotic complications. With increased clinical attention, unnecessary invasive procedures, such as splenectomy, can be avoided and timely initiation of disease-specific treatment possible.

Pulmonary Hypertension in Systemic Lupus Erythematosus: A 6-Year Follow-up Study Cohort. Claudia Hübbe-Tena, Selma Gallegos-Nava, Rafael Bojalil and Luis M. Amezcua-Guerra. Instituto Nacional de Cardiología Ignacio Chávez, Mexico City, Mexico

Background/Purpose: Systemic lupus erythematosus (SLE) may present hemodynamic alterations including pulmonary hypertension (PH). Echocardiography (ECHO) is a noninvasive imaging technique useful to classify pulmonary hypertension (PH) as improbable (sPAP ≤36 mmHg), possible (37–50 mmHg), or probable (>50 mmHg).

Methods: Study cohort with 6-year follow-up including 139 SLE patients. At baseline, demographics, organ involvement, disease activity (SLEDAI-2K), cumulated organ damage (SLICC/ACR), and laboratory analyses including antibody profile were obtained. Serum samples were stored in standard conditions. Clinical follow-up was performed 3 months. SLE patients who had an ECHO for any reason by the time of recruitment (±6 months) were included. From stored sera, levels of endothelin 1 (ET1), monocyte chemotactic protein 1 (MCP1), and interferon gamma (IFNg) were measured by ELISA. Discrete variables are described as percentages and continuous variables as medians (interquartile range). Analyses were performed by either chi-square test for trends or Kruskal-Wallis with Dunn's post-test. Spearman's rank correlation coefficient (r) was used to assess associations. Survival was assessed by the Kaplan-Meier method with log-rank test for trends.

Results: 55 SLE patients were included. Patients were classified in 3 groups by ECHO: improbable PH (n=26, 96% female, age 34.5, 24–46 years); possible (n=16, 81% female, age 49, 38–53 years); probable (n=13, 100% female, age 41, 38–56 years). No differences in demographic or serologic features between groups, whereas organ damage was higher in patients with PH (SLICC/ACR index of 1 (1–2), 3 (1.7–4), and 3 (2–6), respectively; P=0.0009). Active arthritis was present in 12%, 13%, and 38% (P=0.05); history of pulmonary thromboembolism in 8%, 13%, and 46% (P=0.005). Serum levels of ET1, MCP1 and IFNg were similar between groups. The sPAP showed a positive correlation with age (ρ 0.29), disease duration (ρ 0.32), serum creatinine (ρ 0.26), SLEDAI-2K (ρ 0.26), SLICC/ACR (ρ 0.55), left atrium diameter (ρ 0.45), interventricular septum thickness (ρ 0.33), and right ventricular diastolic diameter (ρ 0.71). An inverse correlation with C3 (ρ −0.25) and CH50% (ρ −0.25) was found. Main causes of PH (sPAP >37) were: connective tissue disease (32%), intrinsic cardiac disease (26%), pulmonary thromboembolism (26%), and pulmonary disease (16%). Rates of survival in the first year were: improbable PH 92%, possible PH 94% and probable PH 90%. After three years, these were 92%, 89% and 77%, respectively. After six years 88%, 87% and 68%, respectively.

Conclusion: In SLE, PH (sPAP >50 mmHg) is associated with decreased survival in the medium term. Also, it is related to cumulated organ damage and history of pulmonary thromboembolism. Validated biomarkers in idiopathic PH such as ET1, MCP1 and INFg as well as SLE- and scleroderma-related autoantibodies are not useful to distinguish PH in patients with SLE.

Altered Soluble Inflammatory Mediators Mark Impending Systemic Lupus Erythematosus Disease Flare in European-American Lupus Patients Who Receive Influenza Vaccination. Melissa E. Munroe[1], Jourdan R. Anderson[1], Joan T. Merrill[1], Joel M. Guthridge[1], Virginia C. Roberts[1], Gillian M. Air[1], Linda F. Thompson[1] and Judith A. James[2]. [1]Oklahoma Medical Research Foundation, Oklahoma City, OK, [2]Oklahoma Medical Research Foundation; University of Oklahoma Health Sciences Center, Oklahoma City, OK

Background/Purpose: SLE is a multifaceted autoimmune disease denoted by immune dysregulation that contributes to increased morbidity and mortality in part due to infectious complications. Vaccination against common infections, such as influenza, is recommended for SLE patients to decrease infection risk. Using a unique resource of SLE patients participating in an influenza vaccination protocol with samples available before and at the time of clinically-defined disease flare, this study seeks to identify biomarkers of disease flare.

Methods: Over 6 flu seasons, 101 unique SLE patients and 101 healthy controls (HC) were enrolled in the SLE Influenza Vaccination Cohort. Plasma samples were obtained on the day of vaccination (BL) and at 6 and 12 weeks post-vaccination (FU). Demographics, detailed clinical information (disease activity, medication use), serum autoantibody profiles, and antibody response to influenza were collected at each visit. BL and FU samples from 29 European American (EA) SLE patients who exhibited SELENA-SLEDAI defined disease flare at 6 (n=14) or 12 (n=15) weeks post-vaccination were tested. Each SLE patient was matched by race/gender/age (+/− 5 years)/time of sample procurement/ANA status at BL to a unique SLE patient who did not exhibit disease flare (NF), as well as to a HC. Samples from 14 (n=7 each at 6 and 12 weeks at FU) of 29 SLE patients with flare were compared to samples from the same SLE patients from another year where disease flare did not occur (self nonflare, SNF). Plasma samples were tested for 52 soluble inflammatory mediators, including cytokines, chemokines, and soluble receptors using xMAP multiplex bead-based assay or sandwich ELISA (BLyS and APRIL).

Results: SLE patients who exhibited disease flare had significant ($p \le 0.01$) alterations in 23 soluble mediators at BL compared to unique NF/SNF patients and HC. Altered BL mediators were also seen at time of disease flare, usually with no significant change in analyte levels compared to BL. SLE patients who exhibited disease flare had significantly ($p \le 0.01$) higher levels of BL pro-inflammatory adaptive cytokines, including IL-12, IL-12, IFN-γ, IL-6, and IL-17 compared to NF/SNF SLE patients and HC. Of particular interest were increased TNFR family members at BL in flare SLE patients, including TNFRI, TNFRII, Fas, FasL, and CD40L. Regulatory cytokines, including IL-10 and TGF-β were significantly increased ($p \le 0.01$) at BL in SLE patients not exhibiting disease flare (NF/SNF) compared to flare SLE patients and HC. A number of analytes, including MIP-1α and BLyS, were significantly higher in SLE patients compared to HC, but no difference was seen between flare and NF/SNF in this cohort.

Conclusion: Shed TNF receptors and proinflammatory adaptive cytokines representing Th1, Th2 and Th17 pathways are elevated in lupus patients who flare within the next 6–12 weeks. These remain unaffected by influenza vaccine, suggesting their utility as resilient, predictive biomarkers of flare and that influenza vaccination itself does not further promote risk for flare.

Comparison of the Lupusqol and SF-36 Scores As Valid Measures of Change in Health Related Quality of Life. Zahi Touma, Murray B. Urowitz, Dominique Ibanez, Shahrzad Taghavi-Zadeh and D. D. Gladman. Toronto Western Hospital and University of Toronto, Toronto, ON

Background/Purpose: The LupusQoL questionnaire is a disease-specific instrument for adults with lupus while the short form-36 (SF-36) is a generic questionnaire.

We aimed to compare the LupusQoL and the SF-36 questionnaires to determine if they are comparable measures of change in patients with SLE on standard of care therapy.

Methods: We analyzed the results of SF-36 and LupusQoL questionnaires available from a group of lupus patients who were followed at the Lupus Clinic. Patients were studied if they had at least one follow-up visit within 6 month period while receiving standard of care therapy.

Each of the questionnaires, SF-36 and LupusQoL, includes 8 domains and its scores ranges from 0 (worst possible) to 100 (best possible) quality of life. The SF-36 subscales can be further summarized into 2 component scores: the physical component summary (PCS) and the mental component summary (MCS).

The mean change in the domains scores for both questionnaires was determined by subtracting the scores of the follow-up visits from the score of the baseline visit.

We determined the correlation (Pearson) of the change in scores of LupusQoL and the change in scores of SF-36. The correlation of the comparable domains of LupusQoL was determined with the corresponding domains of SF-36. For each of the non-comparable domains of the LupusQoL questionnaire the correlation was determined with PCS and MCS individually.

Results: 99 patients (91% F) had baseline and at least one follow-up visit available. 44% were Caucasian, 33% Black, 10% Asian and 12% others. For the 99 patients 251 observations were identified for which both SF-36 and LupusQoL questionnaires were available. Age at lupus diagnosis and lupus duration at first

visit were 27.2 ± 12.4 and 11.9 ± 7.7 years. The mean SLEDAI-2K on all visits was 7.49 ± 5.21.

The correlation of the change in scores of the comparable LupusQoL and SF-36 domains ranged from 0.38–0.65. The correlation between LupusQoL Pain and SF-36 Bodily Pain was 0.65, LupusQoL Physical Health and SF-36 Physical Functioning was 0.38, LupusQoL Emotional Health and SF-36 Mental Health was 0.56 and LupusQoL Fatigue and SF-36 Vitality was 0.48 (all p were significant). For the non-comparable domains the correlation of the LupusQoL domains with SF-36 MCS and PCS ranged from 0.02–0.33 (Table 1).

Table 1. Correlation of change in SF-36 and LupusQoL for comparable and non-comparable domains

	Lupus QoL domains	SF–36 domains	
Comparable domains	Pain	Bodily Pain	0.65 (<0.0001)
	Physical Health	Physical Functioning	0.38 (<0.0001)
	Emotional Health	Mental Health	0.56 (<0.0001)
	Fatigue	Vitality	0.48 (<0.0001)
Non–comparable domains	Body Image	PCS	0.09 (0,28)
		MCS	0.28 (0.0007)
	Planning	PCS	0.33 (<0.0001)
		MCS	0.29 (0.0004)
	Intimate Relationships	PCS	0.27 (0.01)
		MCS	0.02 (0.89)
	Burden to others	PCS	0.25 (0.002)
		MCS	0.29 (0.0004)

Conclusion: The correlation of the change in the scores of comparable domains of Lupus QoL and SF-36 ranged from moderate to large. The correlation of the change in the scores of non-comparable domains of Lupus QoL and SF-36 was insubstantial to small. Thus these questionnaires measure different aspects of quality of life and both questionnaires might be used together.

Adjusted Framingham Risk Factor Scoring for Systemic Lupus Erythematosus: Results from an Inception Cohort Followed for Eight Years. Murray B. Urowitz[1], Dominique Ibanez[1], D. D. Gladman[1], SLICC[2] and Systemic Lupus International Collaborating Clinics (SLICC)[2]. [1]Toronto Western Hospital and University of Toronto, Toronto, ON, [2]Toronto, ON

Background/Purpose: There is a high prevalence of premature atherosclerosis among patients with SLE, with a risk 7–9 times that of the general population. The traditional Framingham risk factor underestimates the risk for coronary artery disease (CAD) in patients with SLE. It has been suggested that a modified Framingham risk score (FRS) where each item is multiplied by 2 more accurately identifies patient at Moderate/High risk of CAD, and more accurately predicted subsequent CAD. The aim of this study was to determine whether the modified FRS (mFRS) more accurately reflected the prevalence of CAD(MI, angina, pacemaker) among patients in an inception cohort.

Methods: An inception cohort of SLE patients from 31 centres from 12 countries has been assembled according to a standardized protocol between 2000 and 2012 to study risk factors for atherosclerosis. Only patients with all variables necessary to calculate the FRS at enrolment and who did not have diabetes mellitus were included in this analysis. Patients are followed at yearly intervals according to a standard protocol which included demographics, disease characteristics and classic risk factors for CAD as well as CAD events. Diagnosis of an event was confirmed using standard clinical criteria, relevant laboratory data and imaging where appropriate Sensitivity and Specificity (95% CI) of FRS and MFRS were evaluated in their prediction of future CAD.

Results: At enrolment 853 patients had sufficient data to calculate FRS. Of these, 140 patients had 8 years of follow-up available. 85% female, 50% Caucasian, 11.4% Black, 20.7% Asian 16.4% Hispanic and 1.4% other. 13.6% were current smokers, 22.2% past smokers. Age at diagnosis was 34.2 yrs and disease duration at enrolment was 5.0 mos. BMI was 24.4, and 25.7% were obese. 35%, were hypertensive and 42% had hypercholesterolemia. The 140 patients did not differ from those not followed for 8 years in either demographic features, disease characteristic, atherosclerotic risk factors. Table shows the calculated classic FRS and mFRS for the 140 patients.

	Classic FRS		Modified FRS	
Risk Category	**Number**	**%**	**Number**	**%**
Very low risk	133	95	112	80
Low risk	2	1.4	6	4.3
Moderate risk	2	1.4	6	4.3
High risk	3	2.1	16	11.4
Moderate + High	**5**	**3.5**	**22**	**15.7**

Of the 140 patients 14 subsequently developed CAD, 8 of which are attributed to AS. The sensitivity of the FRS for CAD due to AS was 25.0 (3.2, 65.1) and specificity 97.7 (93.5, 99.5), whereas for the mFRS the sensitivity rose to 50.0 (15.7, 84.3) while the specificity decrease slightly to 86.4 (79.3, 91.7).

Conclusion: The mFRS, where each item is multiplied by 2, more accurately identifies patients at Moderate/High Risk of CAD. It provides higher sensitivity with little loss in specificity. Therefore the mFRS could be used to identify SLE patients for more intensive risk factor modification.

Atherosclerotic Vascular Events in a Multinational Inception Cohort of Systemic Lupus Erythematosus: Incidence Over a Ten Year Period. D. D. Gladman[1], Dominique Ibanez[1], Murray B. Urowitz[1] and SLICC[2]. [1]Toronto Western Hospital and University of Toronto, Toronto, ON, [2]Toronto, ON

Background/Purpose: A large multicentre multinational inception cohort was established to study risk factors for atherosclerosis (AS) in SLE. The purpose of this study was to determine the incidence of vascular events during a 10 year follow-up and their attribution to AS.

Methods: An inception cohort of SLE patients from 31 centres from 12 countries has been assembled according to a standardized protocol between 2000 and 2012 to study risk factors for atherosclerosis. Patients enter the cohort within 15 months of SLE diagnosis ($\geq$4 ACR criteria). Clinical and laboratory features of SLE and comorbidities are gathered in a standardized protocol at yearly intervals. Vascular events (VE) are described and attributed to SLE and AS on a specialized form. Events recorded include myocardial infarction (MI), angina, congestive heart failure (CHF), intermittent claudication (PVD), stroke, transient ischemic attack (TIA). Diagnosis of an event was confirmed using standard clinical criteria, relevant laboratory data and imaging where appropriate. Attribution to AS was made on the basis of lupus disease being inactive at the time of the event, and/or the presence of typical AS changes on imaging or pathology and/or evidence of AS elsewhere. The incidence of VE was calculated over the 10 years for all VE occurring after diagnosis, and then for atherosclerotic VE (AVE). Kaplan-Meier curves were used to estimate the cumulative incidence rates since SLE diagnosis

Results: Since 2000 1844 patients have been entered into the cohort (88.9%F, age at SLE 34.7y). Caucasian 49.2%, Black 16.5%, Asian 14.9%, Hispanic 15.3%, other 4.1%. Thus far there have been 157 VE in 115 patients after the diagnosis of SLE. These include: MI (14), angina (26), CHF (36), PVD (11), TIA (27), stroke (38), pacemaker insertion (5). 64 of the events were attributed to active lupus and 44 to other causes or missing. 49 events in 37 patients were attributed to AS including: MI (8), angina (19), CHF (6), PVD (6), TIA (5), pacemaker (3), stroke (2).

Table. Cumulative incidence of 1st vascular events since diagnosis of SLE

Years since SLE Dx	Number	VE N=115	AVE N=37
0	1844	0.2%	0.1%
1	1479	3.0%	0.7%
2	1305	4.0%	0.9%
3	1097	5.4%	1.4%
4	948	6.2%	1.9%
5	768	7.3%	2.4%
6	600	7.7%	2.5%
7	459	8.9%	2.9%
8	342	9.4%	3.2%
9	233	10.1%	3.9%
10	138	11.2%	4.4%

Conclusion: Over the follow-up of an inception cohort with SLE there were 157 vascular events of which 49 were attributable to AS. The incidence of AVE increased by 0.5% per year reaching a total of 4.4% at 10 years.

Increased Male-to-Female Ratio in Children Born to Women with Systemic Lupus Erythematosus. Evelyne Vinet[1], Sasha Bernatsky[2], Mohammed Kaouache[2], Emil P. Nashi[1], Christian A. Pineau[1], Ann E. Clarke[3], Robert W. Platt[4], Meggan C. Mackay[5] and Cynthia Aranow[6]. [1]McGill University Health Centre, Montreal, QC, [2]Research Institute of the McGill University Health Ctre, Montreal, QC, [3]MUHC, Montreal, QC, [4]McGill University, Montreal, QC, [5]The Feinstein Institute, Manhasset, NY, [6]Feinstein Institute for Medical Research, Manhasset, NY

Background/Purpose: Recent experimental evidence suggests that anti-DNA antibodies, cross-reacting with brainstem neuronal receptors, induce apoptosis and cause a marked preferential loss of female foetuses in SLE murine models. Observational studies assessing the sex of offspring born to women with SLE are scant and limited by their sample size. In a large population-based study, we aimed to determine the sex ratio of children born to women with SLE and to compare with children born to women without SLE.

Methods: We identified all women who had at least one hospitalization for a delivery (either for a stillbirth or live birth) after SLE diagnosis using Quebec's physician billing and hospitalization databases (from 01/01/1989 to 31/12/2009). Women were defined as SLE cases if they had any of the following: 1) at least one hospitalization with a diagnosis of SLE prior to the delivery, 2) a diagnosis of SLE recorded at the time of their hospitalization for delivery, or 3) at least 2 physician visits with a diagnosis of SLE, occurring 2 months to 2 years apart, prior to the delivery. We randomly selected a general population control group, composed of women matched at least 4:1 for age and year of delivery, who did not have a diagnosis of SLE prior to or at the time of delivery. We obtained information on sex for all births occurring in both groups of women, and calculated the respective male-to-female ratio. We performed a multivariate logistic regression, with the offspring's sex as the dependent variable, adjusting for the potential effect of preeclampsia (previously shown to increase the male-to-female ratio in the general population).

Results: 507 women with SLE had a total of 731 births after diagnosis, while 5862 matched control women had 8631 births. The prevalence of preeclampsia was 5.5% (95% CI 4.0, 7.6) in children born to women with SLE and 2.2% (95% CI 1.9, 2.5) in children born to control women. The unadjusted male-to-female ratio was increased in children born to women with SLE (1.26, 95% CI 1.09,1.46) compared with controls (1.06, 95% CI 1.02,1.11). In multivariate analysis adjusting for the effect of preeclampsia, mothers with SLE had substantially increased odds of having male offspring than mothers without SLE (OR 1.19, 95% CI 1.02, 1.38).

Conclusion: Compared to children from the general population, there is a substantial increase in the male-to-female ratio in children born to women with SLE. These results should prompt further research on the male predominance in children born to women with SLE.

Clinical Variables Associated with Thrombosis At Systemic Lupus Erythematosus Diagnosis. Differences Between Patients with Positive/Negative Lupus Anticoagulant. Andrea Hinojosa-Azaola[1], Alba Cicero-Casarrubias[1], Mario César Ocampo-Torres[1], Juanita Romero-Díaz[1] and Jorge Sánchez-Guerrero[2]. [1]Instituto Nacional de Ciencias Médicas y Nutrición Salvador Zubirán, Mexico City, Mexico, [2]Mount Sinai Hospital and University Health Network, Toronto Canada

Background/Purpose: Thrombosis in patients with Systemic Lupus Erythematosus (SLE) is a major cause of morbidity, it occurs in 9–37%, at younger age, and it represents 27% of mortality. Lupus anticoagulant (LA) is strongly associated with thrombosis; however, most events occur in patients who are negative for LA. The aim of our study was to determine the baseline characteristics associated with thrombosis in an inception cohort of SLE patients and in the subset of patients without LA.

Methods: A longitudinal inception cohort of 223 SLE patients (less than 12 months of accrual ≥4 criteria), predominantly female (90%), mean age 27.2 years at diagnosis, was studied. Baseline evaluation included medical history, physical exam, clinical variables, SLE characteristics, SLE activity (SLEDAI-2K), modified damage index (SLICC/DI), autoantibodies, laboratory tests, homocystein and high-sensitivity C-reactive protein (hs-CRP). Thrombotic events were diagnosed on clinical manifestations and confirmed by appropriate studies. Statistical analyses: Descriptive statistics, Student T-test, Mann-Whitney U-test, Chi-square, Fisher exact test, Logistic Regression. P <0.05.

Results: During 1269 patient-years of follow-up, thrombosis occurred in 35 patients (16%), incidence rate 25.6 per 1000 patient-years. Most of the events (57%) occurred at onset or during the first year of diagnosis of SLE. At baseline, patients with thrombosis had lower body mass index (BMI) (p=0.03), smoking (p=0.02), vascular insufficiency (p=0.05), immobilization (p<0.0001), recent surgery (p=0.004), anti-RNP (p=0.04), lupus anticoagulant (LA) (p=0.006), and higher modified SLICC/DI (p=0.03). Since only 8/35 thromboses were associated to LA, we identified those variables associated with thromboses in patients with LA negative: smoking (p=0.004), vascular insufficiency (p=0.03), immobilization (p<0.0001), serositis (p=0.04), and hs-CRP (p=0.02). In the multivariate analysis, BMI (OR 0.79 95% CI 0.65–0.95, p=0.016), anti-RNP (OR 1.02 95%CI 1.00–1.03, p=0.003) and LA+ (OR 8.05 95% CI 1.75–36.88, p=0.007) were independent risk factors for thrombosis in the general cohort. After excluding patients with LA, smoking (OR 6.1, 95% CI 1.7–21.8 p=0.006), vascular insufficiency (OR 28.7 95% CI 2.4–342.9, p=0.008), and immobilization (OR 31.3 95%CI 2.6–381.4, p=0.007) were independent risk factors for thrombosis.

Conclusion: Patients with SLE are at an increased risk of thrombosis, particularly during the first year of diagnosis. Although LA is a strong risk factor, most thrombotic events occur in patients without LA; in this subset, smoking, immobilization and vascular insufficiency are the most important. All of them are potentially modifiable.

Suicidal Ideation in Patients with Systemic Lupus Erythematosus: Incidence and Relationship with Anxiety/Depression Score, Disease Activity and Organ Damage. Chi Chiu Mok[1], Kelly Chan[1] and Paul Yip[2]. [1]Tuen Mun Hospital, Hong Kong, Hong Kong, [2]University of Hong Kong, Hong Kong, Hong Kong

Background/Purpose: To study the incidence of suicidal ideation in patients with SLE and its relationship with anxiety/depression score, disease activity and organ damage

Methods: Consecutive patients who fulfilled the ACR criteria for SLE were recruited for a questionnaire study on suicidal ideation, which was assessed by (1) 3 standard questions on suicidal thoughts and suicidal plans in the past 1 month; and (2) the validated Chinese version of the Beck Scale for Suicidal Ideation (BSSI) for suicidal intention: 19 questions (each scores 0–2, final score is the summation of the scores of the 19 questions (0–38 points; higher score more suicidal intention). History of suicidal attempts and self assessment of suicidal tendency was also included in this tool. Anxiety and depressive symptoms were assessed simultaneously by the Hospital Anxiety and Depression (HAD) scale (0–21 points for each of depression and anxiety). Disease activity of SLE was assessed by SLEDAI and physicians' global assessment (PGA), whereas organ damage since SLE diagnosis was assessed by the ACR SLICC damage index (SDI). The BSSI score was correlated with the demographic and clinical features of the participants, HAD, SLEDAI and SDI score. Linear regression models were established to study the independent factors associated with suicidal intention.

Results: 319 SLE patients were studied (300 women; mean age at SLE onset was 30.2±12.2 years; disease duration 9.0±7.0 years). 43 (13%) patients had clinically active SLE (SLEDAI >=5). 106 (33%) patients had organ damage (SDI >=1). 29 (9%) patients had suicidal thoughts and 4 (1%) patients had suicidal thoughts together with solid plans within 1 month of study. 39 (12%) patients had previous suicidal thoughts/attempts whereas 18 (6%) had documented suicidal attempts. The mean BSSI score was 1.37±3.62 points (0–24). Compared to those without suicidal thoughts within 1 month of study, patients with suicidal thoughts had significantly higher BSSI scores (6.0±6.1 vs 0.89±2.9 points; p<0.001), HAD-anxiety (13.1±5.2 vs 5.70±4.2; p<0.001) and HAD-depression (12.4±4.3 vs 4.50±3.9; p<0.001) scores. Linear regression analysis

revealed that the total BSSI scores (suicidal intention) correlated significantly with HAD-depression (Beta 0.52; p<0.001), HAD-anxiety (Beta 0.47; p<0.001), age (Beta 0.15; p=0.009), male sex (Beta −0.13; p=0.02), previous suicidal attempts (Beta 0.17; p=0.003) and SDI score (Beta 0.21; p<0.001) but not with SLEDAI (Beta 0.05; p=0.44). In a multivariate regression model, only HAD-depression score (Beta 0.30; p<0.001), HAD-anxiety score (Beta 0.28; p<0.001), age (Beta 0.12; p=0.02) and SDI damage score (Beta 0.11; p=0.03) correlated positively and significantly with the total BSSI score.

Conclusion: In this cross-sectional study, suicidal ideation in the preceding month occurred in 9% of patients with SLE, whereas previous suicidal thoughts/attempts were present in 12% of participants. The suicidal intention was stronger in older patients, men, and those with more organ damage, anxiety or depressive symptoms. Suicidal intention did not correlate with disease activity. Further study on the contribution of socioeconomic factors to suicidal ideation in SLE patients is in progress.

Serum Rituximab Levels and Efficiency of B-Cell Depletion: Differences Between Patients with Systemic Lupus Erythematosus and Rheumatoid Arthritis. Venkat Reddy[1], Sara Croca[1], Delia Gerona[2], Inmaculada De La Torre Ortega[2], David A. Isenberg[1], Maria Leandro[1] and Geraldine Cambridge[1]. [1]University College London, London, United Kingdom, [2]Gregorio Marañón Hospital, Madrid, Spain

Background/Purpose: Variability in rituximab-induced B-cell depletion (BCD) occurs in a significant number of patients with Systemic Lupus Erythematosus (SLE) and to a lesser extent in patients with Rheumatoid Arthritis (RA). A failure to adequately deplete (CD19+ B cells <5/μl) probably underlies poor clinical response in many patients with SLE. In this prospective study, we investigated whether the levels of rituximab influence the degree of peripheral BCD.

To determine the serum levels of rituximab at 1 and 3 months post-rituximab in SLE and RA in conjunction with the measurement of absolute number of peripheral CD19+ B cells.

Methods: A total of 16 patients with SLE were included and 23 with RA. All were treated with rituximab (2 × 1g doses given 2 week apart). Rituximab levels at 1 and 3 months post treatment was measured with a capture ELISA using sera diluted at a concentration of 1/40,000. CD19 counts were determined by flow cytometry. Adequate depletion was defined as CD19+ count below 5cells/μl. Data were compared using the Mann Whitney U test for non-parametric data and the Spearman Rank for correlation.

Results: At 1 month, 6 of 15 (40%) patients with SLE and 6 of 23 (26%) patients with RA had CD19 counts >5 cells/μl. The median CD19 count in these patients was 0.02cells/μl and 0.008cells/μl for SLE and RA, respectively. The levels of rituximab were significantly lower in SLE when compared with RA, at both 1 and 3 months after rituximab treatment. The median rituximab level at 1 month for SLE was 43.07μg/ml (range 0–777) and for RA, 391.9μg/ml (range 1.3–2500) (p=0.0008). The median rituximab level at 3 months were <10μg/ml (range 0–54) for SLE and 2.6μg/ml (range 0–1153) for RA (p=0.008). Amongst patients who had depleted well, rituximab levels were significantly lower in patients with SLE when compared with patients with RA at 1 month (p=0.003) and also at 3 months (p=0.008). No such difference was found in patients who did not deplete well. Six patients with SLE had lupus nephritis (LN) and the presence of LN did not influence the levels of rituximab or the degree of BCD, in this small group of patients. The levels of rituximab correlated inversely with the absolute numbers of CD19+ B cells in patients with RA at 1 month (r^2 =0.69) and in patients with SLE at 3 months (r^2=0.51).

Conclusion: Our data indicated that patients with SLE had markedly (>9 fold at 1 month) lower serum levels than RA patients at both 1 and 3 months. A higher proportion of patients with SLE depleted less well with significantly higher residual CD19+ B cells due to factors involved in clearance of rituximab such as impaired recycling through FcRn, internalisation and destruction by target B cells.

Longitudinal Analysis of Plasma Factors and Disease Activity Identifies Von Willebrand Factor As A Biomarker of LUPUS FLARE. Mikhail Olferiev[1], Kyriakos A. Kirou[2], Elena Gkrouzman[3], Dorthe Lundsgaard[4], Klaus S. Frederiksen[5], Jan Fleckner[5] and Mary K. Crow[2]. [1]Mary Kirkland Center for Lupus Research, Hospital for Special Surgery, New York, NY, [2]Hospital for Special Surgery, New York, NY, [3]Mary Kirkland Center for Lupus Research, Hospital for Special Surgery, New York, New York, NY, [4]Novo Nordisk A/S, Måløv, Denmark, [5]NovoNordisk, Copenhagen, Denmark

Background/Purpose: Lupus, a chronic autoimmune disease, is characterized by a variable clinical course, with periods of active disease termed flares. The severity of flares can be measured using clinical scores [SELENA-SLEDAI (SS); BILAG], but those scores do not define or suggest underlying pathophysiologic mechanisms of flare. Identification of a biomarker associated with clinical lupus flare would be useful for disease management, for assessment of response to therapeutic intervention in practice or clinical trials, and might suggest cellular or molecular targets for future therapies. To identify biomarkers that reflect lupus flare, we assessed longitudinal clinical and proteomic data from SLE patients.

Methods: One hundred sixty-nine plasma samples were collected longitudinally (up to 3 years) from 23 SLE patients and 5 healthy donors (HD), and SS and BILAG scores recorded. All SLE patients fulfilled ACR criteria for the disease. A panel of pro-inflammatory cytokines was evaluated using Multi-Analyte Profiling (MAP) technology (Rules-Based Medicine, Austin, TX). Longitudinal data analysis was performed using R (R Development Core Team) and the R packages lme4 and languageR. Data were analyzed using Linear Mixed Effects models (LME). A second validation set of 15 patients (175 visits) was used to confirm changes in the level of selected mediators in relation to clinical flare.

Results: Thirteen plasma factors were identified as significantly increased in SLE patients compared with HD, and 14 plasma factors were significantly deregulated during flaring compared with non-flaring visits, based on LME. However, in paired t-test analysis only von Willebrand factor (vWF) was significantly increased during severe flares compared to both first non-flaring visit before (p<0.02) and first non-flaring visit after (p<0.01) the identified flare. The association of changes in vWF with lupus flare was confirmed in the validation cohort.

Conclusion: vWF is produced by endothelial cells and is required for normal hemostasis and vascular function. Levels of circulating vWF are increased following endothelial cell damage and during acute phase responses. The significantly increased level of vWF during lupus flare in the majority of SLE patients highlights the role of endothelial injury as a major pathogenic mechanism in SLE and identifies vWF as an informative biomarker for patient management and clinical studies.

Incidence Studies of Systemic Lupus Erythematosus in Southern Sweden. Have the Tides Turned? Ragnar Ingvarsson[1], Andreas Jönsen[2], Ola Nived[3], Gunnar Sturfelt[1] and Anders Bengtsson[4]. [1]Department of Clinical Sciences Lund, Section of Rheumatology, Lund, Sweden, [2]Section of Rheumatology, Lund, Sweden, [3]University Hospital - Lund, Lund, Sweden, [4]University Hospital Lund, Lund, Sweden

Background/Purpose: The main objective was to study the incidence of Systemic Lupus Erythematosus (SLE) within a defined area in Southern Sweden over a period of more than 25 years. By prospectively identifying all new cases within this region using validated retrieval methods. A secondary objective was to investigate whether the phenotypic expression of SLE has changed during the study period.

Methods: The health care district of Lund-Orup had a mean population during 1981–2006 of 176.460 persons (>15 yrs of age). SLE cases were identified from multiple sources including diagnosis registries and from central laboratory databases using a previously validated "capture-recapture" methodology (Jonsson et al). The patients were observed prospectively within a structured follow-up program. Diagnosis of SLE was based on the presence of two clinical manifestations typical for SLE together with immunological

abnormalities. Other causes for these manifestations were excluded and the diagnosis was continuously re-evaluated during the follow-up.

Results: One-hundred seventy-five new cases were diagnosed with SLE from 1981–2006. There were 148 women and 27 male patients that received the diagnosis of SLE, with a mean age of diagnosis at 44.3 years. In the first half of the study, from 1981–1993, the incidence of SLE was 5.0/100.000 inhabitants compared to the second half of the study, 1994–2006, where it had decreased to an annual incidence of 2.8/100.000 inhabitants (p≤0.001). During the first half of the study period the highest incidence was among females between the ages 45–54 were it was 15.1/100.000 inhabitants whereas in the second half of the study the incidence was reduced to 3.8/100.000 in this age group (p≤0.001). Between the years 1994–2006 the highest age and sex specific incidence was amongst women between 25–34 years of age (6.6/100.000 inhabitants), unchanged from the prior period. During the whole period the age and sex specific was highest among women between the ages 45–54 (8.9/100.000 inhabitants). The point prevalence of SLE on 31st of December 1993 was 55/100.000 inhabitants compared to the 31th of December 2006 where it was 66/100.000 inhabitants. 163 of the 175 patients fulfilled 4 or more ACR classification criteria SLE giving the criteria a sensitivity of 93 % for diagnosing SLE in our cohort. The disease phenotype did not vary over time.

Conclusion: The incidence rate of SLE in Southern Sweden remains stable in younger females over a 26 year period from 1981–2006. However, the incidence was reduced significantly in the older patients groups in the later period of the study.

Non-White Race, Younger Age, and Use of Primary and Gynecologic Care Are Associated with Higher Rates of Cervical Cancer Screening in Systemic Lupus Erythematosus Patients At a Public Hospital. Jennifer Stichman[1], Angela Keniston[1], Joann Zell[2], Jinoos Yazdany[3], Itziar Quinzanos[1] and Joel M. Hirsh[1]. [1]Denver Health Med Ctr, Denver, CO, [2]National Jewish Health, Denver, CO, [3]University of California San Francisco, San Francisco, CA

Background/Purpose: Patients with Systemic Lupus Erythematosus (SLE) are at increased risk of cervical dysplasia and persistent Human Papilloma Virus (HPV) infection. There are few prior studies looking at cervical cancer screening in SLE, and these have relied upon self-report to document if screening was done appropriately. These studies have also not included uninsured and non-English speaking subjects. We examined performance of cervical cancer screening in patients with SLE at Denver Health (DH) as well as sociodemographic and other predictors of screening.

Methods: Using data from the DH electronic health record (EHR), we identified rheumatology clinic patients with initial encounters between July 2006 and August 2011 who had SLE, were female, and were between the ages of 21–50 years. We queried data from the EHR including age, race/ethnicity, primary language, use of interpreter services and primary payer. We also queried the EHR regarding the rates of cervical cancer screening in this cohort and at DH overall. Manual record review was conducted to review medication use and possible history of hysterectomy. A chi-square test was used to test differences in the proportion of SLE patients with cervical cancer screening documented within one year pre or post index encounter and within three years pre or post index encounter by patient demographics. We looked at screening rates at both 1 and 3 year intervals depending on age, as 2003 American College of Obstetrics and Gynecology guidelines had recommended annual screening in women younger than 30.

Results: One hundred twenty eight patients with SLE were identified. Six of these patients were status post hysterectomy unrelated to cervical cancer. Data was analyzed for the remaining 122 patients. Eighty percent were non-White and half did not have health insurance. Overall, rates of cervical cancer screening within 3 years were 75% in DH primary care clinics and 66% in SLE patients. In our SLE cohort, only 60% of women age 30–50 underwent cervical cancer screening in 3 years, in contrast to 81% of patients age 21–29 (p = 0.0235). In unadjusted analyses, White women were less likely to have screening in 3 years compared to non-White women in the 21–29 age group (p=0.0147). Women in the 21–29 age group with a history of gynecologic care were had a higher likelihood of screening at 3 years (p=0.0378). In the 30–50 age group, having seen a primary care physician was associated with a higher likelihood of screening at 1 and 3 years (p=0.0013 and 0.0040 respectively) and history of gynecology care was associated with increased likelihood of having a screening test at 1 and 3 years

(p=0.0013 and 0.0003 respectively). Patients receiving immunosuppressive medications were no more likely to receive cervical cancer screening than other SLE patients.

Conclusion: We identified a gap in care in large subsets of the SLE patients at DH. White women age 21–29 and patients age 30–50 were less likely than the general primary care DH population to have appropriate cervical cancer screening. Rheumatologists need to help connect female SLE patients of all races and ethnicities with primary or gynecology care services as patients who limit physician visits to rheumatology are at risk of not being screened for cervical cancer.

Effects of Nelfinavir On Anti-dsDNA Antibody Binding and Pro-Inflammatory Cytokine Gene Expression. Maria Espinosa[1], Julisa Patel[2], Meggan Mackay[3], Cynthia Aranow[4] and Betty Diamond[5]. [1]Cohen Children's Hospital-North Shore LIJ, New Hyde Park, NY, [2]Cohen Children's Hospital, New Hyde Park, NY, [3]The Feinstein Institute for Medical Research, Manhasset, NY, [4]Feinstein Institute for Medical Research, Manhasset, NY, [5]Feinstein Institute Med Rsch, Manhasset, NY

Background/Purpose: The hallmark of SLE is pathogenic autoantibody (aab) production that is closely associated with organ damage. Anti-dsDNA aab are specific to SLE; their deleterious effects are mediated by direct binding of aab or anti-dsDNA containing immune complexes to tissue antigen and TLRs leading to stimulation of inflammatory pathways. Current therapies include immunosuppressive/cytotoxic drugs with significant potential toxicities. Protease inhibitors (PIs) such as nelfinavir, in addition to direct anti-viral properties, are safe and well-tolerated and have been shown to have immunomodulatory effects. Previous studies have shown that nelfinavir inhibits murine anti-dsDNA aab binding by ELISA. We hypothesized that nelfinavir would similarly inhibit binding of human anti-dsDNA antibodies from SLE subjects, decrease pro-inflammatory cytokine gene expression in stimulated peripheral blood mononuclear cells (PBMC) and inhibit anti-DNA aab binding to mouse glomeruli *ex-vivo*.

Methods: Sera from 4 SLE subjects with elevated serum anti-DNA aab and increased disease activity (SLEDAI of ≥4) were incubated with increasing concentrations of nelfinavir (1 μM, 10 μM, and 100 μM) and added to the ELISA plate followed by spectrophotometric analysis. Healthy PBMC were stimulated with lipopolysaccharide (LPS)(5μg/mL) or high-mobility group box 1 protein (HMGB1)(10μg/mL) and incubated with nelfinavir (1 μM, 10 μM, and 100 μM). Cytokine gene expression (IL-6, IL-12α, TNFα, INFα, IL-1β) and IFN inducible gene expression (IFIT1, MX1, IFI44, and OAS1) were measured in the PBMCs by PCR. The glomerular binding assay was used to measure inhibitory effects of nelfinavir on murine anti-DNA aab binding to glomerular antigen(s) with and without DNase treatment.

Results: Nelfinavir at 1, 10 and 100 μM concentrations resulted in 59%, 60% and 56% inhibition of DNA binding by ELISA respectively (p=0.01, p=0.02, p=0.01). Increasing concentrations of nelfinavir incubated with LPS-stimulated PBMC resulted in decreased gene expression of IL-12α (99%, 99%, and 99%), TNFα (90%, 90%, and 90%), IFNα (99%, 99%, and 99%) and IL1β (64%, 51%, and 24%). IL6 gene expression was decreased with 1 and 10μM concentrations but increased with 100 μM concentration. HMGB1 stimulated PBMC demonstrated increased expression of TNFα, IL12α, IFNα, IL1β and the IFN inducible genes IFIT 1, MX1, IFI44 and OAS1 that was inhibited by nelfinavir with no clear dose response. IL6 gene expression was not increased by HMGB1 although addition of nelfinavir inhibited the expressed levels. The 100 μM concentration of nelfinavir abrogated glomerular binding of murine anti-DNA aab to glomerular antigens.

Conclusion: Nelfinavir inhibits human anti-dsDNA binding to dsDNA and murine anti-DNA aab binding to glomerular antigen. Additionally, nelfinavir reduces expression of pro-inflammatory cytokines and IFN inducible genes in LPS and HMGB-1 stimulated PBMC suggesting that the mechanism for inhibition may be interference with the antigen binding site of the anti-dsDNA aab. We plan to use these measures as biologic outcome measures for a phase IIa clinical trial exploring the *in-vivo* inhibitory effects of nelfinavir in SLE patients.

Serial Screening Shows That 28% of Systemic Lupus Erythematosus Adult Patients Carry an Underlying Primary Immunodeficiency. Sandro F. Perazzio[1], Reinaldo Salomao[1], Neusa P. Silva[2], Magda Carneiro-Sampaio[3] and Luis Eduardo C. Andrade[4]. [1]Federal University of Sao Paulo, Sao Paulo, Brazil, [2]Escola Paulista de Medicina - Universidade Federal de São Paulo, Sao Paulo, Brazil, [3]Instituto da Criança da Faculdade de Medicina da Universidade de São Paulo (FMUSP), Sao Paulo, Brazil, [4]Universidade Federal de São Paulo, Sao Paulo, Brazil

Background/Purpose: Systemic Lupus Erythematosus (SLE) is known to be associated with deficiency of C1q, C4, and C2. There is high frequency of discoid lesions (2.7%) and SLE (0.5%) in Chronic Granulomatous Disease (CGD). Selective IgA Deficiency (SIgAD) has been associated with juvenile (5.2%) and adult (2.6%) SLE. About 25% of patients with Common Variable Immunodeficiency (CVID) develop autoimmune manifestation, including SLE. Although there are reports of individual primary immunodeficiency (PID) in SLE, there is no systematic study estimating the fraction of SLE adult patients presenting any form of PID. This study aimed to estimate the prevalence of overall PID in a cohort of SLE patients and healthy controls, and to compare the clinical characteristics of the SLE patients with and without PID.

Methods: 300 SLE patients (ACR criteria) and 301 controls (blood donors) underwent clinical examination and were evaluated for total hemolytic complement (CH50), C2, C3, C4A and C4B gene copy number, immunoglobulin isotypes and IgG subclasses, as well as quantification of the oxidative burst in neutrophils. Patients who presented any laboratory indication of PID underwent a novel examination after 60 days for confirmation. Patients with active disease and abnormal results were followed and underwent novel tests after the end of the flare or excluded if no remission was attained up to the end of the study. Cases with low C2 serum levels underwent C2 gene analysis by PCR for confirmation. Those who presented altered unexplained CH50 underwent C1q analysis. Those with C4A and/or C4B low copy number had C4 serum levels determined. Diagnosis of PID was established according to "*2009 International Union of Immunological Societies Expert Committee on PID*".

Results: There were 84 SLE patients (28%) and 10 controls (3.33%) with established diagnosis of PID (p<0.001). SLE patients had a significantly (p<0.01) higher frequency of IgG_2 deficiency (n=37; 12.3%), IgG_3 deficiency (n=24; 8%), IgG_4 deficiency (n=11; 3.6%), and IgM Deficiency (n=24; 8%) as compared to HC (0.3%, 0%, 0%, and 1.6%, respectively). One female patient presented neutrophil oxidative burst profile compatible with CGD gene carrier status (0.33%). There were no cases of C2, C3, C4 or C1q deficiency, CVID, CGD, Hyper-IgM and Hyper-IgE syndromes. Patients with IgG_3 or IgG_4 deficiency presented higher frequency of lupus nephropathy and those with IgM deficiency presented higher prevalence of oral ulcers. Overall PID was not associated with most SLE clinical manifestations, infection rate, immunosuppressant use, age at disease onset, disease duration, comorbidity, SLEDAI and SLICC-DI.

Conclusion: Over one quarter of SLE patients presented some form of PID, largely represented by immunoglobulin deficiency. Due to the important role of immunoglobulins in the clearance of immunocomplex, apoptotic bodies and pathogens, low levels of these components might induce a state of frequent and persistent immunological stimulation, which may foster autoimmunity development in genetically predisposed individuals. Our results suggest that an underlying immunodeficiency state may be involved in the disease pathophysiology in a substantial fraction of SLE patients.

Up-Regulation of A Disintegrin and Metalloprotease with Thrombospondin Type I Repeats-13 Correlates with Ischemic Cerebrovascular Disease in Systemic Lupus Erythematosus Patients Consuelo Lopez de Padilla[1], Molly Hein[1], Cynthia S. Crowson[1], Christopher Choo[2], Abigail B. Green[1], Michelle Petri[3], Hatice Bilgic[4], Emily Baechler Gillespie[4] and Ann M. Reed[1]. [1]Mayo Clinic, Rochester, MN, [2]Rochester, MN, [3]Johns Hopkins University School of Medicine, Baltimore, MD, [4]University of Minnesota Medical School, Minneapolis, MN

Background/Purpose: ADAMTS13 (A Disintegrin-like And Metalloprotease with ThromboSpondin type 1 motif) belongs to a recently described group of metalloproteinase enzymes which possess proteoglycanase and anti-angiogenic activities. ADAMTS13 limits platelet thrombogenesis through the cleavage of von Willebrand factor (vWF) and has been implicated in the pathogenesis of thrombotic thrombocytopenic purpura (TTP), a potentially fatal complication of systemic lupus erythematosus (SLE) and other rheumatic diseases. The pathogenic role of ADAMTS13 in TTP associated to SLE has been investigated; however, although TTP and SLE may have overlapping clinical features, they are distinct entities. We investigated ADAMTS13 messenger RNA (mRNA) levels as a biomarker of disease features in SLE.

Methods: Here, we measured and compared mRNA levels of ADAMTS13 in peripheral blood cells in 309 SLE and 23 healthy subjects by whole-genome microarray using the Illumina Bead Array Platform. We examined correlations of ADAMTS13 mRNA expression levels with clinical features, laboratory parameters and disease activity (systemic lupus erythematosus disease activity index; SLEDAI). Comparisons of mRNA levels and their association with distinct clinical characteristics were assessed using the rank sum test and Spearman rank correlation analysis.

Results: The results showed that the median of ADAMTS13 mRNA expression levels were significantly increased in blood cells of SLE patients (median, 121.3 [25th, 75th quartile, 116.8, 126.4] compared to healthy controls (median, 119.1 [25th, 75th quartile, 114.8, 121.3] (*p=0.028*). No significant differences were found between ADAMTS13 mRNA levels and symptoms associated with the ACR criteria for classification of SLE. Notably, mRNA copy number levels of ADAMTS13 were significantly increased in SLE patients with a history of stroke (n= 11) (median, 126.5, [25th, 75th quartile, 121.3, 129.2]) or Transient Ischemic Attack (TIA) (n= 5) (median, 126.6, [25th, 75th quartile, 126.3, 137.8]) compared to those without stroke or TIA (median, 121.0, [25th, 75th quartile, 116.6, 126.3]; (median, 121.6, [25th, 75th quartile, 116.6, 127.4], respectively) (*p=0.015*; *p=0.024*; respectively). We next sought to compare the mRNA ADAMTS13 levels in the 26 of 309 SLE patients with coronary artery disease (CAD). No significant differences were observed between ADAMTS13 mRNA levels in SLE patients with CAD compared to patients without CAD (*p*=0.35). Similarly, ADAMTS13 expression was not found to be correlated with SLE disease activity.

Conclusion: These results indicate that increased expression of ADAMTS13 mRNA in blood cells is associated with presence of ischemic cerebrovascular disease (stroke and TIA) in SLE patients and suggests a potential role for ADAMTS13 in the pathogenesis of ischemic cerebrovascular disease in SLE patients.

The Small Molecule Activator to ACE2 Prevents the Inhibition of ACE2 Activity by Autoantibodies. Shiori Haga[1], Yuko Takahashi[2], Yukihito Ishizaka[1] and Akio Mimori[2]. [1]National Center for Global Health and Medicine, Research Institute, Tokyo, Japan, [2]National Center for Global Health and Medicine, Tokyo, Japan

Background/Purpose: Angiotensin-converting enzyme 2 (ACE2) is a member of renin-angiotensin system that plays a critical role in regulating blood pressure and cardiovascular function. It is a homologue of ACE and converts angiotensin (Ang) II into Ang-(1–7), which has the vasoprotective effects. Recent studies have demonstrated the therapeutic effects of ACE2 activation by a synthetic molecule or by forced expression of *ace2* cDNA in experimental pulmonary hypertension models. We recently reported that inhibitory anti-ACE2 antibodies were detected in patients with autoimmune diseases (AID) with constrictive vasculopathy, pulmonary arterial hypertension, or persistent digital ischemia. We investigate whether 1-[(2-dimethylamino) ethylamino]-4 (hydroxymethyl)-7- [(4-methylphenyl) sulfonyl oxy]-9H-xanthene-9-one (XNT), ACE2 activator identified by Ferreria *et. al.*[1]) overcomes on the inhibitory effect of anti-ACE2 antibodies in AID patients.

Methods: Immunoglobulin G was purified from sera of 13 vasculopathy and 11 non-vasculopathy patients with protein G sepharose beads. To evaluate the inhibitory effect against ACE2 by anti-ACE2 antibodies, we performed the measurement of ACE2 activity. ACE2 activity was monitored with fluorescent substrate following pre-treatment of ACE2 and purified IgG.

Moreover, the interacting alternation of between ACE2 and IgG by XNT was examined by ELISA and western blot analysis.

Results: ACE2 activity was reduced by IgG purified from sera of 12 of 13 AID patients (92.3 %) with vasculopathy, but not that of 10 of 11 non-vasculopathy patients (90.9 %) and healthy subjects. Furthermore, in 2 of 12 samples retained ACE2 inhibitory effects, XNT overcame the inhibitory effects when added to IgG-ACE2 complex mixture. Moreover, XNT cancelled the binding of anti-ACE2 to ACE2.

Conclusion: The ACE2 activator, XNT increased ACE2 activity suppressed by IgG of AID patients. Our results suggested that XNT cancelled antigen-antibody reaction inducing a dynamic conformation change of ACE2. We propose that it is important to identify the activator which has the inducible capability of structural change against ACE2 and such compound is sufficiently expectable as candidate of therapeutic agent.

Abnormal Neutrophil Development in Human Systemic Lupus Erythematosus. Namrata Singh[1], Mariana J. Kaplan[2], Philip L. Cohen[1] and Michael F. Denny[1]. [1]Temple University, Philadelphia, PA, [2]University of Michigan, Ann Arbor, MI

Background/Purpose: Recent research has increased the appreciation of the contributions of neutrophils to systemic lupus erythematosus (SLE). An abnormal circulating pool of granulocytes has been associated with certain disease manifestations, and we previously developed techniques to isolate these low-density granulocytes (LDGs) from the blood of SLE patients. While LDGs express surface markers consistent with mature neutrophils, their nuclear morphology suggests an immature phenotype. This pattern of mature neutrophils possessing an abnormal nuclear morphology is frequently observed in patients with alterations in granulocyte development, suggesting that neutrophil differentiaton may be disrupted in SLE patients.

Methods: Because disrupted neutrophil development is frequently associated with genomic alterations, we compared genomic alterations in autologous pairs of LDGs and normal-density neutrophils. Somatic alterations were detected by cytogenetic microarray analysis of genomic DNA extracted from LDGs and neutrophils from 13 female SLE patients, as well as neutrophil samples from 9 age-matched healthy female donors. The Affymetrix 2.7M Cytogenetics Microarray chip was used to assess both copy number state and heterozygosity across the genome. For each SLE patient we compared genomic DNA from LDGs to DNA from autologous neutrophils. Variations present in both samples are inherited, while alterations found exclusively in the LDG sample represent the acquisition of additional somatic alterations.

Results: The SLE normal density neutrophils and healthy donor neutrophils had similar levels of copy number variations, most of which corresponded to known variants. In contrast, the LDG samples from SLE patietns had a two-fold increase in copy number alterations relative to either autologous normal-density neutrophils or healthy controls. The elevation in genomic copy number variations in the LDG samples included an increased incidence of both duplications and deletions. These LDG somatic alterations were found in 6 of the 13 patients. Thus, the LDGs isolated from a subset of SLE patients displayed evidence of genomic instability as determined by alterations in copy number. Moreover, these genomic alterations occurred preferentially on certain chromosomes, as opposed to random distribution across the genome. No correlation between genomic instability and the use of immunosuppressive drugs, disease activity or manifestations was observed.

Conclusion: In a subset of SLE patients, the LDGs show an elevated level of genomic alterations that is consistent with genetic damage or instability. These alterations occur in discrete chromosomal intervals, suggesting these regions reflect an increased propensity for damage or that the alteration confers a selective advantage to the affected cell. Whether the inflammatory environment present in SLE patients promotes these genetic alterations, or whether it is an intrinsic property of the SLE genome, remains to be determined.

Co-Localization of C-Reactive Protein, Immunoglobulin G and Complement in Renal Subendothelial Immune Deposits of Proliferative Lupus Nephritis Detected Using Immunogold Electron Microscopy. Christopher Sjöwall[1], Anders I. Olin[2], Thomas Skogh[3], Jonas Wetterö[3], Mattias Mörgelin[2], Ola Nived[4], Gunnar Sturfelt[5] and Anders A. Bengtsson[5]. [1]Linkoping University, Linkoping, Sweden, [2]Infection Medicine, Department of Clinical Sciences, Lund University, Lund, Sweden, Lund, Sweden, [3]Linköping University, Linköping, Sweden, [4]University Hospital Lund, Lund, Sweden, [5]Department of Clinical Sciences Lund, Section of Rheumatology, Lund, Sweden

Background/Purpose: The pattern recognition molecules C-reactive protein (CRP) and complement protein 1q (C1q) are pivotal parts of the innate immune system and display relevant biological functions in the pathogenesis of systemic lupus erythematosus (SLE). Circulating autoantibodies directed against CRP and C1q are frequently found in SLE patients with active disease, especially those with lupus nephritis, and raised serum autoantibody levels reportedly relate to both disease activity and prognosis. This study was performed to assess glomerular localization of IgG, CRP and C1q as a reflection of nephritogenic immune complexes (ICs) in patients with active diffuse proliferative lupus nephritis.

Methods: Renal specimens from five well-characterized patients with active diffuse proliferative lupus nephritis were examined by immunogold electron microscopy to pinpoint glomerular localization of CRP, C1q, C3c and double-stranded (ds) DNA in relation to IgG. Renal biopsies from patients with Henoch-Schönleins purpura, pauci-immune nephritis and renal cancer served as controls. In addition, serum IgG class antibodies against CRP, C1q, and nucleosomes were analyzed by ELISA in the lupus nephritis patients before, during and after renal flares. Informed consent was obtained from all subjects and the research protocol was approved by the Regional Ethics Committee in Lund (H4 207/2005).

Results: Tissue CRP, C1q, C3c and dsDNA were found to co-localize with IgG in renal subendothelial electron dense deposits. Disease controls only showed negligible staining for the tissue markers as compared with lupus nephritis and none had detectable anti-C1q, anti-CRP or anti-nucleosome antibodies. All SLE patients had circulating anti-nucleosome antibodies, and four of five were anti-CRP, anti-dsDNA, and anti-C1q antibody positive at the time of biopsy/flare. Using accumulated data (pre–post nephritis), one could observe that anti-nucleosome and anti-C1q antibody levels were more interrelated ($r=0.42$, $p=0.046$) than were the levels of anti-CRP versus anti-C1q or anti-nucleosome antibodies, respectively.

Conclusion: The results support the notion of a pathogenic role not only for antibodies directed against dsDNA, but also for anti-CRP and anti-C1q in lupus nephritis. The glomerular ICs may have been generated by deposition of circulating ICs or by *in situ* IC formation. The demonstrated correlation between anti-C1q and anti-nucleosome antibodies, but not between these autoantibodies and anti-CRP, indicate that the latter may reflect an independent role in the pathogenesis of lupus nephritis.

Increased C1q, C4 and C3 Deposition On Platelets in Patients with Systemic Lupus Erythematosus – A Possible Link to Venous Thrombosis? Christian Lood[1], Sam Eriksson[1], Birgitta Gullstrand[2], Andreas Jönsen[1], Gunnar Sturfelt[1], Lennart Truedsson[2] and Anders A. Bengtsson[1]. [1]Department of Clinical Sciences Lund, Section of Rheumatology, Lund, Sweden, [2]Department of Laboratory Medicine, Section of Microbiology, Immunology and Glycobiology, Lund, Sweden

Background/Purpose: Patients with systemic lupus erythematosus (SLE) have an increased risk of developing vascular diseases (VD) such as myocardial infarction, stroke and venous thrombosis, which can only partly be explained by traditional risk factors. The role of platelets in this process has not been extensively studied. Platelet activation support complement binding to the platelet surface, and increased C4d has been seen on platelets in SLE patients as well as in non-rheumatic patients with stroke. In this study we investigated *in vivo* platelet deposition of the classical complement pathway components C1q, C4d and C3d in relation to VD in SLE patients. Furthermore, the ability of serum to support *in vitro* complement deposition on fixed heterologous platelets was analyzed.

Methods: Blood from 69 SLE patients and age- and sex-matched healthy individuals was collected in sodium-citrate tubes and platelets isolated by centrifugation. Complement deposition on platelets was detected by flow cytometry.

Results: We could demonstrate that SLE patients had increased C1q, C3d and C4d deposition on platelets as compared to healthy controls (p<0.0001). SLE patients with a history of venous thrombosis had increased complement deposition on platelets as compared to SLE patients without this manifestation (p<0.05). *In vitro* studies demonstrated that serum from patients with lupus anticoagulant, venous thrombosis or the antiphospholipid antibody syndrome supported increased platelet C4d deposition *in vitro* as compared to SLE patients without these manifestations (p<0.05). Our data support the hypothesis that platelet activation and the subsequent complement deposition on platelets are central in development of venous thrombosis in SLE.

Conclusion: Altogether we suggest that complement deposition on platelets could reflect important pathogenetic events related to the development of venous thrombosis in SLE and might be used as a marker for venous thrombosis in SLE.

The Clinical Significance and Expression of P2X7 Purinergic Receptor in Peripheral Blood from Patients with New-Oneset Systemic Lupus Erythematosus. Xiangpei Li, Meiyun Wang, Jinhui Tao, Xiaomei Li and Ning Yu. Anhui Medical University Affiliated Provincial Hospital, Hefei, Anhui, China

Background/Purpose: P2X7 purinergic receptor (P2X7R) is encoded by a gene within the human SLE locus SLEB4. Extracellular adenosine triphosphate (ATP) regulates inflammatory cells by activation this pro-inflammation receptor. Our aim was to describe the expression of the P2X7R on peripheral blood lymphocytes in patients with SLE and explore its significance in the pathogenesis and clinical features of SLE.

Methods: Surface expression of P2X7R on total lymphocytes, CD4+T cells, and CD19+B cell in peripheral blood from 29 SLE patients were determined by flow cytometry. As controls, 28 age and sex-matched healthy subjects (HC) were used. ELISA was performed to detect P2X7R-related serum cytokines IL-1β, IL-6, TNF-α level.

Results: Compared to HC, SLE patients had higher expression of P2X7R on CD4+ T cells (2.21(3.55) *vs* 0.89(1.15) *p*=0.015) and CD19+B cells (11.53(20.01) *vs* 6.66(6.27), *p*=0.037). The same result was also observed in total lymphocytes (1.85(5.75) *vs* 1.19(0.74), *p*=0.082), though it was not statistically significant. As reported before, increase of IL-1β, IL-6 and TNF-α were observed in patients with SLE. Meanwhile, the percentage of P2X7R+ cells in lymphocytes was positively correlated with the serum IL-6 level in SLE patients(*r*=0.449,*p*=0.015). Regarding the clinical manifestations, patients with arthritis showed higher expression of P2X7R on total lymphocytes compared to patients without arthritis(*p*=0.006); Neuropsychiatric lupus (NPSLE) patients had increased P2X7R expression on CD19+B cells. In addition, the percentage of P2X7R+ cells in total lymphocytes and CD19+B cell were both positively correlated with the SLEDAI score (r=0.374, p=0.00 5; r=0.274,p=0.041) and so was that in total lymphocytes with anti-β2GP1.

Conclusion: These preliminary results suggest that an increased expression of P2X7R may contribute to the flare and organ damage of SLE by inducing the secretion of IL-6, which suggests that therapeutic targeting of P2X7Rmight be beneficial for treatment of human SLE.

Estrogen Upregulates Interleukin-21 Production of Clusters of Differentiation 4 Positive T Lymphocytes in Patients with Systemic Lupus Erythematosus. Jennifer Lee[1], Daejun Kim[1], Jae Ho Lee[1], Seung Min Jung[1], Mi-La Cho[2], Seung-Ki Kwok[1], Ji Hyeon Ju[1], Kyung-Su Park[1], Sung-Hwan Park[1] and Ho-Youn Kim[1]. [1]Division of Rheumatology, Department of Internal Medicine, School of Medicine, The Catholic University of Korea, Seoul, South Korea, [2]Rheumatic research center, Catholic University of Korea, Seoul, South Korea

Background/Purpose: Systemic lupus erythematosus (SLE) is an autoimmune disease in which various organs and tissues are damaged through abnormal immune responses mediated by tissue-binding autoantibodies and immune complex deposition. As the majority of SLE patients are women of child-bearing age, estrogen has been suggested to play an important role in the pathogenesis of SLE. One of the proposed roles of estrogen is to induce B cell activation culminating in increased autoantibody production. IL-21, a common-γ chain cytokine, has been shown to be crucial in the differentiation of activated B cells into plasma cells. Based on these concepts, we hypothesized that estrogen contributes to pathogenesis of SLE via IL-21 dependent pathway and investigated the effect of estrogen on the production of IL-21 by T cells and subsequent B cell activation in SLE patients.

Methods: Peripheral blood mononuclear cells (PBMCs) were obtained from peripheral blood of 23 SLE patients and 16 healthy controls. CD4+ T cells, non CD4+ T cells and B cells were isolated using microbeads. Isolated cells were treated with 17-β estradiol at various concentrations for 48hrs (up to 72hrs in some experiments). The expression of IL-21 and its receptor was assessed by measuring the level of protein and mRNA using ELISA and RT-PCR, respectively. The level of immunoglobulin G secreted by activated B cells were measured with specific ELISA.

Results: The expression of IL-21 and its receptor in serum, PBMCs, and CD4+ T cells were higher in the patients with SLE compared to healthy controls. Exposure of CD4+ T cells from SLE patients to 17-β estradiol leads to a dose-and time-dependent increase in the IL-21 expression. The increase was abolished in the presence of MAP kinase (MEK, p38, JNK) inhibitors. B cells of healthy controls showed an increased antibody production when they were co-cultured with estrogen treated CD4+ T cells of patients with SLE. Treatment with anti-IL-21 antibody abrogated the increased antibody production of the co-culture systems, suggesting the increase was mediated by IL-21 dependent manner.

Conclusion: This study revealed the association of estrogen and IL-21 in the pathogenesis of SLE. Estrogen upregulates IL-21 expression of CD4+ T cells via MAPK dependent pathways in SLE patients, which in turn induces increased antibody production by B cells.

Cytokines and Their Relation to Autoantibodies Before Disease Onset in Systemic Lupus Erythematosus. Catharina Eriksson[1] and Solbritt Rantapää Dahlqvist[2]. [1]Department of Clinical Immunology/clinical microbiology, Umeå, Sweden, [2]Umeå University Hospital, Umeå, Sweden

Background/Purpose: Cytokines and autoantibodies are involved in the pathogenesis of systemic lupus erythematosus (SLE). The presence of autoantibodies preceding disease onset by years has been reported both in patients with SLE and in other rheumatic diseases, and changes in cytokine levels have been shown before disease onset in rheumatoid arthritis. The cytokine group interferons and interferon-related molecules are considered to be of importance in SLE pathogenesis. Therefore, we intended to measure cytokine levels, and relate them to autoantibodies, in a northern European population before the onset of symptoms of SLE.

Methods: The register of patients fulfilling the American College of Rheumatology criteria for SLE and with a given date of the onset of symptoms was coanalysed with the register of the Medical Biobank, Umeå, Sweden. Thirty-six patients were identified as having donated blood samples prior to symptom onset. A nested case-control study (1:4) was performed with 144 age- and sex-matched controls identified from the Medical Biobank register (Umeå, Sweden). The cytokines interferon alpha (IFN)-α, interleukin (IL)-4, IL-9, IL-10, interferon inducible protein 10 (CXCL10/IP-10) and monocyte chemotactic protein-1 (CCL2/MCP-1), were analysed before and after onset of symptoms of SLE using a multiplex kit from Millipore on a Bio-Plex Array Reader (Luminex[200]). The associations of these cytokines to autoantibodies (ANA, ENA, anti-dsDNA och anti-histone antibodies), from the same blood samples, before disease onset was estimated.

Results: The IP-10 levels were significantly higher in the individuals who later developed SLE ("prepatients") than in the controls (median value ±IQR) 372pg/mL±293 versus 253pg/mL±192. IFN-α and IP-10 were strongly correlated (p<0.01) and IP-10 had the most obvious association to autoantibodies, being significantly higher in ANA, SSA and Jo-1 positive individuals (p=0.03, 0.01 and 0.03, respectively) and also to autoantibody

positivity over all (p<0.001). MCP-1 was related to SSA and SSB positivity (p=0.009 and 0.047) and with antibody positivity over all (p=0.015), IFN-α with anti-SSB and antibody positivity over all (p=0.027 and 0.025), IL-4 to anti-dsDNA (p=0.019) and IL-10 to anti-RNP positivity (p=0.041). IL-10, IP-10 and MCP-1 increased significantly between the pre-patient sample, 7.44 pg/mL ±8.93, 372 pg/mL± 293 and 278pg/mL ± 475 respectively, and after SLE was diagnosed, 12.3 pg/mL±20.1, 666 pg/mL± 602 and 1098 pg/mL± 765, respectively (p=0.029, <0.0001 and <0.0001 respectively). The cytokines showed no significant changes in relation to time before disease onset or to the debut SLE-symptom.

Conclusion: IP-10, MCP-1 and IFN-α had the clearest relationships with autoantibody formation before disease onset of SLE. Since IFNs and IP-10 were strongly correlated with each other these findings support previous theories that the IFN-system is important in the early SLE pathogenesis and autoantibody formation.

Leukadherin 1, a CR3 Mimetic, Negatively Regulates Toll Like Receptor (TLR) Dependent Inflammatory Responses via Degradation of an Adaptor Protein. Kristen Lee[1], Joanne H. Reed[1], Vineet Gupta[2], Tejaskumar Patel[1], Jill P. Buyon[3] and Robert M. Clancy[1]. [1]New York University School of Medicine, New York, NY, [2]Division of Nephrology and Hypertension, Department of Medicine, University of Miami, Miami, FL 33136, U.S.A., Miami, FL, [3]NYU School of Medicine, New York, NY

Background/Purpose: Systemic Lupus Erythematosus is characterized by continuous and cyclic stimulation of the innate immune system by endogenous nucleic acids. Immune complexes of Ro60, ssRNA and anti-Ro60 have been shown to engage TLR7 and promote secretion of inflammatory mediators. Recent evidence demonstrates that activation of the integrin, CR3, negatively regulates TLR signaling in dendritic cells. Leukoadhedrin (LA1), a novel small molecule, allosterically activates CR3 and suppresses inflammation. This study was initiated to molecularly address whether, and by what mechanism, LA1 downregulates ssRNA-induced TLR7 signaling in macrophages.

Methods: THP-1 cells and PBMC derived CD14+ macrophages from healthy human donors were incubated with TLR7/8 agonists (hY3 (2.5 ug) or R848 (1 uM)) with and without LA1 (7.5μM) added 30 minutes pre or post stimulation. Quantification of TNFα secretion, the readout of TLR7/8 activation, was assessed by ELISA and MyD88 was evaluated by immunoblot.

Results: Exposure of healthy human macrophages to hY3 resulted in a significant release of TNFα compared to unstimulated cells (348±45 vs 4±2 pg/ml, respectively P=0.0001, N=9). Stimulated TNFα release was markedly decreased by pre-treatment with LA1 but not post-treatment (53±47 and 1275±467 pg/ml, respectively, P=0.035, N=6). In parallel with the results for isolated macrophages, TNFα was induced after exposure of THP-1 macrophages to hY3 (315±59 vs 15±13 pg/ml, stimulated vs. unstimulated respectively P=0.0015, N=7). Pre-treatment with LA1 profoundly decreased hY3-induced secretion (18±9 pg/ml, P=0.0013 vs hY3) and exceeded the inhibition observed with a TLR7 inhibitor (117±16 pg/ml, P=0.004 vs hY3). Moreover, R848 stimulated TNFα release was also significantly decreased by pre-treatment with LA1 (1113±218 vs 55±47 pg/ml, respectively P=0.0006, N=11). To identify the potential mechanism for downregulation of TLR7 signaling, adaptor protein degradation was studied. LA1-mediated inhibition of both hY3 and R848 stimulated TNFα release was accompanied by degradation of MyD88 (immunoblot, N=3 for each stimuli), an effect not seen with a TLR7 antagonist, oligonucleotide IRS661 (inhibits at level of TLR ligation, not downstream). Reprobe of blot demonstrated that the expression of actin did not vary with treatment condition. Evidence against cytotoxcity of LA1 was provided by the absence of LDH in culture supernatants. The *ITGAM*assignment of THP-1 cells and all the donor macrophages was homozygous common at rs1143679 supporting that the inhibitory effect of LA1 was applicable to the dominant genotype.

Conclusion: The data suggest that activation of CR3 downregulates macrophage TLR7 signalling via degradation of MyD88. These findings may be particularly relevant in disease states such as SLE and neonatal lupus in which inflammatory cells are triggered by ssRNA containing immune complexes.

Interferon-Alpha Impairs the Survival and Function of Circulating Angiogenic Cells *in Vitro*: A Model of Failed Endothelial Repair in SLE. John A. Reynolds[1], David W. Ray[2], Terence O'Neill[2], M. Yvonne Alexander[1] and Ian N. Bruce[3]. [1]The University of Manchester, Manchester, United Kingdom, [2]University of Manchester, Manchester, United Kingdom, [3]Arthritis Research UK Epidemiology Unit and NIHR Manchester Musculoskeletal Biomedical Research Unit, Manchester, United Kingdom

Background/Purpose: Patients with Systemic Lupus Erythematosus have an increased risk of cardiovascular disease (CVD). No specific targeted therapies for CVD in lupus exist and there are no *in vitro* models to study potential novel agents. Endothelial dysfunction, the earliest stage of vascular damage, is associated with interferon-alpha (IFNα) expression. It has been proposed that IFNα may act by impairing endothelial repair mechanisms. When compared to healthy controls, lupus patients have fewer circulating angiogenic cells (CAC) and endothelial progenitor cells (EPCs). Mixed EPC/CAC populations have been shown to be sensitive to IFNα, resulting in apoptosis and change in phenotype. We aimed to investigate the effects of IFNα2b on an *in vitro* model of angiogenesis/vascular repair.

Methods: Peripheral blood mononuclear cells were obtained from healthy subjects and cultured on human fibronectin in endothelial growth media. Myeloid phenotype was confirmed by LDL uptake/lectin binding and expression of cell surface markers by RT-PCR. Cell survival in response to IFNα2b (0.01–10ng/ml) was determined by the number of LDL-uptake-positive cells at 7 days. An angiogenesis assay was used to study CAC function. Supernatant from CACs cultured for 7 days ± 10ng/ml IFNα2b was added to human aortic endothelial cells cultured on growth factor reduced Matrigel. Tubule formation was assessed at 14 hours using an automated computer algorithm. Mean values of the calculated network parameters were compared using 2-tailed t tests.

Results: CACs expressed markers of both endothelial (CD31) and myeloid lineage (CD14, CD45). In addition, CACs strongly expressed the macrophage markers CD68, CD163 and CD206 suggesting an alternatively-activated (M2) macrophage phenotype. IFNα2b significantly reduced the number of CACs at day 7 in a dose-dependent manner (r^2= −0.769, p<0.0001).

In co-culture with endothelial cells on Matrigel, CACs co-localised to the endothelial tubules but did not form tubule networks alone. CAC supernatant significantly increased the density of the tubule network when in terms of: total pixel area (27781 vs 36283, p=0.0065), number of branches (340.2 vs 510.6, p=0.0434), number of junctions (162.4 vs 241.1, p=0.0104) and number of closed loops within the network (21.8 vs 38.3, p=0.005). IFNα2b significantly reduced the number of closed loops (38.2 vs 24.1, p=0.0094). All other network parameters were reduced by IFNα2b but did not reach statistical significance.

Conclusion: CACs are of myeloid lineage and have angiogenic capacity *in vitro*. CAC supernatant contains potent angiogenic factors which augment endothelial tubule networks. IFNα2b dramatically reduces the survival of CACs *in vitro*, resulting in reduced tubule network formation and may be a mechanism by which IFNα promotes vascular damage in SLE. Quantification of the angiogenic nature of CACs and the effects of IFNα2b, using a tubule formation assay, offers a potential *in vitro* model in which to study the effects of novel vasculoprotective agents in this patient population.

668

Markers of Nitric Oxide and Hydroxyl Radical Formation Are Increased in Proliferative Lupus Nephritis and May Emanate From Increased Nitric Oxide Synthase and NADPH Oxidase Production and Reduced Endothelial Nitric Oxide Synthase-Derived NO Scavenging. Jim Oates, Ahmad Mashmoushi, Thomas Fleury, Ann Hofbauer and Gary S. Gilkeson. Medical University of South Carolina, Charleston, SC

Background/Purpose: The role of redox regulation of cell function in the different International Society of Nephrology/Renal Pathology Society (ISN/RPS) classes of lupus nephritis (LN) is not known. Different reactive intermediate (RI) species lead to differential changes in proteins that are important in transcriptional regulation and signaling. RIs are unstable species that can be measured indirectly by their ability to modify protein tyrosines (Tyr) and phenylalanines to form nitroTyr (NTyr, via peroxynitrite), metaTyr (mTyr, via hydroxyl radicals (OH·), usually

metabolized from SO and H_2O_2), and chloroTyr (ClTyr, via HOCl). This study was designed to address the hypothesis that different classes of LN have distinct profiles of RI production.

Methods: 62 patients with active LN had a renal biopsy with ISN/RPS classification at screening. Serum and urine samples were collected before induction therapy for active LN. Serum (n=62) was analyzed for nitrate and nitrite (NO_X, a marker of nitric oxide (NO) production) by chemiluminescence analyzer. In a random subset of patients (n=34), serum proteins were analyzed for NTyr, mTyr, and ClTyr by HPLC with electrochemical detection and reported as the ratio of modified to unmodified Tyr * 1000. Snap frozen murine renal cortical tissue lysates from MRL/lpr and MRL/lpr NOS3 −/− (endothelial NO synthase or eNOS) mice with active proliferative LN were analyzed for superoxide (SO) production by lucigenen assay with and without inhibitors of NOS and NADPH oxidase. **Results** were normalized to untreated MRL/lpr wildtype control tissue. Groups were compared by Wilcoxen rank sum or Student t test, and $p < 0.05$ was significant.

Results: Those with class IV LN had significantly higher levels of serum NO_X. mTyr was elevated in those with class III and IV LN. In class V LN, NTyr and ClTyr were increased (differences not significant). SO production was increased (to 160%) in MRL/lpr NOS3−/− kidney cortex. This increase was reduced by both L-NMMA (a nonspecific NO synthase inhibitor, 70% of control) and DPI (a nonspecific NADPH oxidase inhibitor, 40% of control).

Table. Levels of markers of RI production in patients with LN by ISN/RPS class

ISN/RPS Class	nitrate + nitrite	mTyr/Tyr*1000	ClTyr/Tyr*1000	Ntyr/Tyr*1000
Pure I	39 (n = 1)	0.6 (n = 1)	0.1 (n = 1)	0.2 (n = 1)
Pure II	30.2 ± 7.2 (n = 9)	0.2 ± 0.1 (n = 4)	0.1 ± 0 (n = 4)	0.3 ± 0.1 (n = 4)
Pure and mixed III	30.4 ± 5.3 (n = 29)	**9 ± 5.5 (n = 17)**	0.1 ± 0 (n = 18)	0.7 ± 0.3 (n = 18)
Pure and mixed IV	**59.6 ± 17.8 (n = 12)**	**7.8 ± 4.2 (n = 8)**	0.6 ± 0.3 (n = 9)	1.1 ± 0.3 (n = 9)
Pure V	24.9 ± 6.3 (n = 10)	0.7 ± 0.4 (n = 4)	13.9 ± 13.7 (n = 5)	21.2 ± 21 (n = 5)

Values reported as means ± standard error. Bolded values are significantly different from other classes.

Conclusion: These results suggest increased NOS activity in class IV LN. In those with proliferative LN, increased OH· production or reduced antioxidant scavenging appears to be occurring. OH· can indirectly come from NADPH oxidase and NO synthase. Higher levels of SO in MRL/lpr cortical tissue from NOS3 −/− mice suggests that eNOS-derived NO can scavenge SO. Reduction of SO with both a NOS inhibitor and an NADPH oxidase inhibitor suggests that both enzymes produce SO, perhaps in a synergistic fashion, in proliferative LN. Therefore, effective therapy for SO-mediated redox signaling in proliferative LN may need to induce increases in the scavenging effect of eNOS-derived NO or target SO directly with scavengers. Myeloperoxidase (forms NTyr and ClTyr) may be an important enzyme target in class V disease.

Serum Anti *N*-Methyl-D-Aspartate Receptor Subunit 1 Antibodies Are Elevated in SLE. Ogawa Eisuke, Nagai Tatsuo, Arinuma Yoshiyuki and Hirohata Shunsei. Kitasato University School of Medicine, Kanagawa, Japan

Background/Purpose: Previous studies have demonstrated that the presence of autoantibodies against *N*-methyl-D-aspartate (NMDA) receptor subunit 2 (NR2) is closely associated with brain damages leading to the development of diffuse neuropsychiatric SLE (NP-SLE). NR1 is another subunit forming functional NMDA receptor with NR2. However, it is not clear whether anti-NR1 antibodies (anti-NR1) might be expressed in SLE. Nor has their role in the pathogenesis in NP-SLE been clarified. The present study therefore explored the serum levels of anti-NR1 in SLE.

Methods: Sera were obtained from 108 patients with SLE, 36 various rheumatic diseases other than SLE (7 patients with RA, 8 with Behcet's disease, 3 with vasculitis syndromes, 6 with SSc, 6 with PM/DM and 6 with MCTD) and 91 healthy individuals. Among the 108 SLE patients, 67 showed neuropsychiatric manifestations. IgG anti-NR1 antibodies were measured by ELISA, using the N-terminal 100-amino acid of murine NR1, which is more than 90% homologous to human NR1. The results were reported as arbitrary units determined using a positive serum. Some sera positive for anti-NR1 were further analyzed for the fine epitopes they recognize, using 4 different preparations of synthetic 25

amino-acid sequences within the N-terminal 100 amino-acid sequence of human NR1.

Results: The mean ± SEM values for serum anti-NR1 in 91 healthy individuals were 4.48 ± 2.19 units/ml. Serum anti-NR1 levels were significantly elevated in SLE (52.18 ± 15.22 units/ml) compared with healthy individuals or with non-SLE rheumatic diseases (4.50 ± 2.23 units/ml). There was no significant difference in serum anti-NR1 between non-SLE rheumatic diseases and healthy individuals. Of note, serum anti-NR1 were significantly higher in NP-SLE (74.60 ± 23.96 units/ml) than those in SLE without neuropsychiatric manifestations ((15.54 ± 5.62 units/ml) (p=0.044)). Finally, anti-NR1 bound most efficiently to the sequence of amino acids between position 57 and position 81 from the N-terminus of human NR1.
Conclusion: The results indicate that anti-NR1 were specifically elevated in SLE patients. Moreover, the data also suggest that anti-NR1 might be involved in the pathogenesis of NP-SLE, presumably through transudation through blood-brain barrier into CNS.

Prolidase Deficiency Induces Antibodies to Sm, Ro60 and Double Stranded DNA. Biji T. Kurien[1], Anil D'souza[2], Skyler P. Dillon[1], Benjamin F. Bruner[3], Timothy Gross[4], Judith A. James[5], Ira N. Targoff[6], Jacen S. Maier-Moore[1], Isaac T.W. Harley[7], Heng Wang[8] and Robert H. Scofield[1]. [1]Arthritis & Clinical Immunology Program, Oklahoma Medical Research Foundation; Department of Medicine, University of Oklahoma Health Sciences Center; US Department of Veterans Affairs Medical Center, Oklahoma City, OK, [2]University of Oklahoma Health Sciences Center, Oklahoma City, OK, [3]Harding University, Searcy, AR, [4]Oklahoma Medical Research Foundation, Oklahoma City, OK, [5]Oklahoma Medical Research Foundation and Oklahoma University Health Sciences Center, Oklahoma City, OK, [6]Oklahoma Medical Research Foun, Oklahoma City, OK, [7]Cincinnati Children's Hospital Research Foundation, Cincinnati, OH, [8]Das Deutsch Center Clinic for Special Needs Children, Middlefield, OH

Background/Purpose: Prolidase is a ubiquitous enzyme found in the cytoplasm. The enzyme specifically cleaves dipeptides containing C-terminal proline or hydroxyproline, in one of the last steps of collagen metabolism. Prolidase deficiency is a rare inborn error of metabolism characterized by the secretion of dipeptides in the urine and a variety of clinical manifestations. Only about 50 patients have been reported with the deficiency, of which approximately 10% have systemic lupus erythematosus.

Methods: A large extended Amish pedigree, having four patients deficient for prolidase, three individuals with heterozygous prolidase activity and eight unaffected individuals, was studied for lupus-associated autoimmunity. Prolidase genetics and enzyme activity were confirmed. Antinuclear antibody was measured using indirect immunofluorescence. Antibodies against extractable nuclear antigens were determined by double immunodiffusion, immunoprecipitation, and BioRad 2200 multiplex bead assay. Serum C1q levels were determined by ELISA.

Results: Two of the four homozygous prolidase deficient patients had a positive ANA. One had anti-dsDNA antibodies, while another had precipitating anti-Ro60 antibodies. Three of the four patients had anti-Sm and anti-chromatin by the BioRad 2200 multiplex bead assay. One of the three heterozygous subjects had a positive ANA and immunoprecipitation of a 75,000 MW protein. Serum C1q levels were not changed in the prolidase deficient patients. The unaffected controls had normal prolidase activity and were negative for autoantibodies.

Conclusion: Prolidase deficiency leads to a loss of immune tolerance to lupus-associated autoantigens even without clinical systemic lupus erythematosus.

Background/Purpose: Systemic lupus erythematosus (SLE) is a prototypic autoimmune disease that is characterized by the presence of antinuclear autoantibodies, complement activation and the formation and deposition of immune complexes resulting in multisystem organ damage. Trends in SLE vary by age, with pediatric SLE (pedSLE) patients presenting with more active, severe and rapidly progressive disease than adult SLE patients. However, the basis for this variation is unknown. In this investigation, we sought to characterize the clinical phenotype associated with the age of diagnosis including pedSLE, adult SLE and late onset SLE in a large multiethnic cohort.

Methods: We evaluated clinical manifestations, disease course and severity (per the Systemic Lupus International Collaborating Clinics/ACR Damage Index) and autoantibody profiles using a total of 2,564 SLE patients with a cumulative presence of at least 4 of 11 revised and updated ACR classification criteria for SLE, self-defined race/ethnicity (African American, European American, Hispanic), disease duration £10 years at enrollment and with at least 2 years follow up included in the PROFILE longitudinal cohort. Patients were stratified by age of onset including pedSLE ($\leq$16 years), adult SLE (17–49 years) and late onset SLE ($\geq$ 50 years). Risk estimates were calculated using multivariable logistic regression, although frequencies are provided herein.

Results: A total of 2,564 SLE patients were evaluated. The mean ($\pm$standard deviation, SD) age at diagnosis in each of three age strata was 14$\pm$3 years, 32$\pm$9 years and 58$\pm$7 years for pedSLE, adult SLE and late onset SLE, respectively and the mean ($\pm$SD) disease duration was 10.9$\pm$8.7 years, 5.7$\pm$5.8 years and 3.8$\pm$3.4 years for each of the respective groups. Across each age of onset group, the majority were female ($\geq$86%) and slightly more pedSLE patients were of African American (38%) or Hispanic (13%) ancestry. We confirm that compared to SLE patients with adult onset, pedSLE patients are more likely to present with acute and severe disease features including discoid rash (27% vs. 18%), serositis (48% vs. 44%), renal involvement (62% vs.

41%), neurologic involvement (18% vs. 10%), hematologic involvement (73% vs. 68%) and immunological involvement (89% vs. 79%). In contrast, SLE patients with late onset were significantly less likely to present with serositis (34%), renal involvement (20%), neurological involvement (8%) and immunological involvement (67%) compared to each of the pedSLE and adult onset SLE groups. Consistent with increasing age, the late onset SLE group demonstrated more damage associated with ocular, neuropsychiatric, pulmonary, cardiovascular, musculoskeletal, diabetes and malignancy domains than did the pedSLE or adult SLE groups, whereas the pedSLE group had significantly more renal damage.

Conclusion: These findings confirm more aggressive disease, particularly renal involvement, in SLE patients presenting in childhood. They further suggest SLE disease manifestations decrease with age of onset throughout adulthood. These results will inform future studies aimed at delineating the etiology and natural history of the more aggressive clinical phenotype observed in children.

Immune Complexes and Autoantibodies to Oxidized Lipids in Systemic Lupus Erythematosus. Yujin Ye, Tianfu Wu and Chandra Mohan. University of Texas, Southwestern Medical Center at Dallas, Dallas, TX

Background/Purpose: SLE is a chronic autoimmune inflammatory disease. Increasing evidence suggest that excess production of reactive oxygen species (ROS) may cause oxidative stress and favor the development of immune-cell dysfunction, autoantigen production and autoantibody development. Oxidized-lipids have chemotactic, immune-stimulatory, and toxic properties and play an important role in the pathogenesis of atherosclerosis and kidney injury in SLE. In the current study, we evaluated the serum levels of oxidized-lipids and their autoantibodies in SLE patients and identified the relationships between oxidized-lipids, auto-antibodies and disease.

Methods: Serum MDA was measured by a colorimetric method and HODE was assayed by mass spectrometry. Serum levels of specific oxidized-LDL immune complex (ox-LDL-IC), autoantibodies to ds-DNA, ox-LDL, MDA-LDL, 9-HODE (9-hydroxy-10,12-octadecadienoic acid), 13-HODE (13-hydroxy-9,11-octadecadienoic acid), POVPC (1-palmitoyl-2-oxovaleroyl-sn-glycero-3-phosphorylcholine) were detected by ELISA in 64 SLE patients (37 with active SLE, SLEDAI > 6) and 9 healthy controls.

Results: (1) Active SLE patients exhibited increased serum levels of anti-ds-DNA-IgG (0.349$\pm$0.039 vs 0.115$\pm$0.018; p=0.0001), anti-MDA-LDL-IgG (1049.0$\pm$116.2 ku/L vs 468.7$\pm$103.6 ku/L; p=0.003), anti-LDL-IgG (1368.0$\pm$183.6 EU/ml vs 654.0$\pm$87.17 EU/ml; p=0.004), anti-9-HODE-IgG (0.632$\pm$0.044 vs 0.298$\pm$0.058; p=0.001), anti-13-HODE-IgG (0.542$\pm$0.047 vs 0.251$\pm$0.048; p=0.0003), anti-POVPC-IgG (0.429$\pm$0.030 vs 0.297$\pm$0.030; p=0.001) and ox-LDL-IC (0.375$\pm$0.018 vs 0.270$\pm$0.022; p=0.003) compared to healthy controls, but decreased serum levels of anti-9-HODE-IgM (0.257$\pm$0.016 vs 0.335$\pm$0.032; p=0.019) and anti-13-HODE-IgM (0.336$\pm$0.025 vs 0.441$\pm$0.042; p=0.029). (2) Serum HODE levels were positively correlated with proteinuria (r=0.68/p=0.002), CRP (r=0.51/p=0.03) and ox-LDL-IC (r=0.45/p=0.04). Serum anti-ox-LDL-IgG was positively correlated with SLEDAI (r=0.34/p=0.02), and negatively with C3 (r= $-$0.39/p=0.01). Anti-9-HODE-IgG was positively correlated with SLEDAI (r=0.27/p=0.02), and negatively with C4 (r= $-$0.3/p=0.01). Anti-POVPC-IgG was positively correlated with SLEDAI (r=0.23/p=0.04), and negatively with C4 (r= $-$0.27/p=0.03).

Conclusion: Active SLE patients exhibit significantly increased serum levels of IgG anti-oxidized-lipid autoantibodies. Taken together with our recent metabolomic screen indicating that oxidized lipids are also elevated in SLE sera (PLOS ONE, June 2012), the current findings suggest that coordinate elevation of oxidized lipids, autoantibodies to these lipids, and immune complexes of these antigen-antibody components could serve as potential serum markers of disease activity in SLE.

Altered Soluble Mediators in Individuals with Incomplete Lupus (ILE) in the Lupus Autoimmunity in Relatives (LAUREL) Study. Melissa E. Munroe[1], Jill M. Norris[2], Joel M. Guthridge[1], Diane L. Kamen[3], Kathy Moser Sivils[1], Timothy B. Niewold[4], Gary S. Gilkeson[5], Michael H. Weisman[6], Mariko L. Ishimori[6], Daniel J. Wallace[6], David R. Karp[7], John B. Harley[8] and Judith A. James[9]. [1]Oklahoma Medical Research Foundation, Oklahoma City, OK, [2]Colorado School of Public Health, Aurora, CO, [3]Arthritis & Clinical Immunology Program, Oklahoma Medical Research Foundation, Charleston, SC, [4]University of Chicago, Chicago, IL, [5]Medical University of South Carolina, Charleston, SC, [6]Cedars-Sinai Medical Center, Los Angeles, CA, [7]UT Southwestern Medical Center, Dallas, TX, [8]Cincinnati Children's Hospital Medical Center; US Department of Veterans Affairs Medical Center, Cincinnati, OH, [9]Oklahoma Medical Research Foundation; University of Oklahoma Health Sciences Center, Oklahoma City, OK

Background/Purpose: SLE is a complex autoimmune disease marked by autoantibody production and immune dysregulation. Identification of at-risk populations is essential to minimize morbidity and mortality from early inflammatory reactions and to identify appropriate individuals for prevention trials. A number of patients have autoantibodies and some clinical features of SLE, but do not meet the required ≥ 4 ACR criteria (or incomplete lupus, ILE). Healthy blood relatives of lupus patients are known to have significantly increased risk of SLE development. Using a unique resource of family members with samples available before and after transition to SLE, we initially found that blood relatives (FDRs) who transition to SLE have altered inflammatory mediators compared to those who remain unaffected. This study seeks to determine potentially pathogenic inflammatory mediators in blood relatives classified with ILE, compared to those who have transitioned to SLE, and matched blood relatives who remain unaffected.

Methods: This study has initially re-enrolled 375 FDRs of known SLE patients with samples available from previous genetic studies for follow-up evaluation; 22 previously unaffected FDRs have transitioned to SLE (≥ 4 ACR criteria) and 17 are classified as ILE (cumulative ACR criteria = 3). Individuals provided detailed clinical and demographic information, and completed the Connective Tissue Disease Screening Questionnaire (CSQ) at baseline (BL) and follow-up (FU). Medical records were obtained and reviewed for ACR classification criteria. BL and FU serum samples were tested for autoantibody production, including ANA, anti-dsDNA, aCLs and precipitating levels of Ro, La, Sm, nRNP, and ribosomal P autoantibodies. We assessed 52 soluble inflammatory mediators, using either xMAP multiplex technology or sandwich ELISA (BLyS and APRIL). Samples from ILE participants were compared to FDRs who transitioned to SLE, as well as race/gender/age ($+/- 5$ years)/ANA status matched FDRs who remain unaffected.

Results: ILE FDRs had BL and FU CSQ scores similar to those who transitioned to SLE classification (*n.s.*), yet > 2 fold higher than matched, unaffected FDRs ($p < 0.001$). Both ILE and SLE had similar BL and FU levels of a number of chemokines, including MIG, MIP-1α, MIP-1β, MCP-3, and eotaxin. Of particular interest were shed TNFR family members (TNFRI, TNFRII, TRAIL, and CD40L) that were 50% higher in ILE FDRs and those who transitioned to SLE than matched, unaffected FDRs ($p \leq 0.01$). Compared with FDRs who transitioned to SLE or remained unaffected, ILE FDRs had significant ($p < 0.05$) BL and FU alterations in 22 (of 52) soluble mediators, most notably innate and adaptive cytokines, including a >2-fold increase in Th2-type cytokines IL-4, IL-5, and IL-13 and regulatory cytokines IL-10 and TGF-β.

Conclusion: FDRs of known SLE patients classified with ILE or transition to SLE demonstrate significantly altered levels of soluble inflammatory mediators. These alterations suggest that multiple perturbations in immune-mediated inflammatory processes occur with accumulation of ACR criteria and potentially allow for identification of individuals at high risk for development of SLE.

Altered Response to B Cell Receptor (BCR) Crosslinking in SLE: Correlation with Genetic Risk Variants Predicted to Impact BCR Signaling. Nan-Hua Chang[1], Timothy Li[1], Paul R. Fortin[2], Dafna D. Gladman[3], Carolina Landolt-Marticorena[4], Jorge Sanchez-Guerrero[5], Murray B. Urowitz[4] and Joan E. Wither[3]. [1]Toronto Western Research Institute, University Health Network, Toronto, ON, [2]University of Laval, Quebec, [3]Toronto Western Research Institute, University of Toronto, University Health Network, Toronto, ON, [4]University Health Network, University of Toronto, Toronto, ON, [5]Mount Sinai Hospital, University Health Network, Toronto, ON

Background/Purpose: Altered B cell signaling has been proposed to play an important role in susceptibility to SLE. In mice, genetic manipulations or polymorphisms that attenuate BCR signaling have been shown to lead to altered selection or survival of self-reactive lymphocytes whereas those that lead to enhanced BCR signaling can breach B cell anergy, with both types of defects reported in various murine models of SLE. Most previous reports indicate that SLE B cells are hyper-responsive to BCR crosslinking. However, these findings contrast with preliminary evidence suggesting that some of the genetic risk variants associated with SLE may lead to attenuated BCR signaling. In this study we have examined the association between these risk variants and the altered B cell function observed in SLE.

Methods: Patients (N=44) satisfying at least 4 ACR criteria and (N=30) healthy age-matched controls without a family history of systemic autoimmune disease were recruited. PBMC were isolated over a Ficoll gradient, rested for 1 hr at 37°C, and then stimulated for 2' with media alone, or 2' and 10' with media containing 20 μg/ml of F(ab')$_2$ goat anti-human IgM. Cells were stained with anti-CD19, -CD27, -IgD, -IgM, and -CD38, to permit gating on naïve mature B cells (CD19$^+$CD27$^-$IgD$^+$CD38$^+$) stratified based on their IgM cell surface expression and transitional B cells (CD19$^+$CD27$^-$IgD$^+$CD38^{++}IgM^{hi}). B cell signaling was examined by Phosflow using anti-pSyk (pY348), -pPLCγ2 (pY759) or -pERK1/2 (pT202/Y204) Ab following fixation and permeabilization. SNP genotyping of subject DNA was performed using TaqMan assays specific for rs2618476 (*BLK*), rs10516487 (*BANK-1*), rs7829816 (*LYN*), and rs2476601 (*PTPN22*).

Results: There was an increased proportion of naïve B cells in SLE patients that had elevated basal levels of pSYK and pERK, suggesting prior activation in-vivo. Following IgM crosslinking, the naïve B cells of SLE patients demonstrated significantly increased levels of p-SYK and trends to increased levels of p-PLCγ2 and p-ERK above basal levels as compared to controls. This increased signaling was most marked in the IgM^{hi} mature naïve and transitional B cell compartments of SLE patients. There was no correlation between the basal levels of phosphorylated signaling molecules and any of the SNPs examined. No association was seen between *BLK* or *LYN* SNPs and any of the phosphorylated signaling molecules following IgM crosslinking. Consistent with attenuated BCR function there was a trend to decreased pPLCγ2 and significantly decreased pERK with the lupus-associated *PTPN22* variant at 10' following IgM crosslinking. The lupus associated *BANK-1* variant was associated with decreased pPLCγ2 at 2'. To further explore the role of non-genetic factors in the B cell hyper-responsive phenotype, serial measurements of pSYK were performed. Significant variations between individual visits were seen in a subset of patients.

Conclusion: No correlation was observed between increased B cell signaling and several of the genetic risk variants predicted to alter B cell receptor function in SLE. It is likely that this phenotype arises from other genetic or non-genetic factors.

Differential Impairment of Serum Cholesterol Efflux Capacity in Patients with Rheumatoid Arthritis and Systemic Lupus Erythematosus. Pier Luigi Meroni[1], Nicoletta Ronda[2], Elda Favari[3], Orietta Borghi[4], Francesca Zimetti[3], Mariapia Adorni[5], Francesca Ingegnoli[6], Maria Gerosa[7], Claudia Grossi[8] and Franco Bernini[5]. [1]Istituto G. Pini, University of Milan, Milano, Italy, [2]Parma, Italy, [3]University of Parma, Parma, Italy, [4]University of Milan, Milan, Italy, [5]39-02-58318176, Parma, Italy, [6]Rheumatology, Istituto G. Pini, University of Milan, Milano, Italy, [7]Division of Rheumatology, Istituto Ortopedico Gaetano Pini, Milan, Italy, [8]Lab of immunology, IRCCS Istituto Auxologico Italiano, Milano, Italy

Background/Purpose: Accelerated atherosclerosis associated with autoimmune diseases is partly due to immune system dysregulation aggravating cardiovascular damage, but little is known on lipid metabolism derangement in this condition. Serum capacity to promote cholesterol efflux from macrophages (CEC) is the first limiting step of the atheroprotective reverse cholesterol transfer process, mainly reflects HDL function and inversely correlates to subclinical atherosclerosis *in vivo*. Moreover, the relevance of

CEC is strengthened by recent evidence of an impact of cholesterol efflux on inflammatory and immune functions of macrophages and endothelial cells. We measured the four main CEC pathways in rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE) patients.

Methods: aqueous diffusion (AD)-, SR-BI-, ABCG1- and ABCA1-mediated CEC was measured by validated radioisotopic *ex vivo* systems in 30 AR and 30 SLE patients, and in 30 age and sex-matched healthy subjects.

Results: SR-BI-mediated CEC (mean±SEM % efflux) was increased in SLE patients (3.84 ± 0.19) as compared to controls (3.20 ± 0.20) and RA patients (2.78 ± 0.17). ABCG1-mediated CEC was reduced in RA and more markedly in SLE (6.04 ± 0.25 and 4.36 ± 0.34, respectively) as compared to controls ($7.13 \pm 0.2\%$). ABCA1-mediated CEC was impaired in SLE (2.55 ± 0.16) as compared to controls and RA patients (3.14 ± 0.19 and 3.54 ± 0.30, respectively). AD-mediated CEC did not differ between the three populations studied. ABCG1-mediated CEC inversely correlated with the disease activity score DAS28 in RA patients. SLE patients as a group showed the lowest ABCG1-mediated CEC in spite of the highest HDL serum level. The correlation between ABCG1-mediated CEC and serum HDL, detected in controls and in SLE patients, was absent in RA. The correlation between ABCG1-mediated and SR-BI-mediated CEC detected in controls and RA patients was absent in SLE.

Conclusion: We report here for the first time a marked and differential CEC impairment in patients with RA and SLE, independent of HDL serum levels, that not only demonstrates a dysfunction and loss of atheroprotective activity of HDL with respect to cholesterol metabolism, but also points to the existence of specific underlying mechanisms in each disease, possibly beyond inflammation. Moreover, the impairment of ABCG1-mediated cholesterol efflux in autoimmune patients, that correlated with disease activity in the RA group, might also have an impact in inflammatory and immune reaction involving macrophages and endothelial cells.

676

A Novel Biomarker: Nucleotide-Binding Oligomerization Domain 27 in Systemic Lupus Erythematosus. Annika Cutinha[1], Yangsheng Yu[2], Kaihong Su[2], James R. O'Dell[1], Lynell W. Klassen[1], Amy C. Cannella[1], Ted R. Mikuls[1], Alan R. Erickson[3], Gerald F. Moore[1] and Michelene Hearth-Holmes[1]. [1]University of Nebraska Medical Center, Omaha, NE, [2]Department of Pathology and Microbiology, Omaha, NE, [3]University of Nebraska Medical Center, LaVista, NE

Background/Purpose: Systemic Lupus Erythematosus (SLE) is a complex autoimmune disease in which a variety of autoantibodies contribute to the diversified disease phenotypes. In our previous studies, we generated more than 300 recombinant antibodies from B cells of SLE patients using the single-cell RT-PCR approach. We found that over 20% of SLE-derived antibodies bind to and activate neutrophils. One of the antibodies recognizes a novel pattern recognition receptor Nucleotide-binding Oligomerization Domain 27 (NOD27), which is recently shown to be involved in anti-viral interferon responses. Administration of this antibody in lupus-prone mice accelerated lupus progression, suggesting a role of anti-NOD27 in lupus pathogenesis. The purpose of this study is to determine if anti-NOD27 autoantibodies are detectable in sera from SLE patients and if the serum levels of anti-NOD27 are elevated in SLE patients with active disease.

Methods: 59 SLE patients who met at least four of the 1982 ACR criteria and 92 healthy volunteers with no known rheumatic diseases were enrolled into the prospective study. The SLEDAI disease activity index was obtained in all patients. Patients with a SLEDAI score of 6 or higher were considered to have active disease. Enzyme-linked immunosorbent assay (ELISA) was performed to determine the serum levels of anti-NOD27 antibodies. Serum titers of complements C3 and C4 and anti-dsDNA antibodies were obtained in each patient. The control group, SLE group and the SLE inactive and active groups were compared with each other for the serum titers of anti-NOD27 using the Mann Whitney test (two-tailed). A $p$value of <0.05 was considered significant. The respective correlation of anti-NOD27 titers with anti-dsDNA, C3, C4, or SLEDAI in SLE patients was calculated using Pearson's correlation test.

Results: The mean anti-NOD27 level in the SLE group was 0.518 (in optical density units; SD 0.26, 95% CI 0.45–0.587), which is significantly higher than that in the control group (mean: 0.398; SD 0.15, 95% CI 0.36–0.45; $p=0.0019$). The mean anti-NOD27 level of the active SLE cohort was found to be higher than that of the inactive SLE cohort (mean: 0.617

versus 0.496) although the difference was not statistically significant, likely related to the limited number of active patients in our cohort (11 of 59). The anti-NOD27 titers were significantly correlated with anti-dsDNA titers ($p=0.0014$, Pearson r $=0.38$) and demonstrated a marginal inverse correlation with the C3 levels ($p=0.047$, Pearson r $= -0.22$). No significant correlation of anti-NOD27 with C4 levels ($p=0.118$, Pearson r $=-0.16$) nor SLEDAI scores ($p=0.074$, Pearson r $=0.19$) was seen.

Conclusion: The novel biomarker anti-NOD27 was found to be significantly elevated in patients with SLE compared to controls in this study and concentrations of anti-NOD27 were significantly correlated with anti-dsDNA titers in our cohort of SLE patients suggesting that anti-NOD27 may be an informative biomarker in SLE. Further studies with larger sample sizes and different cohorts of patients including those with active disease and end organ damage will be needed to evaluate the predictive capacity of NOD27 antibody responses in the future.

Antibodies to Oxidized Low Density Lipoprotein or Anti-Lipoprotein Lipase May Lead to More Atherosclerotic Plaque in a Sub-Set of SLE Patients. Biji T. Kurien[1], James Fesmire[2], Skyler P. Dillon[3], Marianne Reichlin[4], Morris Reichlin[5] and Robert H. Scofield[6]. [1]University of Oklahoma Health Sciences Center, Arthritis & Clinical Immunology Program, Oklahoma Medical Research Foundation; US Department of Veterans Affairs Medical Center, Oklahoma City, OK, [2]Oklahoma Medical Research Foundation, [3]University of Oklahoma Health Sciences Center, Oklahoma City, OK, [4]Oklahoma Medical Res Fndn, Oklahoma City, OK, [5]Oklahoma Medical Research Foun, Oklahoma City, OK, [6]Arthritis & Clinical Immunology Program, Oklahoma Medical Research Foundation; Department of Medicine, University of Oklahoma Health Sciences Center; US Department of Veterans Affairs Medical Center, Oklahoma City, OK

Background/Purpose: Premature atherosclerosis is associated with systemic lupus erythematosus (SLE). Oxidized low density lipoproteins (ox-LDL) are important in atherosclerosis and have been reported in SLE in association with anti-phospholipid antibodies. Our earlier work showed increased susceptibility of SLE Patients with anti-Ro 60, La and Ro 52 to develop anti-oxidized LDL. In this study we tested the hypothesis that atherosclerotic plaque may be associated with anti-oxLDL and anti-lipoprotein lipase in a specific autoantibody sub-set of SLE.

Methods: We studied 114 SLE patients and 117 age and sex matched normal controls. Antibodies directed against lipoprotein lipase (ALPL), oxidized low density lipoprotein (anti-oxLDL), and low density lipoprotein (ALDL) were measured by enzme-linked immunosorbent assay. Total cholesterol, LDL, HDL, triglycerides and HDL-Trig were also measured. Plaque was measured by bilateral carotid ultrasound. The study was approved by the Institutional Review Board of the Oklahoma Medical Research Foundation and all subjects signed informed consent forms. The patient population (age range of 16– 87 years; average age 43) was 104 females and 10 males.

Results: Double immunodiffusion studies showed that sixty three SLE subjects did not have autoantibodies against extractable nuclear antigen (ENA), 14 had antibodies against ribonucleoprotein (RNP), 16 had anti-Ro60, 7 had anti-Ro60/La, 6 had anti-SmRNP, 4 had unidentified precipitin lines and 4 had miscellaneous antibodies. The ENA negative group had a significantly higher plaque measured as carotid intimal thickening (0.9 ± 1.71; p$<$ 0.05) compared to normal controls (0.54 ± 1.26), but did not have significant levels of anti-oxLDL (OD = 0.41 ± 1.62), ALPL (OD = 0.35 ± 0.18) and ALDL (OD = 0.1 ± 0.09) compared to anti-oxLDL (0.165 ± 0.13), ALPL (0.39 ± 0.2), ALDL (0.09 ± 0.1) in normal controls. The group with anti-RNP antibodies had significant levels of anti-oxLDL (0.29 ± 0.27; p$<$0.005) compared to control group. However, the anti-RNP group did not have significant levels of ALPL (0.39 ± 0.19), ALDL (0.14 ± 0.139) or plaque (0.79 ± 1.43) compared to control group. The 16 subjects with anti-Ro60 had significant anti-oxLDL level (0.26 ± 0.15; p$<$0.003) and plaque (1.29 ± 0.25; p$<$0.02) compared to controls, but no differences in ALPL (0.36 ± 0.16) or ALDL (0.11 ± 0.11). The 7 SLE subjects with anti-Ro60/La had signficantly higher levels of ALPL antibodies (0.56 ± 0.246; p=0.05) compared to control group. This group had the highest levels of ALPL antibodies compared to all other SLE groups. The anti-SmRNP group did not behave significantly different from normal controls with respect to plaque (0.5 ± 0.55), anti-oxLDL (0.265 ± 0.15), anti-LDL (0.14 ± 0.12) or ALPL (0.471 ± 0.27). There was no significant difference in plaque when

anti-oxLDL+/ALPL+ or anti-oxLDL-/ALPL- SLE subjects were compared to either anti-oxLDL+/ALPL+ or anti-oxLDL-/ALPL- normal controls.

Conclusion: Plaque appears to segregate in anti-Ro/La, anti-Ro and ENA negative groups either with or without anti-oxLDL or ALPL.

Estrogen Modulation of ZAS3 Is Mediated Through Estrogen Receptor α: An Underlying Mechanism of Gender-Bias in Systemic Lupus Erythematosus? Nicholas Young[1], Alexandra Friedman[1], Lai-Chu Wu[1] and Wael N. Jarjour[2]. [1]The Ohio State University Medical Center, Columbus, OH, [2]Ohio State University, Columbus, OH

Background/Purpose: Global population data has indicated that post-pubertal females have decreased rates of infectious diseases when compared to male counterparts and preadolescent or postmenopausal females. In contrast, many autoimmune diseases like Systemic Lupus Erythematosus (SLE) have a significant bias towards post-pubertal women. ZAS3 is an important immuno-regulatory transcription factor involved in both B and T cell maturation and function. We hypothesized that post-pubertal females have more robust immune responses in part through estrogen's regulation of ZAS3. In this study, we examine the influence of estrogen over ZAS3 expression and the functional implication of ZAS3 deficiency on the immune response.

Methods: Wild type (WT) mice were injected subcutaneously with estrogen (E2) daily for 5 days and lymphoid tissues were harvested. Transgenic mice with a luciferase reporter under the control of kB binding sites were bred into ZAS3 knockouts and luciferase activity in males and females was measured by IVIS. Peripheral blood mononuclear cells (PBMCs) isolated from healthy subjects and SLE patients were subjected to experimental analyses of gene expression and assayed for proliferation or cytokine production in the presence of either anti-CD3 or tetanus toxoid with or without estrogen. Nuclear extracts were isolated for EMSA analysis from E2-treated lymphocyte cell lines.

Results: Estrogen treated mice had elevated ZAS3 expression in the spleen, thymus, bone marrow, and lymph nodes when compared to PBS-injected controls. NFkB-mediated luciferase reporter activity in female ZAS3 knockout mice was significantly lower than WT controls, whereas males exhibited no significant differences. Further, ZAS3 knockout mice expressed significantly lower peroxisome-proliferator activated receptor gamma (PPARγ) expression. ZAS3 was also found to be significantly elevated at baseline in SLE patients when compared to age and sex-matched healthy controls. PBMCs from healthy females incubated *in vitro* with estrogen or estrogen receptor alpha (ERα) agonist showed significant upregulation of ZAS3. Similarly, ZAS3 expression was upregulated in response to estrogen both on the protein and RNA level in T Cells, B Cells, monocyte, and NK cell lines. EMSA analysis with intronic estrogen receptor response element probes within the ZAS3 region revealed that ERα binds directly and that E2 stimulation enhanced complex formation. Furthermore, estrogen significantly enhanced the cellular proliferation responses in primary PBMCs cultured with anti-CD3 or Tetanus toxoid. When these cells were stimulated with E2, we also demonstrated significant production of MIP-1β.

Conclusion: Primary human PBMCs display a heightened ZAS3 response to E2 and this effect is mediated at least in part through NFkB and leads to PPARγ upregulation. Furthermore, The E2/ERα-mediated stimulation of ZAS3 expression occurs through direct, genomic interactions with intragenic enhancing elements. Taken together, this data suggests that E2 lowers the threshold of activation by priming the immune system of females. While this may be beneficial in the defense against foreign antigens, it can be detrimental in the development of autoimmunity.

ZAP70+ B Cells and Plasmablasts As Markers of Disease Activity and Remission in Systemic LUPUS Erythematosus Nephritis. Elisa Gremese, Barbara Tolusso, Laura Messuti, Marcin Nowik, Silvia Canestri, Luca Petricca, Maria Rita Gigante and Gianfranco Ferraccioli. Division of Rheumatology, Institute of Rheumatology and Affine Sciences, Catholic University of the Sacred Heart, Rome, Italy

Background/Purpose: To analyze differences in B cells subsets distribution in patients with renal systemic lupus erythematosus (SLE). To define possible cellular biomarkers of active nephritis and of remission in renal disease in SLE patients.

Methods: 60 SLE patients with renal involvement 49 females (82%); mean age 36.9 ± 11.0 years; 37 with active disease and 23 with disease in remission) were analyzed for the distribution of circulating peripheral blood B cell subpopulations by staining for surface markers CD45, CD19, CD38, IgD, CD27 (CD27/IgD classification (Sanz et al. SeminImmunol 2008) and intracellular marker ZAP-70 (Tolusso et al. ClinImmunol 2009) by flow cytometry. All patients had a WHO class III or IV nephritis diagnosed by renal biopsy. Patients with active nephritis were recruited at the renal disease onset, while patients in remission were recruited if the nephritis was in stable remission for at least 12 months. Fourteen patients with active disease at the study entry were reassessed for PB B cell subpopulations at the time of renal remission (nephritis remission criteria in at least two consecutive observations and on an oral steroid dosage<7.5 mg/day).

Results: The 37 subjects with active renal involvement showed higher percentages of CD19/ZAP70+ cells compared to 23 patients with nephritis remission ($13.1\pm10.5\%$ vs$5.4\pm4.5\%$, respectively; p=0.002), as well as of plasmablasts (CD27/CD38+: $10.6\pm7.4\%$ vs $6.3\pm5.8\%$, respectively; p=0.03).There was no differences in other B cells subpopulations between active and inactive lupus nephritis.

In the 60 SLE renal patients, the percentage of CD19+/ZAP-70+ cells directly correlated with disease activity index (SLEDAI) (r=0.44, p=0.002), inversely with complement fractions C3 and C4 (C3: r=−0.44, p=0.001, C4: −0.45, p=0.001), with the number of lymphocytes (r=−0.55, p<0.001) and of the CD19+ B cells (r=−0.61, p<0.001). Moreover, the pool of ZAP70+ B cells directly correlated with the memory cells subsets (CD27+IgD-: r=0.41, p=0.002, CD27-IgD-: r=0.34, p=0.01) and with plasmablasts (r=0.39, p=0.004) and inversely with naive B cells (CD27-IgD+: r=−0.48, p<0.001). The 14 patients evaluated in the follow-up showed a significant reduction of the percentage of ZAP70+ B cells at remission ($4.3\pm2.8\%$) with respect to nephritis onset ($14.4\pm11.6\%$, p=0.002), as well as of the plasmablasts (CD19+/CD27+CD38+: $10.7\pm8.0\%$ at baseline *vs* $5.7\pm2.9\%$ at remission; p=0.05).

Conclusion: The pool of CD19+/ZAP70+ cells is associated with SLE activity parameters (SLEDAI, low complement, low lymphocytes and CD19+ count) and with the B cell memory compartment in SLE patients with renal involvement. The expansion of ZAP70+ B cells and plasmablasts characterizes active renal disease and their reduction is associated with the remission state, suggesting their possible role as biomarker in SLE nephritis.

Plasma Level of Galectin-3 Binding Protein Reflects Type I Interferon Activity and Is Highly Increased in Patients with Systemic Lupus Erythematosus Christoffer T. Nielsen[1], Ole Østergaard[2], Line V. Iversen[1], Christian Lood[3], Anders A. Bengtsson[4], Anne Voss[5], Søren Jacobsen[6] and Niels H. H. Heegaard[1]. [1]Statens Serum Institut, Copenhagen S, Denmark, [2]Statens Serum Institute, Copenhagen S, Denmark, [3]Department of Clinical Sciences Lund, Lund, Sweden, [4]Department of Clinical Sciences Lund, Section of Rheumatology, Lund, Sweden, [5]Odense University Hospital, Odense C, Denmark, [6]Copenhagen University Hospital, Copenhagen, Denmark

Background/Purpose: Ongoing production of type I interferons (IFN) is a key element in the pathogenesis of systemic lupus erythematosus (SLE). Type I IFNs trigger the over-expression of IFN-regulated genes, including galectin-3-binding protein (G3BP). G3BP serves as a scavenger receptor and is a potent immune stimulator. It mediates cellular adhesion and binding to the extracellular matrix of the basement membrane. Thus G3BP may serve as a measure of type I IFNs and has potentially important pathogenic roles in cell-cell interaction and immune complex trafficking in SLE. We here explore the relationship between type I IFN activity and plasma G3BP, compare plasma concentrations of G3BP in two cohorts of SLE patients to patients with systemic sclerosis (SSc) and healthy controls (HCs), and correlate G3BP concentrations with clinical and serological parameters.

Methods: Plasma and serum concentrations of G3BP were quantified using a commercially available ELISA. Type I IFN activity was assessed by

an Mx1-driven luciferase reporter gene assay. Gene expression scores from 12 genes in peripheral blood mononuclear cells from 26 SLE patients and 10 HCs were compared to plasma concentrations of G3BP. Plasma and serum concentrations were compared in 4 SLE and 4 SSc patient samples. G3BP concentrations in 70 SLE patients were compared to HCs (n =51) and patients with systemic sclerosis (SSc, n =111). Additionally, G3BP levels were validated in an independent cohort of SLE patients (n =67) and HCs (n =50). Non-parametric correlation analyses were used to explore associations between G3BP concentrations and clinical and serological parameters in the two SLE cohorts. In 14 SLE patients consecutive serum samples (3 or 4 per patient, >6 months apart) were analysed and correlated to disease activity (SLEDAI).

Results: G3BP plasma concentrations correlated significantly with the Mx-1 driven luciferase reporter gene assay (r =0.56, p =0.0005) and INF-α gene expression scores (r =0.54, p =0.0002). No significant difference between serum and plasma levels of G3BP was observed (p =0.17). Plasma concentrations were similar in the two SLE cohorts (p =0.42) and highly significantly increased compared to HCs and SSc patients (p <0.0001 and 0.0009, both those with diffuse and limited cutaneous disease). Significant associations (p<0.05) with SLEDAI, cell counts, anti-dsDNA, and active nephritis could not be confirmed in the validation cohort. Temporal variations in serum concentrations were observed in the consecutive SLE-samples but were not associated with disease activity (SLEDAI).

Conclusion: The level of circulating G3BP is elevated in SLE patients compared with HCs and SSc patients. The SLE-specific elevated levels of G3BP correlated with type I IFN activity. G3BP could thus serve as an easy accessible measure of type I IFN gene activation. Additionally, this study highlights G3BP as an IFN-inducible effector molecule that may have a central role in SLE pathogenesis and thus putatively is a possible new target for therapeutic intervention.

Interferon Alpha Decreases Endothelial Nitric Oxide Synthase Function and Expression in Human Umbilical Vein Endothelial Cells. Joy Buie and Jim Oates. Medical University of South Carolina, Charleston, SC

Background/Purpose: Premenopausal SLE patients have a devastating increase in cardiovascular disease (CVD) and major associated cardiovascular events (MACE) that are not fully explained by Framingham risk factors. Recent in vitro studies suggest that Type I interferons promote endothelial progenitor cell dysfunction and apoptosis while others have shown that Type I interferon gene signature correlates with increased endothelial dysfunction (ED) in SLE. Although causes of ED are likely multifactorial, all pathways converge on the diminished activity of endothelial nitric oxide synthase (eNOS). The low levels of nitric oxide (NO) produced by eNOS has anti-inflammatory, anti-thrombotic, and anti-vasoconstrictive properties all important in preventing atherosclerosis. We examined the effects of IFN-alpha on eNOS gene expression and phosphorylation.

Methods: Human umbilical vein endothelial cells (HUVECs) were cultured and treated as described below. Changes in eNOS expression in response to IFN-α (100, 1000 IU) were quantified by real-time PCR. Functional changes in response to vascular endothelial growth factor (VEGF 50ng/ml, 30 minutes) were assessed by immunoblot. We also evaluated the effect of serum from patients that induce a type I IFN signature (induction of two inducible genes (MX1 and IFIT1); IFIGs) from 5 patients and 2 controls on eNOS expression and VEGF mediated function. Gene expression was assessed using RT[2]PCR and phosphorylated serine 1177 eNOS expression using immunoblot. Type I IFN neutralization studies (IFN-α antibody(Ab), IFNα receptor (IFNAR) Ab) were also performed and eNOS expression was assessed.

Results: HUVECs treated with IFN-α at 100IU and 1000IU exhibited a significant reduction in eNOS gene expression at 24 hours (33% and 42%, respectively) and a reduction in VEGF-induced phosphorylation at the serine 1177 site (64% and 50%, respectively) after 24 hours. SLE serum also caused a 40% reduction in eNOS gene expression in human aortic endothelial cells (HAECs) compared to normal serum. However, addition of IFN neutralizing antibodies to serum did not reverse observed effects on eNOS gene changes.
Conclusion: SLE patients are at an increased risk for vascular disease, and 40% of patients present with IFN signature gene expression. Recent studies suggest that Type I IFNs are important for prediction of vascular endothelial function in SLE patients. Endothelial nitric oxide synthase (eNOS) protects the endothelium from damage and our preliminary data suggest that IFNα may have detrimental effects on eNOS expression and function. Thus, a rational target for the effect of IFNα on endothelial function may be the downstream effects of IFNα on eNOS gene expression and protein activation.

IL-12p70 Levels Play a Role in Damage Accrual in SLE Patients. Eoghan M. McCarthy[1], Ruth Lee[1], Joan Ni Gabhann[2], Siobhan Smith[2], Michele Doran[3], Gaye Cunnane[3], Donough G. Howard[1], Paul G. O'Connell[1], Caroline Jefferies[2] and Grainne M. Kearns[1]. [1]Beaumont Hospital, Dublin 9, Ireland, [2]Royal College of Surgeons in Ireland, Dublin, Ireland, [3]St. James's Hospital, Dublin, Ireland

Background/Purpose: Whilst the role of cytokines in promoting disease activity in SLE is well established, the relationship between cytokines in those who sustain irreversible damage and those who remain damage free over long term follow up is less well studied. An IL-12 driven Th1 polarisation has been proposed as a promoter of irreversible renal damage in patients with lupus nephritis but studies have not extrapolated these findings to composite all organ damage scores.The primary objective of this is to explore the role of IL-12p70 in the aetiology and pathogenesis of SLE in a homogenous Irish Caucasian population.

Methods: Patients who met at least 4 of the American College of Rheumatology (ACR) criteria for SLE were included. To gain entry all patients had to confirm they were of Irish descent for three generations. Serum levels of the following cytokines - IL-1β, IL-10, IL-12p70 and TNF-α - were quantitatively determined by electrochemiluminescence. Demographic data, disease activity as per SLEDAI and damage scores (SLICC) at 5 year follow-up were calculated.

Results: 45 patients were included in the study.

The levels of TNF-α(44.6pg/ml v 5.23pg/ml, p<.001), IL-1(2.8pg/ml v.62pg/ml, p<.001) and IL-10(7.143pg/ml v 2.76pg/ml, p<.001) were significantly higher in patients when compared to controls. IL-12p70 responses were lower in patients than controls, with an IL-12p70 level of 4.6pg/ml recorded in patients and 6.195pg/ml in controls (p=.39).

The ratio of all Th1 cytokines assayed to IL-12 was significantly higher in SLE patients when compared to controls. The levels of IL-1β/IL-12 and TNF-α/IL-12 were 5 times and 4.4 times higher respectively in patients than controls (p<.001). A similar result was seen for Th2 cytokines with the IL-10/IL-12 ratio 3.7 times higher in patients when compared to controls(p<.001).

The IL-1/IL-12 ratio was significantly higher in those patients who suffered new damage compared to those who remained damage free(1.02 v.44, p<.005) at five year follow up. A similar difference was seen in the IL-10/IL-12 ratio (3.07 v 1.88, p<.027) and the TNF/IL-12 ratio (8.14 v 5.04, p<.038).

When the Spearman correlation was computed for SLEDAI and the above cytokine ratios no significant correlation was observed with respect to disease activity. Despite this lack of association with disease activity, when a similar analysis was performed for the cytokines ratios and damage accumulation over the follow-up period a significant correlation was seen between damage accrual and the IL-1/IL-12 ratio (r = 0.431,p=0.003), IL-10/IL-12 ratio (r =0.351,p =.018) and TNF/IL-12 ratio (r = 0.28,p=.028), indicating IL-12 plays a key role in damage accrual in concert with both Th1 and Th2 cytokines.

When the respective ratios were analysed as per ACR diagnostic criteria significant differences were observed for the IL-1/IL-12 ratio(1.86 v.78,p<.0362), IL-10/IL-12 ratio(3.58 v 2.2, p<.0084) and TNF/IL-12 ratio(30.6 v 6,p<.0097) with respect to renal involvement only.

Conclusion: Our results highlight that increased Th1 and Th2 cytokine levels relative to IL-12p70 in this homogenous Caucasian SLE patient population are seen in patients with renal involvement and are associated with increased accrual of damage at five year follow-up.

Prevalence of Inhibitory or Non-Inhibitory Autoantibodies to Angiotensin Converting Enzyme 2 (ACE2) in Patients with Systemic Lupus Erythematosus. Yuko Takahashi[1], Shiori Haga[2], Yukihito Ishizaka[2] and Akio Mimori[1]. [1]National Center for Global Health and Medicine, Tokyo, Japan, [2]Research Institute, National Center for Global Health and Medicine, Tokyo, Japan

Background/Purpose: We previously reported that inhibitory autoantibodies to angiotensin converting enzyme 2 (ACE2) predisposed individuals to connective tissue diseases (i.e., scleroderma or systemic lupus erythematosus [SLE]) and constrictive vasculopathies. That study included SLE patients with digital ulcer, scleroderma patients with pulmonary arterial hypertension (PAH), and control patients with remitted SLE without vasculopathy. Preliminary data in our further experiment suggested that patients with active SLE without vasculopathy also had high titers of serum anti-ACE2 antibodies. This study investigated the presence of anti-ACE 2 antibodies in patients with SLE and evaluated the effects of these antibodies on ACE2 activity.

Methods: Serum samples were obtained for this study from 35 non-vasculopathy patients with active SLE, three vasculopathy patients with both SLE and PAH, and 44 control patients with rheumatoid arthritis (RA). The sera were assessed for anti-ACE2 antibodies by enzyme-linked immunosorbent assay (ELISA) using purified recombinant human ACE2. Twenty-six non-vasculopathy patients with remitted SLE, 21 of whom were described in our previous study, were also (re)examined by ACE2 ELISA as a control. ELISA score above the baseline level, which was determined using sera from 28 healthy subjects, were classified as positive for anti-ACE2 antibodies. IgG fractions were prepared, using protein G sepharose beads, from the sera of subjects with high ACE2 ELISA scores and were used to evaluate inhibition of ACE2 activity *in vitro*.

Results: All three PAH patients with SLE were positive for anti-ACE2 antibodies (mean optical density [OD], 0.63 ± 0.32). Of the 35 non-vasculopathy patients, 32 (91%) with active SLE were positive for anti-ACE2 antibodies (mean OD, 0.78 ± 0.42), and the mean ELISA score was significantly higher than that of remitted SLE patients (mean OD, 0.18 ± 0.15; $p < 0.00000001$) or RA patients (mean OD, 0.06 ± 0.05; $p < 0.0000000001$). Using serum IgG fractions from SLE patients with high ACE2 ELISA titers, statistically significant suppression of ACE2 activity *in vitro* was found for 1/15 non-vasculopathy patients, 3/3 PAH patients ($p = 0.0049$), and 7/7 vasculopathy (PAH or digital ulcer) patients ($p = 0.000047$), including four who were described in our previous study.

Conclusion: Most patients with active SLE or vasculopathy were positive for serum anti-ACE2 antibodies, and inhibitory antibodies were associated with vasculopathy, but not with active SLE.

Correlation of Signal Transducers and Activators of Transcription-1 and Microrna-146a with Anaemia and Other Clinical Features in Systemic Lupus Erythematosus Patients. Paul R. Dominguez-Gutierrez, Angela Ceribelli, Minoru Satoh, Eric S. Sobel, Yi Li, Westley H. Reeves and Edward K.L. Chan. University of Florida, Gainesville, FL

Background/Purpose: Anaemia is one of the most common haematological manifestations in SLE patients, occurring in about 50% of active cases. STAT1 is a critical signalling molecule required for the activation of type-1 interferon (I-IFN), CCL2, and CXCL10, all of which are upregulated in SLE. Overexpression of STAT1 has been described as responsible for anaemia in mouse models. CCL2 and CXCL10 are considered as biomarkers for flares. miR-146 has been reported to be downregulated in peripheral monocytes of SLE patients. The aim of this study is to analyze how these components are involved in anaemia in SLE, and what factors can influence their abnormal expression.

Methods: Blood samples were collected from 30 healthy donors and 100 SLE patients (European Americans (EA) 49; African Americans (AA) 34; Latin Americans (LA) 12; others 5)) fulfilling ACR criteria; 58 patients had samples collected from 2 or more visits. Total RNA, isolated from leukocytes, was analysed by Taqman qPCR. miRNA copy number was determined by a standard curve. Expression of I-IFN signature genes and chemokines were determined by the $\Delta\Delta C_T$ method. **Results** were correlated with clinical data and analysed by Wilcoxon/Kruskal-Wallis Test and Fisher's exact test.

Results: Comparing biomarker expression in anaemic vs. non-anaemic SLE, we detected a significant increase of IFN score ($p < 0.0001$), STAT1 ($p < 0.0001$), miR-146a ($p < 0.0004$), CCL2 ($p < 0.0004$), and CXCL10 ($p < 0.015$) in the anaemic SLE patients. Lupus Nephritis (LN), one of the most common serious complications in SLE, can be responsible for anaemia. As expected, LN patients are more likely to be anaemic than patients without nephritis (likelihood ratio (LR) =3.7; $p < 0.024$). Anaemic SLE patients displayed significantly higher STAT1, miR-146a, CCL2, and CXCL10 than SLE without anaemia, whether or not nephritis was present. The use of prednisone (PDN) but not mycophenolate and hydroxychloroquine is consistent with more active SLE in our cohort and thus may explain the association of anaemia with PDN. PDN users were more likely to be anaemic (LR= 10.7; $p < 0.0010$). However, STAT1, miR-146a, CCL2, and CXCL10 were significantly higher in anaemic SLE patients regardless of PDN therapy when compared to those who were not anaemic, whether or not they were on PDN. According to the clinical literature, lupus in AA tends to be more aggressive than in EA. Similarly, AA were more likely to be anaemic than EA (LR= 8.41; $p < 0.0032$). Both miR-146a and STAT1 were significantly higher in anaemic AA ($p < 0.019$ and $p < 0.020$ respectively) compared to non-anaemic AA. These markers in anaemic EA ($p < 0.025$ and $p < 0.0065$ respectively) were significantly higher than non-anaemic EA. CCL2 was significantly higher in anaemic EA compared to non-anaemic EA, but this was not observed in AA. No significant trend was observed for CXCL10.

Conclusion: Anaemic SLE patients demonstrated a significant increase of STAT1, miR-146a, CCL2, and CXCL10 vs non-anaemic patients. Furthermore LN and PDN did not alter STAT1, miR-146a, CCL2, and CXCL10 in anaemic SLE patients. For ethnic analysis, anaemic AA and EA SLE patients were associated with significantly higher levels of miR-146a and STAT1 that could play a prominent role in anaemia.

Using a Library of Synthetic Autoantigen Mimics to Discover Biomarkers of Systemic Lupus Erythematosus. Akshai Lakhanpal[1], Jiexia Quan[1], Sayed Zaman[1], Nancy J. Olsen[2] and David R. Karp[1]. [1]UT Southwestern Medical Center, Dallas, TX, [2]Penn State MS Hershey Medical Center, Hershey, PA

Background/Purpose: The natural history of systemic lupus erythematosus (SLE) is felt to evolve from a state of normal immunity to serologic autoimmunity and then to pathologic autoimmunity. This process may take several years, and can include a time when only one or two clinical features are present. We have used the term incomplete lupus erythematosus (ILE) to describe such individuals. This study was undertaken to search for biomarkers that characterize ILE, specifically autoantibodies that differentiate these subjects from healthy controls (HC) with moderate to high levels of antinuclear antibodies.

Methods: A library of 7-mer peptoids (polymers of *N*-substituted glycine) was synthesized on Tentagel beads using 10 different monomer amines, leading to a theoretical complexity of 10^7 different species. This bead-coupled library was then depleted of compounds that bound to pooled IgG from HC as well as HC with ANA but no evidence of SLE. The bead library was probed with pooled IgG from individuals with ILE. Peptoids from the positively selected beads were purified, identified by tandem MS, re-synthesized and coupled to ELISA plates. Individual serum samples from subjects with ILE, SLE, RA and controls were then tested for peptoid reactivity.

Results: Screening 375,000 compounds yielded 100 beads that bound ILE IgG. 12 of these were chosen for further analysis and 8 had appropriate full-length peptoid structures. The peptoids with the greatest discrimination a pool of HC sera, designated ILE-2, and ILE-7, were chosen for ELISA analyses. Using individual samples from the training serum pool, the mean ELISA reactivity for 38 SLE patients was significantly different than all 40 HC sera (2.98 vs. 0.638, $p < 0.0001$). The area under the ROC curve was 0.96 with a sensitivity of 89% and specificity of 97%. The mean values for individual ILE patients using the

ILE-2 ELISA were also significantly different from HC (1.81 vs. 0.492, p = 0.0025). A validation set of 40 HC, 18 ILE, and 64 SLE subjects was characterized using the mean + 2SD value for HC. Even with a more stringent cut-off, ILE patients were still significantly different than controls (p = 0.0007), although a proportion of ILE patients fell into the ILE negative range. ILE-2 and ILE-7 reactivity was found at a low level in the subset of ANA+ RA patients, but not in ANA- RA patients or other disease controls.

Conclusion: A novel, un-biased chemical library can serve as practical mimics for unknown autoantigens. The ligands can be used immediately in analytic assays. The peptoids identified in this screen have excellent ability to identify subjects with lupus-related autoimmunity and discriminate them from ANA-positive control subjects.

Cell-Type Specific Type I Interferon Signatures in Autologous Stem Cell Transplanted Lupus Patients: Different Molecular Behavior Between CD4+ T Cells and Monocytes. Chieko Kyogoku[1], Joachim R. Grün[1], Tobias Alexander[2], Robert Biesen[2], Falk Hiepe[2], Thomas Häupl[2], Andreas Radbruch[1] and Andreas Grützkau[1]. [1]German Rheumatism Research Centre Berlin (DRFZ), an institute of the Leibniz Association, Berlin, Germany, [2]Charité University Hospital Berlin, Berlin, Germany

Background/Purpose: Systemic lupus erythematosus (SLE) is a chronic inflammatory autoimmune disease that affects multiple organs, whose pathology is mainly caused by the augmented interferon (IFN) signaling pathway. The aim of this study was to analyze the particular contribution of CD4+ T cells and monocytes with respect to cell type-specific IFN signatures detectable in patients with SLE by global gene expression profiling. The major focus was set on the comparison of disease-active and -inactive patients either by standard drug treatment or by autologous stem cell transplantation (ASCT) that is assumed to completely reset the autoreactive immunologic memory.

Methods: Affymetrix Human Genome U133 Plus 2.0 Array were made from purified peripheral CD4+ T cells from 6 active SLE (SLEDAI>6), 2 inactive SLE (SLEDAI<2) by standard drug treatment and 3 inactive SLE who underwent ASCT as well as 3 healthy donors (ND). In addition, using the same donors, arrays were made from purified peripheral monocytes from 1 active SLE, 1 inactive SLE, 3 ASCT-treated SLE and 3 ND. ASCT-treated patients in this study have achieved long-term remission with SLEDAI 02, whose blood were taken at the time point of 611 years after ASCT. A reference list of 2220 IFN pathway-related genes was obtained from a recent publication on PBMCs and used to estimate IFN imprints in SLE patients.

Results: In CD4+ T cells, inactive SLE showed a marginal IFN-imprint characterized by 233 only weakly expressed probe sets compared to active SLE characterized by 573 probe sets. Unexpectedly, 562 differentially expressed probe sets were also identified in ASCT-treated patients who are under long-term remission. However, considering the absolute magnitude of expression of IFN-regulated transcripts, the imprint in ASCT-treated patients was much weaker than in active SLE. For example, significantly up-regulated expression levels of IFI27/IFIT1/IFI44L was greater in active SLE (fold change; FC 41.4/15.8/11.3, respectively) than in ASCT-treated patients (FC 11.8/5.8/4.8), and no significant regulation was observed in inactive SLE. It was obvious that monocytes showed a more complex IFN response characterized by 918 differentially expressed probe sets in active SLE. Marginal IFN-imprint characterized by 652 and 592 probe sets were observed in monocytes respectively from inactive SLE and ASCT-treated patients. Different fromCD4+ T cells, monocytes from ASCT-treated patients showed no apparent IFN signatures. For example, significantly up-regulated expression of IFI27/IFIT1/IFI44L were observed in active SLE (FC 125.1/9.8/8.4), but not in ASCT-treated patients and inactive SLE.

Conclusion: We could show for the first time detailed cell type-specific IFN signatures for CD4+ T cells and monocytes isolated from active and inactive SLE patients. Most interestingly, the intriguing question comes up, why only CD4+ T cells, but not monocytes of ASCT-treated patients, are characterized by an apparent IFN imprint although patients are under long-term remission. Our results indicate for a cell type-specific pro-inflammatory cytokine memory in CD4+ T helper lymphocytes even after ASCT-therapy in patients with SLE.

Gammadelta T Cells and Their Intracellular Cytokine Profile in Peripheral Blood of Patients with Systemic Lupus Erythematosus. Lingyun Sun, Xia Li and Zhimin Lu. Department of Rheumatology and Immunology, the Affiliated Drum Tower Hospital of Nanjing University Medical School, Nanjing, China

Background/Purpose: Gammadelta T cells represent a minor population of human peripheral blood T lymphocytes. As very rapid cytokine-producing cells, gammadelta T cells can regulate other ƒnlymphocytes activation and assist their local inflammatory function. Systemic lupus erythematosus (SLE) is a multi-organ damage autoimmune disease characterized by lymphocyte dysfunction and aberrant cytokine production. The aim was to detect gammadelta T cells numbers in the peripheral blood mononuclear cells (PBMCs) and analyze their intracellular cytokines profile (IFN-γ, IL-4, IL-10, IL-17, TGF-b).

Methods: Gammadelta T cells were detected in peripheral blood from 42 SLE patients and 20 normal controls by flow cytometry (FACS). Lupus disease activity was evaluated with a SLEDAI (SLE Disease Activity Index) score. Active SLE was defined as SLEDAI≥8. Annexin-V/PI double-staining FACS analysis was employed to observe the proportion of the apoptotic gammadelta T cells in 6 active SLE patients and 6 normal controls, respectively. The percentages of cytoplasmic cytokines including IFN-γ, IL-4, IL-10, IL-17 and TGF-b were examined in 20 SLE patients and 10 normal controls by FACS analysis.

Results: The percentages of gammadelta T cells were remarkably down-regulated in active SLE patients (2.96±1.84%, n=30) compared with that of inactive (5.31±3.05%, n=12) and normal controls (6.83±2.85 %, n=10, both p<0.01). The absolute number of gammadelta T cells decreased significantly in active SLE patients ($1.72±1.58×10^7$/L, n=30) than that in inactive SLE ($5.27±3.60×10^7$/L, n=12, p<0.01), both lower than in normal controls ($10.07±4.99 ×10^7$/L, n=10, both p<0.01). There was increased gammadelta T cells apoptosis (17.03±8.71%, n=6) in SLE patients than in normal controls (6.67±1.18%, n=6, p<0.05). The positive rate of gammadelta T intracellular IFN-γ, IL-4, IL-10 and TGF-bƒn production in 20 SLE patients were 33.19±20.20 %, 1.04±0.93 %, 1.91±0.98 % and 2.20±1.97 %, significantly higher than that of 10 normal controls (IFN-γ: ƒn5.87±4.63%, IL-4: 0.30±0.34%, IL-10: 0.18±0.31%, TGF-bƒ[a]0.21±0.22%, all p < 0.01). While there were no differences in the percentages of IL-17-positive gammadelta T cells betweenƒn SLE patients (0.14±0.24%, n=20) and normal controls (0.18±0.31%, n=10).

Conclusion: Gammadelta T cells are down-regulated in SLE partly due to excessive apoptosis. Gammadelta T cells secret both pro- and anti-inflammatory cytokines in SLE microenvironment, suggesting these cells participate in both the regulation and the propagation of lupus.

Expression of the Mer Receptor Tyrosine Kinase On Peripheral Blood Mononuclear Cells From Systemic Lupus Erythematosus Patients. Brendan A. Hilliard[1], Gaetano Zizzo[1], Margaret K. Linan[1] and Philip L. Cohen[2]. [1]Temple University School of Medicine, Philadelphia, PA, [2]Temple University, Philadelphia, PA

Background/Purpose: The Mer tyrosine kinase (Mertk) is necessary for optimal removal of apoptotic cells in animal models. Its ligation by apoptotic cell-bound protein S and GAS 6 also leads to an associated suppression of innate immunity. Thus, Mertk may have a role in controlling immune responses to antigens exposed on apoptotic cells. Immunoreactivity to such antigens is a defining characteristic of systemic lupus erythematosus. We therefore compared the level of expression of Mertk in leukocytes from the blood of normal human subjects and patients with lupus erythematosus (SLE).

Methods: Tumor cell lines known to express Mertk at the mRNA level or by western blot were used to identify antibodies that could reliably detect the Mertk and the related Tyro3 kinase by immunofluorescence. Flow cytometry of isolated peripheral blood mononuclear cells was subsequently used to compare the levels of Mertk and Tyro3 on leukocytes from the blood of SLE patients (n=23) and normal control individuals (n=14). Monocytes were identified by their high expression of CD14 together with their forward and side scatter characteristics and in some experiments by their lack of CD15 expression. Myeloid dendritic cells were identified by their lack of lineage specific markers CD3, CD14, CD19, CD56, high expression of CD11c and

low expression of CD123. Plasmacytoid dendritic cells were identified by their lack of lineage specific markers, their high expression of CD123, and low expression of CD11c.

Results: Mertk was detected on dendritic cells (DC) and monocytes from both normal individuals and from SLE patients. There was reduced Mertk expression on myeloid dendritic cells from SLE patients compared to controls (p<.03), whereas on plasmacytoid dendritic cells there was very low expression in both groups. For monocytes, high levels of Mertk expression were observed on the small CD16+ population, whereas the much larger CD16- population of monocytes expressed low levels of Mertk. There was no difference in monocyte Mertk expression on cells from SLE patients compared to controls. Tyro3 was barely detectable on any peripheral blood leukocytes, and there were no statistical differences on its expression in any of the cell types examined.

Conclusion: Myeloid DC from lupus patients express lower levels of Mertk than cells from normal individuals. Mertk expression on monocytes and plasmacytoid DC from SLE patients is not different from expression on cells from normal controls. Because Mertk is an important receptor for clearance of apoptotic cells and because DC Mertk expression regulates cytokine production, the observed lower expression of MertK on myeloid DC may lead to a lack of control of their activation and contribute to the hyper activation of immunity in lupus.

Activation of the Interferon Pathway Is Dependent Upon Autoantibodies in African-American SLE Patients, but Not in European-American SLE Patients. Kichul Ko, Yelena Koldobskaya, Elizabeth Rosenzweig and Timothy B. Niewold. University of Chicago, Chicago, IL

Background/Purpose: Gene expression studies have been instrumental in defining important aspects of the complex immunological pathogenesis in systemic lupus erythematosus (SLE) which is a heterogeneous disease that manifests differently by ancestry, and by the presence of autoantibodies directed at RNA binding proteins (anti-RBP). Moreover, anti-RBP antibodies are associated with high serum interferon (IFN)-α, which plays an important role in pathogenesis of SLE. Our overall hypothesis was that the molecular pathogenesis of SLE differs between African-American (AA) and European-American (EA) SLE patients, and between those with anti-RBP antibodies and those who lack these antibodies. We aimed to explore this hypothesis using peripheral blood gene expression profiling.

Methods: Whole blood RNA from 33 female SLE patients and 16 matched female controls from AA and EA ancestral backgrounds was analyzed on Affymetrix Gene 1.0 ST gene expression arrays. Two-tailed t-tests were performed to compare the expression values between cases and controls in each ancestry. Differentially expressed genes with a cutoff P of 0.05 were further explored using Ingenuity Pathway Analysis (IPA) to compare the top canonical pathways amongst the sample groups. An independent replication cohort of more than 100 SLE patient samples and 30 controls was used to test the hypotheses generated by the microarray data, using qPCR to quantify gene expression.

Results: Both AA and EA female (AAF and EAF respectively) patients with positive anti-RBP antibodies (RBP+) showed similar IFN-related canonical pathways such as IFN Signaling ($P = 1.3 \times 10^{-7}$ and 6.3×10^{-11} in AAF vs. EAF patients respectively), Antigen Presenting Pathway ($P = 1.8 \times 10^{-5}$ and 2.5×10^{-6}) and a number of pattern recognition receptor pathways. The key pathway difference was shown between AAF and EAF patients with negative anti-RBP antibodies (RBP-) as EAF patients also showed IFN Signaling ($P = 1.0 \times 10^{-5}$) and Antigen Presenting Pathway ($P = 1.3 \times 10^{-11}$) whereas AAF patients with RBP- did not reveal any IFN-related pathways. A replication study was performed through qPCR on 3 IFN-inducible genes, IFIT1, MX1 and PKR, and showed similar results. All three genes were strongly up-regulated in RBP+ patients in both ancestries, and PKR was up-regulated in EAF patients with RBP- but these findings were completely absent in AAF patients with RBP-.

Conclusion: Our data show that IFN-induced gene expression is completely dependent on the presence of autoantibodies in AA SLE patients but not in EA patients. Further studies are needed to explore other novel pathways that may define the heterogeneity in SLE, especially in the RBP- AA group.

Molecular Analysis of 9G4+ Antibodies in Systemic Lupus Erythematosus. Christopher Richardson[1], Asiya Seema Chida[2], Erin Fox[1], Lin Silver[1], Diana G. Adlowitz[1], Scott Jenks[2], Elise Palmer[1], Christopher Tipton[2] and Ignacio Sanz[2]. [1]University of Rochester, Rochester, NY, [2]Emory University, Atlanta, GA

Background/Purpose: Elevated titers of serum autoantibodies expressing the 9G4 idiotype are highly specific for SLE and correlate with disease activity and clinical manifestations. 9G4+ antibodies have been shown to be reactive to a wide variety of autoantigens, including B cells, dsDNA, and cardiolipin. In this study we analyze the molecular characteristics that contribute to this autoreactivity.

Methods: A panel of 9G4+ monoclonal antibodies was generated from single FACS-sorted naïve (CD19+IgD+CD27-CD24+CD38+) and isotype-switched memory (CD19+IgD-CD27+) B cells from SLE patients and healthy controls. Site-directed mutagenesis of the hydrophobic patch and light chain exchange were performed. Monoclonal antibodies were tested by ANA, dsDNA, and cardiolipin ELISA. Reactivity to B cells and apoptotic cells was determined by flow cytometry. The contribution of the hydrophobic patch, the HCDR3, and light chains to binding of the various self-antigens was analyzed.

Results: A significant percentage of 9G4+ monoclonal antibodies were reactive to autoantigen, including Hep-2 nuclear antigens (65%), B cells (48%), apoptotic cells (22%), dsDNA (9%), and cardiolipin (7%). Strong binding to apoptotic cells, dsDNA, and cardiolipin was more common among antibodies derived from SLE memory cells. Site-directed mutagenesis showed that B cell binding is mediated by the VH4–34-encoded FR1 hydrophobic patch (which also determines the expression of the 9G4 idiotype). By contrast, autoreactivity to the other SLE-related antigens is patch-independent and is actually enhanced by elimination of the 9G4 idiotype. In addition, apoptotic cell and ANA-dsDNA reactivity correlate with the charge of the HCDR3, while B cell binding does not. Finally, light chains can substantially change VH4–34-associated autoreactivity.

Conclusion: Our findings show that 9G4+ antibodies are reactive to several antigens important in SLE pathogenesis, and bind antigen in two fundamentally different ways. We also show that the intrinsic autoreactivity imprinted by the expression of 9G4+ VH4–34 heavy chains can be substantially modulated by somatic hypermutation and light chain replacement.

691

Characterization of Pro-Inflammatory Cytokines and Vitamin D Levels in a Lupus Cohort and Correlation with Disease Activity. Rohan Willis[1], Praveen Jajoria[1], Brock E. Harper[1], Emilio B. Gonzalez[1], Michelle Petri[2], Ehtisham Akhter[2], Hong Fang[2] and Silvia S. Pierangeli[1]. [1]University of Texas Medical Branch, Galveston, TX, [2]Johns Hopkins University School of Medicine, Baltimore, MD

Background/Purpose: Multiple cytokines play a role in the immune dysregulation seen in systemic lupus erythematosus (SLE) and the local inflammatory responses that ultimately lead to tissue injury. IL6, TNFα, sCD40L, IFNα and IFN inducible cytokines such as MCP1 and IP10 are correlated with disease activity as measured by the SLEDAI, SLAM-R, ESR and anti-dsDNA antibody titres. Elevated VEGF and IL1β levels have been demonstrated in patients with antiphospholipid syndrome (APS). Low serum 25-hydroxy vitamin D (25OH-VD) levels are found in sera of pts with SLE and have been associated with higher fatigue and pain scores. Studies assessing lupus disease activity and Vit D levels have shown contradictory results. As such we sought to determine the proinflammatory biomarkers elevated in a cohort of SLE patients compared to controls, the correlation with disease activity levels and the prevalence of abnormally low vitamin D levels.

Methods: 388 patients with samples from baseline visit were selected from a longitudinal cohort of SLE subjects. IFNα2, IL1β, IL6, IL8, IP10, TNFα, VEGF and sCD40L levels were determined by a multiplexed immunoassay [Millipore]. Disease activity was assessed using SELENA-SLEDAI scores. 25OH-VD levels were measured using either a chemiluminescence or ELISA assay, and pts classified into 3 groups: normal (25OH-VD >30 ng/mL), insufficient (20–30) and deficient (<20). The

non-parametric two-sample median test was used to compare medians of cytokines in SLE pts vs controls. Pearson correlation was used to identify association of disease activity and physician global assessment (PGA) with cytokine levels.

Results: Most cytokines were significantly elevated in SLE patients vs controls, with the exception of IL8 that was significantly elevated in controls (Table). Of 379 subjects with 25OH-VD results, 36.1% (137/379) had deficiency, 29.3% (111/379) had insufficiency and 34.6% (131/379) had normal 25OH-VD levels. IP10 correlated with PGA and SLEDAI (PGA:0.15, p=0.0034 and SLEDAI:0.26, p<0.0001). All other correlations of cytokines and 25OH-VD with PGA and SLEDAI were not significant.

Table 1. Levels of cytokines in SLE patients vs control group

Cytokines	Controls/Median (N=30)	SLE/Median (N=388)	P–value
INFα2	0	10.37	0.012
IL–6	0	0.63	0.0025
IL–8	27.40	7.07	<0.0001
IL–1β	0	0.02	0.0004
TNFα	0	7.52	<0.0001
VEGF	88.30	158.65	0.0025
IP–10	96.22	413.48	<0.0001
sCD40L	16.39	2163.51	<0.0001

Conclusion: This study confirms numerous reports of elevated proinflammatory cytokines in SLE patients. Interestingly, over 2/3 of this population of SLE patients had below normal vitamin D levels but no correlation with SLEDAI or PGA was seen. The IFN-inducible cytokine IP10 correlated with increased disease activity as determined by both objective and subjective measures.

A Phase 1 Multicenter, Open-Label Study of MEDI-546, a Human Anti-Type I Interferon Receptor Monoclonal Antibody, in Adults with Scleroderma.

Avram Z. Goldberg[1], Thomas D. Geppert[2], Elena Schiopu[3], Tracy M. Frech[4], Vivien M. Hsu[5], Robert W. Simms[6], Stanford L. Peng[7], Yihong Yao[8], Nairouz Elgeioushi[8], Bing Wang[9], Linda Chang[9] and Stephen Yoo[8]. [1]North Shore-LIJ Health System, Lake Success, NY, [2]Metroplex Clinical Research Center, LLC, Dallas, TX, [3]University of Michigan, Ann Arbor, MI, [4]University of Utah School of Medicine, SLC, UT, [5]RWJ Med Schl Scleroderma Prog, New Brunswick, NJ, [6]Boston University School of Medicine, Boston, MA, [7]Benaroya Research Institute at Virginia Mason Medical Center, Seattle, WA, [8]MedImmune, Gaithersburg, MD, [9]MedImmune, Hayward, CA

Background/Purpose: Type I interferons (IFNs) have been implicated in the pathogenesis of scleroderma. This phase 1 study evaluated safety, pharmacokinetics (PK), pharmacodynamics, and immunogenicity of single and multiple intravenous doses of MEDI-546, a human monoclonal antibody directed against the type I IFN receptor, in adults with scleroderma.

Methods: Subjects ($\geq$18 years) who met the American College of Rheumatology criteria for scleroderma and had a modified Rodnan Total Skin Score $\geq$2 in an area suitable for repeat biopsy were enrolled in this multicenter open-label, dose-escalation study. Six cohorts received single doses (0.1, 0.3, 1.0, 3.0, 10.0, or 20.0 mg/kg) and 3 received multiple doses (0.3, 1.0, or 5.0 mg/kg weekly $\times$ 4) of MEDI-546. Subjects were evaluated through day 84 for single-dose groups and day 105 for multiple-dose groups. Safety assessments included adverse events (AEs) and laboratory tests. Serial blood samples were collected from all subjects for the determination of serum concentration of MEDI-546, the expression of type I IFN-inducible genes, and the presence of antidrug antibodies (ADAs).

Results: Of the 34 subjects, 33 completed the study. No trends in the type, frequency, or severity of AEs reported or laboratory abnormalities assessed were observed with increasing doses of MEDI-546. No deaths occurred during the study. Of the 4 treatment-emergent serious AEs (SAEs) reported, 1 (chronic myelogenous leukemia) was considered to be possibly treatment-related. The other 3 SAEs not considered to be treatment-related occurred in 2 subjects; 1 had vertigo and the other had osteomyelitis and skin ulcer. The most common treatment-emergent AEs were upper respiratory tract infection, headache, diarrhea, nausea, arthralgia, fatigue, and pruritus. Two subjects discontinued MEDI-546 after the first dose: 1 was due to an SAE of vertigo and an AE of head injury and discontinued the study 3 months later; the other was due to a non-SAE of normocytic anemia. MEDI-546 exhibited nonlinear PK at lower dose levels presumably due to the IFN receptor-mediated clearance. ADAs were detected in 2/21 subjects in the single-dose cohorts and 3/11 in the multiple-dose cohorts; 1 subject had persistent titers. The presence of ADAs had no effect on serum drug levels. At baseline, 22 subjects had positive type I IFN gene signature scores in whole blood. Subjects with positive baseline type I IFN gene signature score in whole blood reached or approached maximum inhibition of this signature within 1 day after dosing. The suppression persisted through day 84 in subjects receiving MEDI-546 at single-dose 20.0 mg/kg and multiple-dose $\geq$1 mg/kg. MEDI-546 at single-dose $\geq$0.3 mg/kg and multiple-dose $\geq$1 mg/kg suppressed the type I IFN gene signature in skin 7 and 28 days, respectively, after dosing.

Conclusion: The PK of MEDI-546 was subject to IFN receptor-mediated clearance at low-dose levels. The presence of ADAs had no apparent impact on PK. Decreased type I IFN gene expression in whole blood was seen at doses of $\geq$3 mg/kg after 1 day of dosing; expression decreased in skin after 7 days. These results and the safety profile observed in this study warrant further clinical development of MEDI-546.

693

A Placebo-Controlled Phase II Study of Hyperimmune Caprine Serum in Diffuse Cutaneous Systemic Sclerosis: Safety and Potential Efficacy.

Niamh P. Quillinan[1], Deirdre McIntosh[2], Syed Haq[2] and Christopher P. Denton[3]. [1]UCL Medical School, London, United Kingdom, [2]Daval International Ltd, Eastbourne, East Sussex, United Kingdom, [3]UCL, London, United Kingdom

Background/Purpose: We have performed a study to explore safety and tolerability of hyperimmune caprine serum (AIMSPRO®) prepared under GMP conditions in established diffuse cutaneous systemic sclerosis (dcSSc). Potential measures of efficacy and biological activity were also examined.

Methods: A double-blind parallel group placebo controlled clinical trial was performed under clinical trial authorisation with regulatory authorisation and institutional ethical approval. After informed consent, 20 patients with established dcSSc of greater than 3 years duration not receiving immunosuppressive therapy were randomised to receive either active (n=10) or placebo formulation (n=10) by subcutaneous twice weekly injection over 26 weeks. Clinical assessments evaluated over 26 weeks included modified Rodnan skin score (MRSS), pulmonary function indices and HAQ-DI.

Results: There were no safety concerns during this study. Frequency of adverse events was not different between active and placebo groups; 154 AE occurred in those receiving placebo and 139 AE in the AIMSPRO® treated subjects. The commonest adverse event was minor injection site reaction occurring in 12 subjects. There were 6 SAE in 3 subjects in the placebo group and 4 SAE in 3 subjects receiving active treatment. No SAE was judged treatment related.

Mean ($\pm$SD) baseline MRSS for the study cohort was 15.1 $\pm$7.1, with no significant difference between active or placebo groups. Mean skin score fell by 1.4$\pm$4.7 units with active treatment but worsened by 2.1$\pm$6.4 units on placebo. This difference did not reach statistical significance (p=0.18, unpaired t-test) but more cases on active treatment showed significant improvement of more than 4 units and over 20% of baseline MRSS (5/10) compared with placebo (1/10; p=0.01, Fisher exact test). HAQ-DI (Mean$\pm$SD) at baseline was 1.15$\pm$0.07 for active and 1.59$\pm$0.63 for placebo group and at 26 weeks was 1.24$\pm$0.98 for active and 1.56$\pm$0.55 for placebo. These changes were not statistically different (p=0.34, unpaired t-test).

Lung function indices (Table 1) showed a trend of benefit for active treatment compared to the placebo group for those variables that reflect respiratory effort (FVC and FEV1). DLco and TLC did not change during the study.

Table 1.

		Baseline	26 weeks	Units	p-value (unpaired t-test)
FVC	active	2.68±0.76	2.76±0.69	Litres	p=0.06
	placebo	3.12±2.96	2.96±0.92		
FEV1	active	1.99±0.45	2.02±0.44	Litres	p=0.10
	placebo	2.31±0.66	2.21±0.66		
DLco	active	5.73±1.80	5.61±1.87	mmol/min/kPA	p=0.36
	placebo	5.99±2.19	5.67±2.28		

Conclusion: These results demonstrate tolerability and safety of this novel biological agent in established diffuse cutaneous SSc. The value of a placebo treated control group in small clinical trials evaluating skin disease in SSc is confirmed. Potential improvement in MRSS in cases receiving active therapy and trends of improvement for pulmonary function indices suggest that this intervention may be of clinical benefit and warrants further evaluation.

Nilotinib (Tasigna™) in the Treatment of Early Diffuse Systemic Sclerosis: A Single Group, Open Label Pilot Clinical Trial. Jessica K. Gordon[1], Morgana L. Davids[1], Kamini Doobay[1], Cynthia Magro[2], Horatio F. Wildman[2], Stephen L. Lyman[1], Mary K. Crow[1] and Robert F. Spiera[1]. [1]Hospital for Special Surgery, New York, NY, [2]Weill-Cornell Medical Center, New York

Background/Purpose: Tyrosine kinase inhibitors (TKI) which selectively antagonize c-abl and PDGFR have been shown in preclinical models to decrease fibrosis. TKIs are therapies of interest for Systemic Sclerosis (SSc) with potential efficacy observed in several, but not all, open label studies of imatinib. Side effects relating to fluid retention were common and led to intolerance in some patients. Nilotinib is a second-generation TKI with increased potency and a different side effect profile compared to imatinib, specifically with less associated fluid retention.

Methods: In this single group, open label, pilot trial, we recruited 10 adult patients with diffuse cutaneous (dc) SSc of less than 3 yrs duration since the initial SSc symptom apart from the Raynaud's Phenomenon. Patients were treated with nilotinib 400 mg po twice daily. Patients were excluded if they had a QTc>450 msec. Concurrent immunosuppressive treatment was not allowed. The primary endpoint was safety as assessed by the number of adverse effects (AEs) and serious (S)AEs, and the primary efficacy endpoint was change in the Modified Rodnan Skin Score (MRSS) after 6 mo. Secondary endpoints include forced vital capacity (FVC), diffusion lung capacity (DLCO) and other measures. After 6 mo patients are offered continued treatment for an additional 24 mo. Skin biopsies are performed at baseline and after 6 and 12 mos.

Results: Nineteen patients were initially screened; 5 were excluded due to baseline QTc>450 msec. At baseline the median age was 46 (IQR 33, 52), 80% were female, 50% were Caucasian, and disease duration was 0.7 yrs (0.5, 1.7). 30% were SCL70 and 50% were PolIII positive. 30% had ILD. 70% demonstrated an increase in the MRSS in the 1 mo btwn screen and baseline, and 40% had tendon friction rubs. The baseline MRSS was 27.5 (IQR 22, 35).

Seven patients completed 6 mo; 3 patients stopped early − 2 due to Grade 1–2 QTc prolongation and 1 due to progression of preexisting coronary artery disease. 42 AEs and 2 SAEs were observed during the treatment period; 83% were considered to be at least possibly related to nilotinib. 97% of AEs were grade 1 or 2. No fluid retention was observed.

In the 7 patients who completed 6 mo of treatment, the MRSS improved from a baseline of 27 (IQR 22, 30) to 22 (16, 28) at 6 mo, p=0.047. The FVC was 81% predicted (73, 86) at baseline and 74% (69, 83) at 6 mo, p=0.25, and the DLCO was 73.5% (67, 81) at baseline and 68% (66, 84) at 6 mo, p=0.5. The physician global assessment improved from 61.3 (56.7, 81.3) to 32 (42.3, 55.3), p<0.01. There were no significant differences noted in the following: oral aperture, hand extension, finger to palm distance, ESR, SHAQ-DI, SF-36 mental or physical components, or the Medsger Severity Scale.

Conclusion: Nilotinib was tolerated by the majority of patients in this study. The MRSS improved significantly with 6 mo of treatment in this very early and active group of patients. The FVC and DLCO remained stable as did the additional outcome measures. Tolerability was limited primarily by mildly prolonged QTc, which is a known side effect of nilotinib and an exclusion criterion for continuation in this study. Baseline QTc prolongation also limited patient eligibility. Further study of nilotinib is warranted in a randomized controlled manner.

695

Comparison of Intense Pulsed Light and Laser Treatment of Telangiectases in Systemic Sclerosis. Graham Dinsdale[1], Andrea Murray[1], Tonia Moore[1], Janice E. Ferguson[2], Holly Ennis[1], Christopher E.M Griffiths[3] and Ariane Herrick[1]. [1]School of Translational Medicine, University of Manchester, Manchester Academic Health Science Centre, Salford Royal NHS Foundation Trust, Manchester, United Kingdom, [2]Dermatology Centre, Salford Royal NHS Foundation Trust, Manchester, United Kingdom, [3]Dermatology Centre, University of Manchester, Manchester Academic Health Science Centre, Salford Royal NHS Foundation Trust, Manchester, United Kingdom

Background/Purpose: Cutaneous telangiectases commonly occur in systemic sclerosis (SSc) and are distressing for the patient due to their perceived unsightly appearance. The current standard treatment is pulsed dye laser (PDL) therapy which is effective but often painful and does not prevent re-occurrence. Side effects include transient bruising and hypopigmentation. Intense pulsed light (IPL) is a potential alternative treatment using short, high-energy pulses of white light to destroy telangiectases via photothermal effects. IPL causes minimal bruising and no additional side effects compared to PDL. Our aim was to carry out an intra-patient comparison of PDL and IPL treatment of SSc-related telangiectases to determine relative efficacy and tolerability.

Methods: 20 patients (median 58 (range 49–72) years; 1 male) with SSc and approximately bilaterally-symmetric areas (face or upper limb) of telangiectases were recruited (1 withdrew after baseline). Patients were randomised to PDL treatment on the left/right side, with IPL treatment on the other. Following patch test of treatments (week −2; no adverse reactions reported), patients attended 3 treatment sessions at weeks 0 (baseline), 4 and 8. Photographs, dermoscopy and laser Doppler (LD) images of the treatment area were recorded prior to each treatment. Post-treatment, patients returned at 16 weeks and 9 months for repeat imaging and assessment. Photographs were assessed by comparison with baseline/previous image on a standardised scoring scale (−2 "much worse" to +2 "much better"). Dermoscopy images were assessed in the same way as the photographs. Average perfusion for 3 cardinal lesions on each side was extracted from the LD imaging data. Statistical analysis was carried out in SPSS.

Results: Both PDL and IPL treatment resulted in clinical improvement at most time points (Table 1, mean score values positive), as assessed by photographs and dermoscopy. The exception was dermoscopy at the week 16/month 9comparison, which showed slight negative (PDL) or zero (IPL) mean scores suggestive of worsening or neutral appearance of telangiectases. The differences between scores for PDL and IPL suggest that PDL was associated with greater treatment response. Analysis of LD images (ANOVA) showed no significant difference between PDL and IPL treatment response at any time point; however, when comparing baseline perfusion to that at Week 16 (paired-t test) significant differences were found for PDL (median [interquartile range]: baseline 3.3 [2.7–4.7], week 16 2.4 (1.5–3.2), p=0.009) but not IPL (baseline 3.4 [2.5–4.1], week 16 2.8 (1.9–3.1), p=0.053). There were no reported side effects with IPL; PDL caused transient bruising.

Table 1.

	Comparison	IPL	PDL	p–value (IPL–PDL difference)
Photographs‡	**Week 4 vs baseline (n=17)**	1.2 (1.0, 1.4)	1.3 (1.0, 1.5)	0.56
	Week 8 vs baseline (n=16)	1.4 (1.1, 1.8)	1.5 (1.2, 1.8)	0.62
	Week 16 vs baseline (n=15)	1.4 (0.9, 1.8)	1.7 (1.4, 2.0)	*0.01
	Month 9 vs Week 16 (n=8)	0.3 (−0.2,0.7)	0.3 (−0.1,0.7)	0.80
Dermoscopy‡	**Week 4 vs baseline (n=17)**	0.6 (0.3, 0.8)	0.8 (0.6, 1.0)	*0.02
	Week 8 vs baseline (n=16)	0.7 (0.4, 0.9)	1.0 (0.8, 1.3)	*0.04
	Week 16 vs baseline (n=13)	0.8 (0.6, 1.1)	1.3 (1.0, 1.5)	*0.02
	Month 9 vs Week 16 (n=6)	−0.0 (−0.5,0.5)	−0.3 (−0.6,0.0)	0.22

‡ – mean score (95% C.I.), *p<0.05

Conclusion:

1) IPL and PDL are both effective treatments of SSc-related telangiectases, as assessed in this intra-patient study by photographs and dermoscopy.

2) PDL therapy produces a greater treatment response than IPL; however IPL has fewer side effects.

Risk Factors for EARLY Mortality in Scleroderma Patients: A Report From the EULAR Scleroderma Trials and Research Group (EUSTAR) Database. Patricia E. Carreira[1], Loreto Carmona[2], Beatriz E. Joven[3], Christopher P. Denton[4], Yannick Allanore[5], Ulrich A. Walker[6], Marco Matucci-Cerinic[7], Ulf Müller-Ladner[8] and Eustar[9]. [1]Hospital Universitario 12 de Octubre, Madrid, Spain, [2]Universidad Camilo José Cela, Villanueva de la Cañada, Spain, [3]HOSPITAL UNIVERSITARIO 12 DE OCTUBRE, Madrid, Spain, [4]UCL, London, United Kingdom, [5]Paris Descartes University, Rheumatology A department, Cochin Hospital, Paris, France, [6]Universitäts-Poliklinik, Felix-Platter Spital, Basel, Switzerland, [7]University of Florence, Florence, Italy, [8]Kerckhoff-Klinik GmbH, Bad Nauheim, Germany, [9]Florence

Background/Purpose: To identify risk factors for early mortality in a large group of recently diagnosed systemic sclerosis (SSc) patients

Methods: EUSTAR collects prospectively the Minimal Essential Data Set (MEDS), on all sequential patients fulfilling the American College of Rheumatology diagnostic criteria in participating centres, in an annual basis. Patients with disease duration of less than 3 years at the first EUSTAR entry, and with at least one follow-up visit, were selected. Baseline data from the first visit were compared between SSc cases registered as dead up to December 2011, and living patients. Kaplan-Meier analysis was used to estimate survival, and Cox proportional hazards regression analysis, corrected by age at the end of follow-up, was used to identify factors associated with early mortality.

Results: From 1188 patients, 671 (19% men) had at least one follow-up visit. From those, 276 had diffuse and 348 had limited disease. Mean age at entry was 53 ± 15 years, and at first non Raynaud symptom 50 ± 15 years. Mean disease duration was 19 ± 6 months and time between the onset of Raynaud and first non Raynaud symptom was 4 ± 7 months. After 43 ± 24 months of follow-up from the first visit and 57 ± 26 months from the first non Raynaud symptom, 111 patients (17%) were dead. Death occurred after 43 ± 27 months from the first non Raynaud symptom. Mean survival for the whole group was 116 (95%CI 110–122) months. By Cox proportional hazards regression multivariate analysis, main risk factors for mortality were: higher skin score (HR 1–03, 95%CI 1.003–1.05, p=0.02), acute phase reactants elevation (HR 1.8, 95%CI 1.1–2.8; p=0.02), joint contractures (HR 1.8; 95%CI 1.1–2.8; p=0.002), CK elevation (HR 1.9, 95%CI 1.1–3.3, p=0.04), cardiac blocks (HR 2.1, 95%CI 1.3–3.3, p=0.004), diastolic dysfunction (HR 2.1, 95%CI 1.3–3.3, p=0.002) and ischemic ulcers (HR 1.9, 95%CI 1.2–2.9, p=0.007). When only diffuse patients were analyzed, CK elevation, FVC below 80% and pulmonary hypertension were the risk factors for mortality. In the other hand, bad prognostic factors in limited patients were joint contractures, CK elevation, cardiac blocks, proteinuria and renal crisis.

Conclusion: In this large group of SSc patients, risk factors for early mortality are higher skin involvement with more severe vascular disease and cardiac involvement, especially if associated to elevated acute phase response. Muscular and cardiac involvement appear as a risk factor for mortality both in limited and diffuse disease, whereas lung and renal involvement have a mayor impact in diffuse and limited cases respectively.

Demographic, Clinical, Serologic and Socioeconomic Measures Each Predict Mortality in Scleroderma. Allan C. Gelber, Rebecca L. Manno, Adrianne Woods, Ami A. Shah, Francesco Boin, Laura K. Hummers and Fredrick M. Wigley. Johns Hopkins University, Baltimore, MD

Background/Purpose: The epidemiologic literature has identified several demographic, clinical and serologic predictors of mortality in systemic sclerosis (scleroderma). Yet, relatively few cohorts are of sufficient size and racial composition to examine the independent contribution of these parameters to survival. We sought to determine the adjusted risk of mortality in scleroderma associated with gender, race, disease subset, and serologic and socioeconomic status in a large observational cohort study.

Methods: Between January 1, 1990 and December 31, 2009, a total of 2217 patients with scleroderma, either African American (n=409, 18%) or Caucasian (n=1808, 82%), were evaluated at a single university medical center. The vital status of the cohort was ascertained using the Social Security Death Index; cumulative incidence of mortality was estimated using Kaplan-Meier analysis. Next, the independent risk of mortality was estimated using Cox proportional hazards analysis, with adjustment for age at disease onset and disease duration, in addition to each variable depicted in the table below.

Results: This cohort of 2217 patients was 1838 (83%) female; mean age (+SD) at disease onset was 46 (+14) years. Among these patients, 1387 (63%) manifested the limited and 830 (37%) the diffuse cutaneous subtype of disease. Overall, 1846 (83%) fulfilled ACR criteria for scleroderma, whereas 361 (16%) satisfied at least 3 of 5 CREST criteria. Among the 1511 patients whose sera was tested for anti-centromere, and 1393 assayed for anti-topoisomerase antibodies, 452 (30%) and 294 (21%) were seropositive, respectively. In addition, 11% of the cohort had medical assistance or no health insurance, whereas 89% had Medicare or private insurance. During a median follow-up period of 4 years, 700 patients died. Overall, cumulative mortality at 1 and 5 years of follow-up was 8% and 32%, respectively. The relative risk of mortality, in two multivariate models, was as follows:

Multivariate Model 1	Adjusted RR	95%CI	Multivariate Model 2	Adjusted RR	95%CI
Male vs Female	1.4	1.1–1.9	Male vs Female	1.4	1.1–1.9
African American vs Caucasian	1.5	1.1–2.1	African American vs Caucasian	1.3	1.0–1.8
Diffuse vs Limited	1.4	1.0–1.8	Diffuse vs Limited	1.2	0.9–1.5
Topoisomerase antibody, pos vs neg	1.0	0.7–1.3	Anti–centromere antibody, pos vs neg	0.8	0.6–1.0
Health Insurance, MA/no vs Mdcr/yes	1.2	0.8–1.7	Health Insurance, MA/no vs Mdcr/yes	1.4	1.0–1.8

Conclusion: Persons with scleroderma who are male, African American, with diffuse cutaneous disease, and those without private or Medicare health insurance, experienced a heightened risk of mortality. Anti-centromere, but not topoisomerase, antibody was protective against mortality. These findings imply that demographic, clinical features, serologic and socioeconomic status, each impact upon and contribute to the risk of survival in scleroderma.

External Validation of a Two-Year Mortality Risk Prediction Rule in Early Diffuse Systemic Sclerosis Patients. Robyn T. Domsic[1], Svetlana Nihtyanova[2], Stephen R. Wisniewski[3], Michael J. Fine[4], C. Kent Kwoh[5], Christopher P. Denton[6] and Thomas A. Medsger Jr.[7]. [1]University of Pittsburgh, Pittsburgh, PA, [2]Royal Free Hospital, Medical School, London, England, [3]University of Pittsburgh, Graduate School of Public Health, Pittsburgh, PA, [4]University of Pittsburgh and Center for Health Equity Research and Promotion, VA Pittsburgh Healthcare, Pittsburgh, [5]University of Pittsburgh and VA Healthcare System, Pittsburgh, PA, [6]UCL, London, United Kingdom, [7]Univ of Pittsburgh, Pittsburgh, PA

Background/Purpose: The ability to risk stratify patients for short term mortality is important in SSc patient care and clinical trial design; but there is no externally validated short term mortality model in early diffuse cutaneous systemic sclerosis (dcSSc). We have previously used a prospectively enrolled large American single center SSc databank to develop and internally validate a 4-factor risk stratification model for two year mortality. Our objective was to externally validate this two year mortality model in a European population of early dcSSc Caucasian patients.

Methods: A large European single-center prospectively enrolled SSc databank was used to identify an inception cohort of adult early dcSSc seen for an initial visit between 2000 and 2006 to serve as the external validation cohort. Patients were considered to have early dcSSc if their first visit occurred< 2 years after the first symptom attributable to SSc with skin thickening proximal to the elbows or knees. Vital status was determined using the UK National Care Records Service.

We used a 4-factor model (age at first visit, gastrointestinal severity, skin thickness progression rate and presence of anemia) to calculate a total sum score (range of −1 to 8) and risk stratify patients into low, moderate and high risk for two year mortality in the original derivation and external validation cohort. Multiple data imputations were used for missing data in the validation

cohort. Stratum-specific chi-squares were compared for the low, moderate and high risk groups.

Results: Of 160 European early dcSSc patients, 110 were Caucasian, and formed the external validation cohort. The validation cohort had a mean age of 51.2 ± 12.4 years, was 74% female and a mean modified Rodnan skin score (mRss) of 26.6 ± 8.1. Median disease duration from first SSc symptom was1.02 years (IQR 0.78, 1.49), or 0.78 years (0.52, 1.17) from first non-Raynaud symptom. There was no significant difference in age, gender, disease duration or mRss between the validation and derivation cohort. At two years, 7.3% had died in the validation cohort, compared to 22.6% in the original derivation cohort (p=0.0005). The stratum-specific comparison of mortality rates using this risk model are shown in Table 1. There was no difference in prediction of low or moderate risk groups between the models.

Table 1. Comparison of risk class specific two-year mortality rates in the derivation and validation cohorts

Risk Class (sum of points)	Derivation cohort (n=252)		Validation cohort (n=110)		p-value
	total n	% who died	total n	% who died	
Low (≤ 0)	63	1.6	33	3.0	0.64
Moderate (1–2)	108	14.8	61	8.2	0.21
High (3 ≤)	81	49.4	16	12.5	0.006

Conclusion: We have now validated a two year mortality risk stratification model for early dcSSc patients in American and European cohorts. In this external validation, the model accurately predicted those at low and moderate risk of death at two years from the first visit. There was a significantly lower rate of death in the validation cohort, possibly related to the inclusion of only recent patients or differences in the underlying populations, which may have affected performance in the high risk group. This model may be used to risk stratify patients for short-term mortality.

Endothelial Dysfunction and Vascular Stiffness in Early Diffuse Systemic Sclerosis. Robyn T. Domsic[1], Dana Ivanco[1], Hunter C. Champion[1], Ali Shoushtari[1] and Thomas A. Medsger Jr.[2]. [1]University of Pittsburgh, Pittsburgh, PA, [2]Univ of Pittsburgh, Pittsburgh, PA

Background/Purpose: Vascular dysfunction is a hallmark of systemic sclerosis (SSc). Current theories postulate endothelial injury and dysfunction as an early event in SSc pathogenesis. Prior cross-sectional studies suggest endothelial dysfunction and increased vascular stiffness in SSc, but generally use longstanding patients. Our aim was to measure and describe endothelial function and vascular stiffness in an inception cohort of early diffuse SSc patients.

Methods: Early diffuse SSc was defined as < 2 years from the first symptom attributable to SSc and skin thickening proximal to the elbows or knees. SSc patients were matched 1:1 with age (± 2 years), gender and race matched healthy controls. Vasodilators were held for 24 hours. Aortic pulse wave velocity (PWV) was used to assess vascular stiffness by averaging two measures recorded simultaneously at the carotid and femoral arteries. In a quiet and temperature controlled exam room, all underwent assessment of endothelial function with three validated methods: 1) assessment of endothelial-dependent flow-mediated dilation (FMD) by ultrasound before and after reactive hyperemia (RH) of the medium-sized brachial artery induced by pneumatic cuff for 5 minutes; 2) endothelial-independent vasodilation of the brachial artery before and after nitroglycerin (NTG); 3) assessment by Endo-PAT™, which measures the pulse wave amplitude before and after RH using a pneumatic probe on the index finger. FMD was expressed as % change in diameter after RH and NTG. EndoPAT calculates a reactive hyperemia index (RHI), with a RHI of < 1.67 previously validated as the cut-off for endothelial dysfunction. Differences in PWV, FMD, NTG and RHI were assessed by paired t-tests.

Results: 16 early diffuse SSc patients were compared to 16 age, gender and race-matched controls. The mean age in cases was 48.9 years (controls 48.2), 56% were female, 94% Caucasian and 6% Asian. The median disease duration at time of vascular study was 1.2 years (0.9, 1.8), and the mean modified Rodnan skin score 20.8 ± 8.3. 86% of patients experienced Raynaud phenomenon, 37% had digital pitting scars and none had renal crisis. 69% were on immunosuppressive agents. There was no difference in PWV between patients (6.58 ± 1.40) compared to controls (6.28 ± 1.04; p=0.67).

The median FMD % change after RH was not significantly different in cases and controls (4.6% ±5.1 vs 5.0%±5.3; p=0.10), or after NTG administration (p=0.90). However, there was a significant difference in EndoPAT RHI of 1.20 (±0.56) for patients and 2.06 (±0.52) for controls (p=0.002). Overall, 80% of patients had abnormal RHI suggesting ED, compared to 20% of controls.

Conclusion: There is no difference in large vessel vascular stiffness between early diffuse SSc patients and age, gender and race matched controls. Similarly, there is no difference in brachial-artery FMD to RH or NTG, suggesting no difference in endothelial function of the medium-sized arteries. However, there was significantly increased endothelial dysfunction of the small arterioles as measured by EndoPAT. These results suggest that endothelial changes occur in smaller arterioles and microvascular beds in early SSc, but not in macrovascular beds.

Clinical Correlation of Flow-Mediated Endothelium-Dependent Vasodilatation in Systemic Sclerosis. Takehiro Takahashi[1], Yoshihide Asano[1], Eisuke Amiya[2], Masaru Hatano[2], Atsuko Ozeki[2], Aya Watanabe[2], Shuichi Kawarasaki[2], Tomoko Nakao[2], Zenshiro Tamaki[1], Takashi Taniguchi[1], Yohei Ichimura[1], Tetsuo Toyama[1], Masafumi Watanabe[2], Yasunobu Hirata[2], Ryozo Nagai[2] and Shinichi Sato[1]. [1]Department of Dermatology, University of Tokyo Graduate School of Medicine, Tokyo, Japan, [2]Department of Cardiovascular Medicine, University of Tokyo Graduate School of Medicine, Tokyo, Japan

Background/Purpose: Systemic sclerosis (SSc) is a multisystem autoimmune disease characterized by initial vascular injuries and resultant fibrosis of skin and certain internal organs. Evidence has shown that vascular impairment in SSc may be a sign of endothelial dysfunction involving both microvascular and macrovascular systems. Ultrasound assessment of brachial artery endothelial-dependent flow-mediated dilation (FMD) is a noninvasive instrumental evaluation that is routinely performed as an index of macrovascular function. We evaluated the association of FMD with clinical features of SSc to assess the possible contribution of endothelial dysfunction to the developmental process of clinical features associated with this disease.

Methods: Twelve healthy controls and thirty-five consecutive patients with SSc (mean age 53 ± 17 years and 57 ± 11 years, respectively) were studied. In patients, clinical symptoms, such as swollen fingers, nailfold bleeding (NFB), pitting scars, digital ulcers, and Raynaud's phenomenon, were meticulously recorded. Eighteen patients had limited cutaneous SSc (lcSSc) and 17 had diffuse cutaneous SSc (dcSSc). Ultrasound assessment of FMD was performed on all patients. Correlation between FMD value (%FMD) and various typical symptoms, disease duration, and subtype of SSc was studied.

Results: There was significant decrease in %FMD in patients compared to healthy controls (5.72% versus 7.71%, respectively; p = 0.041). Especially, lcSSc patients had significantly lower %FMD values than healthy controls (5.25% versus 7.6%, p = 0.016), while the levels in dcSSc patients (6.8%) were comparable to those of healthy controls. Furthermore, in lcSSc patient group, patients with decreased %FMD had much longer disease duration than those with normal %FMD (p = 0.0088), while the age of these two patient groups was comparable. As for clinical symptoms, lcSSc patients with decreased %FMD showed much higher prevalence of digital ulcers and elevated RVSP than those with normal %FMD (for each; 75% versus 10%, p = 0.040). In addition, there was a trend towards the increase in the prevalence of decreased %DLco, but not decreased %VC, in lcSSc patients with decreased %FMD as compared to those with normal %FMD.

Conclusion: Endothelial function evaluated by %FMD is markedly impaired in SSc patients. lcSSc patients with decreased %FMD exhibited a significantly higher prevalence of clinical symptoms associated with vasculopathy. Furthermore, the values of %FMD greatly and inversely correlated with disease duration in lcSSc patients. Collectively, %FMD is potentially a powerful tool to evaluate the damage of vascular system in SSc, especially in limited cutaneous subtype of this disease.

Vascular Differences Associated to Genetic Polymorphisms of Endothelial Nitric Oxide Synthase in Mexican Patients with Systemic Sclerosis. A Preliminary Report. Maria Pilar Cruz-Dominguez[1], Maria Angeles Martinez-Godinez[2], Angel Miliar-Garcia[2], Daniel Hector Montes-Cortes[3], Olga Vera-Lastra[4], Luis J. Jara-Quezada[5] and Anabel Reyes-Salazar[6]. [1]Hospital de Especialidades Centro Medico Nacional La Raza., Mexico, DF, Mexico, [2]Escuela Superior de Medicina. IPN, Mexico, D.F., Mexico, [3]Hospital General CMN La Raza, IMSS, Mexico DF, Mexico, [4]MD, Mexico City, Mexico, [5]Hospital de Especialidades Centro Médico La Raza, IMSS, Mexico City, Mexico, [6]Hospital de especialidades Centro Medico National "La Raza", IMSS, Mexico, D.F., Mexico

Background/Purpose: Vascular dysfunction usually is observed before clinically detectable fibrosis of systemic sclerosis (SSc). The eNOS catalyses the synthesis of **nitric oxide** (NO), which maintains basal vascular tone **and endothelial** function. **Abnormal production of** e-NOS and/or iNOS impairs NO availability causing vascular disease. Genetic polymorphism may participate in these alterations.

Objective: To investigate vascular differences associated to polymorphisms T-786C and G894T of the *eNOS* gene on differential expression of eNOS/iNOS in the skin and vascular Duplex Sonography parameters of SSc patients.

Methods: We included 139 consecutive SSc patients. The genotyping of T-786C and G894T polymorphisms of *eNOS* gene was performed by **Polymerase Chain Reaction Real-Time Assay**. The control group included 180 age-matched healthy volunteers. For the eNOS/iNOS skin expression we included 31 patients (14 lcSSc and 17 dcSSc).

Results: In lcSSc: T-786C prevalence was TT65.5%, TC30.2% and CC4.3% (OR 1.8, IC 0.4–7.9 associated to SSc); and the G894T prevalence was GT74.3%, GT20.3% and TT5.4% (OR 1.94, IC 0.54–7.04 associated to SSc). In dcSSc: the T-786C prevalence was TT76.6%, TC20%, and CC3.3%, and G894T polymorphism was GT 82%, GT 18% and TT 0% without association with SSc. In control group: the prevalence of T-786C polymorphism was TT68.45%, TC29.4%, and CC2.22%; for G894T polymorphism was GG74.1%, GT23.02%, TT2.87%. The mean relative expression of eNOS was $10.17 +/- 15.5$ and iNOS of $7.6 +/- 13.05$ in lcSSc. For dcSSc the mean relative expression of eNOS was $1.74 +/- 1.16$ and iNOS of $2.1 +/- 2.5$. $1.08 +/- 0.3$ and $1.36 +/- 0.7$ in skin of volunteers of control group. Left brachial intima-media thickness was statistically significantly greater in allelic variants of eNOS in SSc (p=0.025).

Conclusion: In the skin of both subtypes of systemic sclerosis, the relative expression of eNOS and iNOS is increased. Genetic polymorphisms of eNOS is associated with anormal intima-media thicknes in SSc patients.

Arterial Stiffness Is Increased in Systemic Sclerosis: A Cross-Sectional Comparison with Matched Controls. Gene-Siew Ngian[1], Joanne Sahhar[2], Ian Wicks[3] and Sharon Van Doornum[4]. [1]The University of Melbourne, Parkville, Australia, [2]Monash Medical Centre, Clayton, Australia, [3]Royal Melbourne Hospital, Parkville, Australia, [4]The University of Melbourne, The Royal Melbourne Hospital, Melbourne, Australia

Background/Purpose: Atherosclerosis may be increased in systemic sclerosis (SSc)[1]. Increased arterial stiffness is a predictor of cardiovascular and all-cause mortality across a wide range of patient populations. Our aim was to determine if arterial stiffness is elevated in SSc and to evaluate correlates of arterial stiffness in SSc patients.

Methods: We performed two studies: 1) a comparison of arterial stiffness in 40 SSc patients free from cardiovascular disease or significant vascular manifestations of SSc (i.e. pulmonary arterial hypertension or scleroderma renal crisis) and 40 age- and sex-matched healthy controls, and 2) an analysis of determinants of arterial stiffness in a larger, unselected cohort of 80 SSc patients (which included the 40 patients from study 1). Arterial stiffness was measured using the augmentation index (AIx) and carotid-femoral pulse wave velocity (PWV), both of which increase with increasing arterial stiffness.

Results: In study 1 the SSc and control groups were well matched for age (52.2 vs 50 years respectively), sex (80% female in both groups) and cardiovascular risk factors. SSc patients had significantly higher AIx than controls ($31.2 +8.4$ vs $20.9 + 12.6\%$ respectively, $p<0.001$), with a non-significant increase in PWV ($7.3 +1.8$ vs $6.8 +1.1$m/s respectively, p=0.101).

In study 2, univariate analysis of the entire SSc cohort revealed that higher AIx was significantly associated with age ($p<0.001$), disease duration (p=0.001), anti-centromere antibody positivity (p=0.016), calcium channel blocker (CCB) therapy (p=0.004), systolic blood pressure (BP) (p=0.001) and diastolic BP (p=0.029). Higher PWV was significantly associated with age ($p<0.001$), disease duration (p=0.001), anti-centromere antibody positivity (p=0.022), lack of anti-Scl-70 antibody positivity (p=0.001), lower modified Rodnan skin score (p=0.016), angiotensin converting enzyme inhibitor therapy (p=0.035), systolic BP ($p<0.001$) and diastolic BP ($p<0.001$). After adjusting for age, CCB therapy remained predictive of higher AIx (p=0.014) and systolic ($p<0.001$) and diastolic (p=0.005) BP remained predictive of higher PWV.

Conclusion: Compared with healthy controls, SSc patients had increased arterial stiffness, with significantly higher AIx and non-significantly higher PWV. This suggests that patients with SSc may have an increased prevalence of subclinical atherosclerosis. After adjusting for age, CCB therapy was associated with higher AIx, which is paradoxical given that CCB therapy in hypertensive individuals decreases arterial stiffness, if anything[2]. Given that CCBs are first-line therapy for Raynaud's phenomenon in SSc, this association could reflect generalized vasculopathy rather than atherosclerotic disease. Prospective studies in large cohorts of patients are warranted to clarify this point and elucidate other determinants of arterial stiffness in SSc.

703

Vascular Ischemic Events in Systemic Sclerosis - a Cross-Sectional Comparision with population-Based Controls. Annica Nordin[1], Kerstin Jensen-Urstad[2], Lena Björnådal[1] and Elisabet Svenungsson[1]. [1]Rheumatology Unit, Karolinska Institutet, Stockholm, Sweden, [2]Department of Clinical Physiology, Södersjukhuset, Karolinska Institutet, Stockholm, Sweden

Background/Purpose: To investigate the occurrence of ischemic vascular events and subclinical atherosclerosis in patients with systemic sclerosis (SSc) and matched population controls.

Methods: 111 SSc patients (74% of the patients in Stockholm County) and 105 controls were investigated in this population-based study. Previous ischemic vascular events were defined as:

1. Ischemic heart disease (IHD): myocardial infarction (confirmed by electrocardiography and a rise in plasma creatine kinase, muscle and brain fraction (CK-MB) or troponin T) or angina pectoris (confirmed by exercise stress test)

2. Ischemic cerebral vascular disease (ICVD): cerebral infarction (confirmed by computer tomography) or transitory ischemic attacks (TIA, defined as transient focal symptoms from the brain or retina with a maximum duration of 24 hours),

3. Ischemic peripheral vascular disease (IPVD): intermittent claudicatio + ankle-brachial index (ABI) < 0.9 or peripheral arterial thrombosis/embolus (confirmed by angiogram or Doppler flow studies).

As measures of subclinical atherosclerosis intima media thickness (IMT) and plaque occurrence was determined with carotid ultrasound and the ABI was calculated.

Results: Mean age was 62 ± 12 years for patients and controls. In the patient group disease duration was 9.4 (5.6 – 17.4) years, 78% had limited cutaneous systemic sclerosis (lsSSc) and 32% had anti-centromere antibodies (ACA). Ischemic vascular events were more common in the patients (18% vs 7%, p=0.01) due to an increased occurrence of both ischemic heart disease (IHD) and ischemic peripheral vascular disease (IPVD) (12% vs. 4% p=0.03 and 8% vs. 1% p=0.02 respectively). Ischemic cerebral vascular disease was uncommon in both the patient and control group. On a group level frequency of plaques, IMT or ABI did not differ between SSc patients and controls, but the subgroup of patients with ACA had more plaques in comparison both to other SSc patients (67% vs. 39%, p=0.006) and to controls (67% vs. 41%,

p=0.02). Patients with ACA also had more ischemic events than other patients (32% vs 11% p=0.01) and controls (32% vs 7% p=0.0003).

	Patients (n = 111)	Controls (n = 105)	Odd Ratio (95% CI)	P-value
Event % (n)	18 (20)	7 (7)	3.1 (1.2–7.6)	0.01
IHD % (n)	12 (13)	4 (4)	3.3 (1.1–10.6)	0.03
ICVD % (n)	3 (4)	3 (3)	0.9 (0.2–4.7)	ns
IPVD % (n)	8 (9)	1 (1)	9.2 (1.1–73.7)	0.02
Plaque % (n)	48 (52)	41 (43)	1.3 (0.7–2.3)	ns
			b-coefficient	
IMT mm	0.68 ± 0.13	0.68 ± 0.13	−0.02	ns
ABI	1.13 (1.1–1.2)	1.12 (1.1–1.2)	−0.08	ns

Conclusion: Patients with SSc have more ischemic heart disease and ischemic peripheral vascular disease than controls. The subgroup of SSc patients with ACA seems to be at particularly high risk to develop both ischemic event and premature atherosclerosis. This group should thus be followed closely and vascular prevention considered at an early stage when indicated. The importance to investigate subgroups of well-characterized patients is underscored by this study.

Decreased Number of Endothelial Progenitor Cells in Systemic Sclerosis Patients with Early Disease. Fernando V. Andrigueti, Maria I. Arismendi, Pâmela C.C. Ebbing and Cristiane Kayser. Universidade Federal de São Paulo, São Paulo, Brazil

Background/Purpose: Microangiopathy and endothelial dysfunction are present in early phases of Systemic sclerosis (SSc), resulting in decreased blood flow and tissue ischemia. Several mechanisms including insufficient angiogenesis, and defective vasculogenesis mediated by endothelial progenitor cells (EPCs), might be involved in the vascular abnormalities in SSc patients. However, different data have been reported regarding the number and function of EPCs in different clinical subsets of SSc patients. This study aimed to evaluate the circulating number and the in vitro culture of EPCs in SSc patients with early disease compared to healthy controls.

Methods: Thirty-one consecutive SSc female patients (mean age 42.7 years) with less than four years of Raynaud's phenomenon (RP) and 20 age-matched healthy women (mean age 39.9 years) were included. All patients fulfilled the ACR classification criteria for SSc (1980) or the LeRoy and Medsger criteria (2001). Peripheral blood samples (30mL) were collected from each subject at rest. Flow cytometry was performed to quantify the absolute number of EPCs. EPCs were identified by the co-expression of CD34, CD133 and vascular endothelial growth factor receptor type 2 (VEGFR2) and were expressed as the number of EPCs per 10^6 lymphomononuclear (LMN) cells. Besides, in vitro culture of EPCs was performed, and the number of EPC colony-forming units (CFU) per well was quantified in each sample. All procedures were performed according the EULAR recommendations and executed immediately after blood collection. Plasma VEGF levels were assessed by ELISA. p<0.05 were considered statistically significant.

Results: Among SSc patients, the mean duration of RP was 3.75±1.96 years and the mean duration of the first SSc symptom other than RP was 3.24±1.85 years. Digital ulcers were present in ten patients. SSc patients showed decreased number of EPCs (108.6±87.2 vs 246.8±241.4 /10^6LMN, respectively, p=0.04), and decreased number of EPC CFUs compared to controls (14.6±9.1 vs 20.9±11.5 CFUs, respectively, p=0.034). There was no significant difference in the number of EPCs between SSc patients with digital ulcers and those without digital ulcers at the time of the evaluation (90.5±73.2 vs 121.4±96.5 /10^6LMN, respectively, p=0.4). There was a positive correlation between the number of circulating EPCs and the number of EPC CFUs. There was no difference in VEGF levels between patients and controls (88.3±57.9 vs 83.8±74.6 ng/mL, p=0.34).

Conclusion: The present study showed originally decreased EPCs in SSc patients with early disease onset, suggesting presence of defective vasculogenesis in early stages of the disease. Therefore, EPCs could be an important therapeutic target for preventing vascular complications in patients with early stages of SSc.

Adipose Derived Stem Cells As an Alternative Source of Cellular Repair for Vascular Dysfunction in Systemic Sclerosis. Nevin Hammam[1] and Hazem Orabi[2]. [1]Assiut University, Assiut, Egypt, [2]Knuppe Molecular Laboratory, San Francisco, CA

Background/Purpose: Systemic sclerosis (SSc) is autoimmune disease characterized by autoimmunity, diffuse fibrosis in the skin and internal organs, and vasculopathy in moderate size arteries and arterioles. The vasculopathy associated with SSc is one of the major contributors to the clinical manifestations of the disease and can result in non healing ulcers, gangrene and digit loss, hypertension and cardiovascular disease and it has a profound impact on the quality of life. Endothelial injury, smooth muscle cells proliferation and fibrosis of the vessel wall result in lumen occlusion and tissue hypoxia that is treated currently with pharmacologic agents. New therapies including stem cells are needed to reconstitute the diseased vascular tissue. Adipose derived stem cells (ADSCs) represent an ideal stem cell source for SSc vasculopathy therapy.

The aim of this study is to investigate if human ADSCs can be differentiated into smooth muscle cells (SMC) and endothelial cells (EC) and if these differentiated cells can be constructed into cell sheets and vascular tissue.

Methods: Human ADSCs were isolated expanded, induced into EC and SMC using endothelial growth medium-2 (EGM-2) and Transforming growth factor (TGF-β1) respectively. The growth and morphology of the cells were followed up for 4 weeks. The phenotype of induced cells were checked for SMC markers; actin, calponin and heavy chain myosin and for endothelial cell markers; CD31 and Von Willebrand factor (vWF) through immunocytochemistry and western blot. The induced SMC and EC cells were used to construct either SMC and EC cell sheets or bilayered vascular structures by culturing them in special culture dishes. Confluent cultured cells were harvested as a contiguous cell sheet only by lowering temperature. The cell sheets and vascular structures were stained with H&E and Masson Trichrome and verified for smooth muscle markers and for endothelial cell markers. The formation of extracellular matrix of the both cell sheets was tested using Picrosirius Red staining and collagen IV.

Results: The induced cells showed positive staining for endothelial cell markers after 2 weeks and smooth muscle markers after 3 weeks for SMC cells. The western blot confirmed their phenotype conversion. The cell sheets and vascular structures were detached easily in a consistent manner by lowering the temperature in intact and viable condition. The monolayer cell sheets were formed of 2–5 cell layers that showed positive staining for either SMC or EC markers. They also showed positive staining for Picrosirius Red and collagen IV indicating the formation of extracellular matrix. Vascular structures exhibited upper layer of EC and multiple layers of SMC with collagen layer in between.

Conclusion: The results showed the ability of human ADSCS to form SMC and EC and constitute renewable source for cellular therapy. The cell sheets and vascular structures made of ADSCs form new technology for improvement of vascular dysfunction in SSc.

Excess Mortality From Atherosclerotic Cardiovascular Disease in Systemic Sclerosis Compared to Lupus and Rheumatoid Arthritis. Amish J. Dave[1], Bharathi Lingala[2], David Fiorentino[3], Eswar Krishnan[1] and Lorinda Chung[4]. [1]Stanford University, Stanford, CA, [2]Stanford University, Redwood City, CA, [3]Stanford University School of Medicine, Redwood City, CA, [4]Stanford Univ Medical Center, Palo Alto, CA

Background/Purpose: Patients with autoimmune connective tissue diseases (CTD), including systemic lupus erythematosus (SLE) and rheumatoid arthritis (RA), are at increased risk for atherosclerotic cardiovascular disease (ASCVD) compared with the general population. Recent reports indicate an increased prevalence of ASCVD in patients with systemic sclerosis (SSc), thought to be mediated through inflammatory mechanisms affecting vascular integrity, including endothelial cell damage and increased collagen deposition. Our aim was to utilize the Nationwide Inpatient Sample (NIS) to assess the prevalence of and mortality risk associated with ASCVD among hospitalized patients with SSc.

Methods: The NIS is a national, annual, representative survey of hospitalized patients in the US. We examined the in-hospital frequency and mortality rates of specific diagnoses and procedures associated with ASCVD

among hospitalized adult patients with SSc using data from the NIS from 1993 to 2007. The following diagnoses and procedures were identified by ICD-9 codes: coronary artery disease, myocardial infarction, cerebrovascular accidents, coronary artery bypass grafts, and percutaneous transluminal coronary angioplasty. Analyses were weighted so results are standardized to the US population as a whole. Using logistic regression, we compared the odds of death among hospitalized SSc patients with each ASCVD diagnosis or procedure to patients with SLE or RA, and to a control group that excluded patients with any CTD diagnosis and were matched to cases by age, gender, and race. Multivariate analyses controlled for demographics, comorbid diseases using the Charlson comorbidity index, elective vs. emergent hospitalizations, and the number of diagnoses.

Results: A total of 308,452 hospitalizations of SSc patients occurred in the US between 1993 and 2007. The mean age was 61.5 years, 84% were female, and 59% were white. 12% of all SSc hospitalizations were associated with an ASCVD diagnosis or procedure, compared with 11% of SLE and 15% of RA hospitalizations. SSc hospitalizations associated with ASCVD were 1.5 times more likely to result in death compared with SSc hospitalizations not associated with ASCVD (OR 1.5, 95% CI 1.4–1.6, p<.001). Highest odds of in-hospital death were associated with CAD/MI (OR 1.7, 95% CI 1.6–2.0, p<.001) and CVA (OR 1.4, 95% CI 1.2–1.6, p<.001). Multivariate analyses showed that SSc hospitalizations associated with ASCVD were more likely to result in death than hospitalizations of SLE (OR 1.6, 95% CI 1.4–1.9, p<.001), RA (OR 2.6, 95% CI 2.3–3.0, p<.001), and control patients (OR 1.6, 95% CI 1.4–1.8, p<.001) with ASCVD.

Conclusion: Although the frequency of hospitalizations associated with ASCVD in SSc patients is similar to that in SLE and RA patients in the US, there is an increased risk of in-hospital death associated with SSc. Further studies are necessary to determine whether the underlying vasculopathy, which affects the micro- and macrovasculature in SSc patients, contributes to increased mortality associated with ASCVD.

Risk of Cancer in Systemic Sclerosis: Meta-Analysis of Population-Based Cohort Studies. Akira Onishi[1], Daisuke Sugiyama[2], Akio Morinobu[1] and Shunichi Kumagai[3]. [1]Kobe University Graduate School of Medicine, Kobe, Japan, [2]School of Medicine, Keio University, Tokyo, Japan, [3]Shinko Hospital, Kobe, Japan

Background/Purpose: The risk of cancer compared with general population has been elevated in several connective tissue diseases. However, the standardized incidence ratios (SIRs) for overall cancer in patients with systemic sclerosis (SSc) were inconsistent. Moreover, most of existing studies were limited in size and based on hospital case series, with attendant selection and referral biases. We therefore aimed to examine, using meta-analysis, cancer risk in patients with SSc deriving from population-based cohort studies, as compared with the expected risks in age- matched background populations.

Methods: We searched five different databases (MEDLINE, Scopus, CINAHL, Web of Science and Cochrane Collaboration databases), reference lists of retrieved studies and review articles from January 1966 until May 2012. Population-based cohort studies relevant for determining cancer risk in patients with SSc were included. All papers fulfilling the strict inclusion criteria were scrutinized for data on population size, time of follow-up and observed to expected cancer rates (standardized incidence ratio (SIR)). Two investigators independently evaluated the quality of the studies by using a scoring system that was created on the basis of a recently used system designed with reference to MOOSE, QUAST and STROBE. Data syntheses were based on random effects model.

Results: Seven articles were included. The pooled SIR for overall cancer was 1.50 (95% CI: 1.23–1.83). The pooled SIR of 1.85 (95% CI: 1.49–2.31) for men was significantly higher than that of 1.33 (95% CI: 1.18–1.49) for women (p =0.009) and stratification on sex eliminated heterogeneity. Stratification based on type of SSc did not produce statistically significant differences in the pooled SIR between limited SSc and diffuse SSc (p = 0.98). The significant increased risk of cancer of the lung (SIR: 3.18; 95% CI: 2.09–4.85), the liver (SIR: 4.36; 95% CI: 2.00–9.51), the hematological system (SIR: 3.55; 95% CI: 1.70–7.43), non-Hodgkin lymphoma (SIR: 2.71; 95% CI: 1.43–5.14), leukemia (SIR: 2.75; 95% CI: 1.32–5.73) and the bladder (SIR: 2.00; 95% CI: 1.06–3.77) was observed. The pooled SIR for non-melanoma skin cancer was significantly increased only in men, while the pooled SIR for bladder cancer was significantly increased only in women.

The appearance of funnel plots was symmetrical and Egger's test results were not significant ($p = 0.60$).
Conclusion: In conclusion, SSc are associated with an increased risk of cancer, particularly lung, liver, hematological and bladder cancer. Men with SSc are at higher cancer risk than women.

Histological Features of Localized Scleroderma*'en Coup De Sabre'*: A Study of 16 Cases. Takashi Taniguchi, Yoshihide Asano, Zenshiro Tamaki, Kaname Akamata, Naohiko Aozasa, Shinji Noda, Takehiro Takahashi, Yohei Ichimura, Tetsuo Toyama, Miki Sugita, Hayakazu Sumida, Yoshihiro Kuwano, Miki Miyazaki, Koichi Yanaba and Shinichi Sato. University of Tokyo Graduate School of Medicine, Tokyo, Japan

Background/Purpose: Scleroderma is a chronic disease of unknown etiology characterized by skin fibrosis and is divided into two clinical entities: localized scleroderma and systemic sclerosis. Localized scleroderma differs from systemic sclerosis in that it is not accompanied by Raynaud's phenomenon, acrosclerosis, and internal organ involvement. Early lesions of localized scleroderma are histologically characterized by lymphocytic perivascular infiltration in the reticular dermis and swollen endothelial cells. However, there have been few information regarding histological features other than these findings in localized scleorderma. Since en coup de sabre (ECDS) is a certain subset of localized scleroderma with a relatively uniform clinical image, we focused on this disease subset and evaluated its histopathological features.

Methods: We retrospectively evaluated 16 patients with ECDS on the basis of clinical and histological findings. For each patient, age, disease duration, and clinicopathologic data were obtained. Skin biopsies were evaluated for the following features: epidermal atrophy, spongiosis, vacuolar degeneration of the basal cell layer, necrotic keratinocytes, thickening of dermal collagen bundles, perivascular or periappendiceal inflammatory infiltrate, vacuolar changes of follicular epithelium, and melanin incontinence.

Results: Regardless of clinical manifestations, vacuolar degeneration at the dermoepidermal junction was found in all ECDS patients. Furthermore, melanin incontinence was seen in 11 (69%) patients. Importantly, keratinocyte necroses, which are frequently accompanied with severe vacuolar degeneration, were restricted to 2 patients with early and active lesions. Vacuolar changes in hair follicular epithelium were seen in 8 (50%) patients. Regarding the histological features in the dermis, dermal fibrosis was found in all patients, but the degree of fibrosis did not correlate with disease duration. In early ECDS patients (disease duration of < 3 years), moderate to severe perivascular and/or periappendiceal lymphocytic infiltration and vacuolar changes in follicular epithelium were prominent, while epidermal atrophy was less frequently observed, compared with late ECDS patients (disease duration of ≥ 6 years).

Conclusion: Vacuolar degeneration at the dermoepidermal junction is a common histological feature in ECDS and perivascular and/or periappendiceal lymphocytic infiltration and vacuolar degeneration of follicular epithelium are characteristic especially in early ECDS, further supporting a canonical idea that the elimination of mutated epidermal cells by immune surveillance contributes to tissue damage and resultant fibrosis in localized scleroderma.

Fingertip Skin Hardness in Limited Scleroderma: Durometry versus Manual Assessment.

Thomas Osborn[1], Eric Matteson[1], Floranne Ernste[2], Cynthia S. Crowson[1], Deana D. Hoganson[3] and Irene Z. Whitt[4]. [1]Mayo Clinic, Rochester, MN, [2]Mayo Clinic Rochester, Rochester, MN, [3]Mercy Arthritis and Osteoporosis Center, Urbandale, IA, [4]NIH/NIEHS/ Environmental Autoimmunity Group, Bethesda, MD

Background/Purpose: Skin manifestations of scleroderma involve the digits in nearly all patients. Assessment of change at the level of digital skin involvement is difficult. The Modified Rodnan Skin Score (MRSS) is the most commonly used assessment for quantifying skin involvement. Its use is limited to measuring thickness at only two locations: the dorsum of the third digit of each hand. Recently, the use of a durometer to measure finger hardness at these two sites provided the possibility of improved quantitative assessment of skin involvement. The purpose of this study was to compare manual palpation and durometry as alternate methods of measuring finger involvement in scleroderma.

Methods: Fingertip pads of 30 patients with limited scleroderma (Scl cases), were compared with 30 age- and gender-matched controls without scleroderma. Skin hardness was assessed by manual palpation of the distal phalangeal palmar pad areas digits 1–5 bilaterally, using a scale of 0–3, with 0 indicating no involvement and 3 indicating extreme hardness. After calibration, durometry was performed in the same areas using a Rex 1600 Type 00 durometer rated on a scale of 0 (softest) to 100 (hardest). Two independent investigators recorded their findings on each patient in all digits using both methods. After 1 hour, Scl cases were remeasured by the same two investigators. Manual and durometry-based skin scores were obtained by averaging all digits for each assessment. Intra-class correlation (ICC) coefficients were used to assess differences in skin scores between investigators and repeatability.

Results: Mean age of cases and controls was 56 years (min: 30, max: 80) and 80% were female. There was a significant difference between the mean rating of all digits of Scl-cases and controls using either the manual (mean 1.5 vs 0.1; p<0.001) or the durometer method (mean 38 vs. 15; p<0.001). Between right and left hands, measurements for each finger were compared separately. Only manual ratings of the fifth digits were found be significantly different with right having a higher rating than left. Comparing each hand overall, both the manual durometer measurements showed that the left hand had significantly higher ratings than the right (manual: mean difference=0.19, p=0.008; durometer: mean difference=3.26, p=0.002). Intra-rater variability was low, as demonstrated by a high correlation in initial values recorded by individual raters and values recorded after one hour (ICC>0.90). Inter-rater variability was assessed comparing one main rater's measurements of Scl-cases to other raters. All raters seemed to agree with the main rater (ICCs ≥0.69) for any finger.

Coefficients did not change significantly from baseline to 1 hour assessment. Minimal detectable difference was smaller for durometry (11%) than for manual palpation (29%) indicating durometry may be able to detect smaller changes than manual rating.

Conclusion: Manual palpation and/or durometry performed on distal phalangeal palmar pads provided reproducible tools to assess skin hardness in fingers of Scl patients. Both have minimal inter- and intra-observer variability. Durometry may be able to detect smaller changes than manual palpation. It may have greater utility clinically and in clinical trials.

Optical Density Measure of the Papillary Dermis Discriminates As Abnormal Clinically Uninvolved Skin in Systemic Sclerosis and Correlates with Severity of Skin Thickness.

Giuseppina Abignano[1], Sibel Z. Aydin[2], Concepcion Castillo-Gallego Jr.[3], Daniel Woods[4], Adam Meekings[4], Dennis McGonagle[1], Paul Emery[1] and Francesco Del Galdo[1]. [1]University of Leeds, Leeds Institute of Molecular Medicine and LM-BRU, Leeds, United Kingdom, [2]Medeniyet University, Goztepe Training and Research Hospital, Istanbul, Turkey, [3]Hospital Universitario La Paz, Madrid, Spain, [4]Michelson Diagnostics Ltd, Kent, United Kingdom, Kent, United Kingdom

Background/Purpose: Skin involvement in systemic sclerosis (SSc) is often primary outcome in clinical trials and its severity inversely correlates with prognosis. Nevertheless, an objective quantitative imaging biomarker to assess skin fibrosis is still lacking in SSc. Optical Coherence Tomography (OCT) is a imaging technology that measures optical density (OD) of a substrate and can provide high contrast 2 mm deep skin images with a 5–10 micron resolution. Concurrent validity and reliability of such technique to assess skin involvement in SSc have been previously reported.[1] The aim of this study was to determine whether OD of the dermis as assessed by OCT could be used to quantitatively discriminate healthy skin from clinically uninvolved SSc skin and to correlate with clinical assessment of skin thickness in SSc patients (construct validity).

Methods: A total of 393 OCT scans of hands and forearms on 20 SSc patients and 15 healthy controls (HC) were performed employing topical probe "VivoSight" (Michelson Diagnostics). Matlab software was employed to calculate mean OD of the scans. Signal changes within epidermis (ED), Dermal-Epidermal Junction (DEJ) and dermis of SSc patients and HC were analysed and collated to a unique graph. Construct validity was determined by correlation with the current gold standard, the modified Rodnan Skin Score (mRss). The minimum (Min) value of OD before the dermis and the maximum (Max) value of OD in the dermis were considered to compare the forearm skin OCT mean A-scans of SSc patients and HC. ROC analysis of HC and mRSS=0 mean A-scans suggested that the OD value at 300 (± 16) micron was the one with best sensitivity/specificity ratio in discriminating HC vs clinically unaffected skin. We therefore included the mean value of OD at 300±16 micron for further analysis. Statistical analysis was performed employing Pearson correlation, one-way Anova and Bonferroni correction tests as appropriate.

Results: OCT mean A-Scans showed a different pattern in HC and four mRSS groups. SSc affected skin showed a consistent decrease of OD in the papillary dermis (PD), which caused a loss of definition of the DEJ. Max OD values of the PD in HC and the four mRSS subgroups was significantly different across the five groups (P<0.0001) and showed a significant correlation with mRSS (r=−0.69, P<0.0001). Similarly, Min OD values were significantly different across the five groups (P<0.0001) and showed a strong correlation with mRSS (r=−0.6, P=0.0002). In both cases after Bonferroni correction for multiple variables, the difference in Min and Max OD remained significant between HC or mRSS=0 and patients with mRSS=2 or 3, suggesting that these measures correlated with skin involvement but could not discriminate between HC and patients with mRSS=0 or 1. On the contrary, OD300 was significantly different between HC and patients with mRSS=0 or 1 (P<0.001).

Conclusion: The decrease of OD in the PD in skin fibrosis as assessed by OCT is a valid quantitative outcome measure of skin fibrosis.

Sensitivity to change ability of OCT is under evaluation to determine whether the technique could be used as outcome measure of skin involvement in SSc in clinical intervention trials and clinical management.

Myopathy Is a Poor Prognostic Feature in Systemic Sclerosis: Results From the Canadian Scleroderma Research Group. Michelle Jung[1], Murray Baron[2], Marie Hudson[3], Ashley Bonner[4], Janet E. Pope[5] and Canadian Scleroderma Research Group[6]. [1]Western University, London, ON, [2]Jewish General Hospital, Montreal, QC, [3]McGill University, Montreal, QC, [4]McMaster University, Hamilton, ON, [5]St. Joseph's Health Care London, London, ON, [6]Montreal, QC

Background/Purpose: Myopathy/myositis is associated with more severe systemic scleroderma (SSc). The aim of this study was to determine such clinical information from the Canadian Scleroderma Research Group database (CSRG).

Methods: Data from the CSRG are collected annually on SSc patients. Two surrogate markers for myopathy used in this study were elevated creatine kinase (CK) and physician-reported history of myopathy/myositis of the patients. Comparisons were made between those with and without myopathy/myositis to determine the strongest associations with this complication; overall, in lcSSc and dcSSc and in early dcSSc subset. Survival with and without myopathy/myositis was determined.

Results: The study included 1143 patients with mean of 8 years of duration. Elevated CK occurred in 5.6%; 9.7 % had a history of inflammatory myositis or myopathy according to physician; 5.7% had proximal muscle weakness. Those with elevated CK compared to remainder were more likely to be male (24.5 % in elevated CK vs. 12.6 % in normal CK; p<0.013), younger (51.93 vs. 56.07 years, p<0.045); have dcSSc, (40.4 % vs. 37.9 %; p<0.002), physician-reported history of myositis/myopathy (45.3 % vs. 8.5 %, p< 0.000), tendon friction rubs (30.0 % vs. 13.4 %; p<0.001), FVC < 70 % (23.9 % vs. 13.1 %; p<0.039), RNP antibody (12.0 % vs. 5.0 %, p < 0.032), Topo1 antibody (26.0 % vs. 14.4 %, p < 0.026), higher skin scores (MRSS 16.14 vs. 9.81; p<0.000), and higher HAQ score (0.98 vs. 0.79; p<0.011). When using logistic regression younger age male, dcSSc, early dcSSc, tendon friction rubs, higher MRSS, Topo1, RNP, PMScl, and FVC<70% were associated with elevated CK. Survival was less in those with myopathy/myositis or elevated CK (p=0.003 and p=0.025 respectively). Those with elevated CK had less survival (p=0.025). Results were similar when the other definition of myopathy/myositis.
Figure 1. Survival in those with elevated CI vs. without (p=0.025). Disease duration is recorded as time (years) since first Raynaud's symptoms at entry into CSBG registry.
Figure 2. Survival in those with history of myositis/myopathy vs. those without (p<0.001). Disease duration is recorded as time (years) since first non-Raynaud's symptoms at entry into CSBG registry.

Conclusion: Myopathy/myositis has a worse prognosis with respect to function and other organ involvement (ILD) and survival.

712

Autoantibodies to Survival of Motor Neuron (SMN) Complex Are Common in Patients with Anti-U1RNP/Sm and Are Associated with Features of Scleroderma and Myopathy. Jason YF Chan, Yi Li, Angela Ceribelli, Eric S. Sobel, Westley H. Reeves, Edward K.L. Chan and Minoru Satoh. University of Florida, Gainesville, FL

Background/Purpose: Survival of motor neuron (SMN) complex that plays a key role in small nuclear ribonucleoproteins (snRNPs) assembly and interacts with snRNPs has recently been identified as a novel target of autoantibodies in patients with polymyositis/dermatomyositis (PM/DM). Although isolated anti-SMN complex antibodies are uncommon autoantibody specificity associated with PM/DM, their frequent coexistence with anti-snRNPs (U1RNP, Sm) autoantibodies was noticed. Clinical significance of autoantibodies to SMN complex coexisting with anti-snRNPs was examined in unselected cohort of rheumatology clinic.

Methods: Sera from patients enrolled to Center for Autoimmune Disease (n = 1966, including 453 SLE, 132 scleroderma, 125 PM/DM, 130 RA, 61 Sjšgren's syndrome) were screened for their autoantibody specificities by immunoprecipitation (IP) using ^{35}S-labeled K562 cells extract. Anti-SMN complex antibodies were determined based on IP of the stable SMN complex (38kD SMN and 120–130kD gemin3 and 4). Antibodies directed to SMN protein were measured by ELISA using SMN recombinant protein. Antibodies to SMN complex were also tested by anti-SMN antigen-capture ELISA using monoclonal antibodies. Clinical information was from the database and chart review.

Results: Anti-snRNPs antibodies were identified in 266 sera (174 anti-U1RNP, 13 anti-U1/U2, and 79 anti-Sm+U1RNP). Although isolated anti-SMN complex antibodies were found previously only in 2 patients with PM, anti-SMN complex antibodies coexisting with anti-snRNPs (11% in anti-U1 or -U1/U2RNP, 6% in anti-Sm+U1RNP) were clearly detected in 28 cases. Prevalence of anti-SMN among anti-snRNPs(+) sera was 14% in Caucasian (P = 0.069 vs African American (AA)), 7% in AA, and 15% in Latin. Levels of anti-SMN antibodies (recombinant protein) were also low in AA (P < 0.005 vs Caucasian, P < 0.05 vs Latin). Clinical features of anti-SMN+snRNPs(+) were compared with anti-snRNPs(+) alone patients (table). Although the diagnosis of SLE and anti-Sm antibodies appears to be less in the anti-SMN+snRNPs(+) group, clinical features of SLE in this group of patients were similar to those of anti-snRNPs(+) patients. Anti-SMN group has more muscle weakness (P = 0.026) and diagnosis of PM/DM (P = 0.051). Diagnosis of SSc (P = 0.022) and features associated with SSc, Raynaud's phenomenon (P = 0.0008) sclerodactyly (P = 0.016), pitting scars (P = 0.03), and interstitial lung disease are more common in anti-SMN+snRNPs(+) group vs anti-snRNPs(+) alone.

Conclusion: Anti-SMN complex antibodies produced in a tight association with anti-snRNPs are relatively common. Anti-SMN complex antibody positive patients have higher prevalence of clinical features associated with SSc and PM/DM.

Clinical features of anti-SMN+snRNPs vs anti-snRNPs antibody positive patients

	Anti-SMN + snRNPs (n = 28)	Anti-snRNPs (n = 239)	
Caucasian	54% (14/26)	36% (87/239)	P = 0.09
Diagnosis of SLE	54% (14/26)	69% (161/235)	ns
Anti-Sm	18% (5/28)	31% (74/238)	ns
Diagnosis of PM/DM	8% (2/26)	3% (6/234)	ns
Elevated CPK	21% (4/19)	30% (55/184)	ns
Muscle weakness	26% (6/23)	9% (19/206)	P = 0.026
Diagnosis of SSc	15% (4/26)	3% (8/235)	P = 0.022
Raynaud's	79% (19/24)	41% (82/198)	P = 0.0008
Sclerodactyly	26% (6/23)	8% (16/199)	P = 0.016
Pitting scars	26% (6/23)	10% (19/199)	P = 0.03
Interstitial lung disease	23% (5/22)	13% (25/198)	ns

Rpp25 Is a Major Target of Autoantibodies to the Th/to Complex As Measured by ELISA and a New Chemilumiscence Assay. Michael Mahler[1], Cristina Gascon[1], Sima Patel[1], Angela Ceribelli[2], Edward K.L. Chan[2] and Minoru Satoh[2]. [1]INOVA Diagnostics, Inc., San Diego, CA, [2]University of Florida, Gainesville, FL

Background/Purpose: Anti-nuclear antibodies (ANA) play an important role in the diagnosis of systemic autoimmune diseases including systemic sclerosis (SSc). A significant portion of ANA in SSc are directed against nucleolar antigens including the Th/To antigen. Several proteins of the Th/To complex have been reported to react with anti-Th/To antibodies. Although known for over 20 years, anti-Th/To antibodies are rarely used in routine testing algorithms to aid in the diagnosis of SSc. Furthermore, little is known about the clinical association of autoantibodies targeting the individual components of the Th/To antigen. The objective of the present study is to evaluate the newly developed ELISA and chemiluminescence immunoassay (CIA, QUANTA Flash, INOVA) to measure autoantibodies to Rpp25 using immunoprecipitation (IP) as reference method.

Methods: A component of Th/To antigen (Rpp-25) was expressed as histidine-tagged recombinant protein in *E.coli* and purified by a standard method. Anti-Rpp25 antibodies in human sera were tested by ELISA and QUANTA Flash (fully automated on the BIO-FLASH System), and compared with results by immunoprecipitation as a standard. Anti-Th/To by IP was based on detection of 7–2 and 8–2 RNA by immunoprecipitation and silver staining of RNAs. The first cohort consisted of 121 SSc patients including 8 anti-Th/To positive samples confirmed by IP, enrolled in the University of Florida Center for Autoimmune Diseases (UFCAD) registry from 2000–2012. Previously described eight anti-Th/To positive Italian SSc sera from Spedali Civili di Brescia (Brescia, Italy) were also included in some analysis. For evaluation of the QUANTA Flash Rpp25 assay, 10 anti-Th/To positive sera were randomly selected based on the available amount of sera. As controls, sera were collected from ANA positive asymptomatic healthy individuals (n=42), from rheumatoid arthritis patients (n=20) and from random healthy individuals (n=10).

Results: The reactivity to Rpp25 by ELISA was significantly higher in anti-Th/To IP positive than in negative samples ($p<0.0001$). A sensitivity of 64.7% (95% CI 38.3–85.8%) and a specificity of 99.1% (95% CI 95.3–100.0%) was determined. To verify the results using a second method, anti-Th/To IP positive sera and negative controls were tested using the Rpp25 assay on the BIO-FLASH. At cut-off selected by receiver operating characteristic analysis 9/10 (90.0%) of the anti-Th/To positive sera but none of the controls were positive for anti-Rpp25 antibodies by BIO-FLASH ($p<0.0001$). Thus a sensitivity of 90.0% (95% CI 55.5–99.7%) and a specificity of 100.0% (95% CI 95.0–100.0%) were found. Ten samples were tested by ELISA and BIO-FLASH for anti-Rpp25 reactivity and the results were highly correlated (rho=0. 96, 95% CI 0.85–0.99; $p<0.0001$).

Conclusion: Rpp25 is a major target of autoantibodies to the Th/To autoantigen complex. Autoantibodies to Rpp25 detected by ELISA and especially CIA show excellent agreement with IP for anti-Th/To antibodies. The new assays may help to make this long-known antibody specificity widely available to clinicians. Further studies are needed to evaluate the clinical utility of the new assays.

Line Blot Assay, a Screening Test for Autoantibodies in Systemic Sclerosis (SSc). Kae Takagi[1], Yasushi Kawaguchi[1], Sayuri Kataoka[2], Yuko Ota[3], Yuko Okamoto[2], Masanori Hanaoka[1], Hisae Ichida[1], Takahisa Gono[1], Yasuhiro Katsumata[2] and Hisashi Yamanaka[1]. [1]Institute of Rheumatology, Tokyo Women's Medical University, Tokyo, Japan, [2]Tokyo Women's Medical University, Tokyo, Japan, [3]Institute of Rheumatology,Tokyo Women's Medical University, Tokyo, Japan

Background/Purpose: Detection of auto-antibody is informative for diagnosis of SSc. Line blot assay (LBA) provides a quantitative in vitro assay for detecting human IgG class auto-antibodies against 13 different antigens simultaneously. The aim of our study is to evaluate availability of LBA for SSc in clinical setting, and assessing the sensitivity comparing with other conventional assay.

Methods: LBA strips coated with thin parallel lines of 13 synthesized antigen (CENPA, CENPB, U1RNP, fibrillarin, RNAPIII(RP11 ARP155), NOR90, Th/To, PM-Scl100, PM-Scl75, Ku, Ro-52, PDGFR) captures serum auto antibody. Captured autoantibody is detected by Alkaline Phosphatase conjugated second antibody combined with automated scan system. Serum samples from SSc patients in our hospital were investigated. Anti-Scl70 antibody and anti-centromere antibody was also measured using conventional DID assay.

Results: Serum from 80 SSc patients, 75 female and 5 male patients between 51.7 ± 15.2 years old, were investigated. Eighty SSc patients consisted with 47 diffuse cutaneous SSc (dcSSc) type and 33 limited cutaneous SSc (lcSSc) type patients. Anti nuclear antibody positivity detected by indirect immunofluorescence methods was 92.5%. Higher total skin score (MRSS), complications of lung fibrosis, Raynaud's phenomena, and arthritis were more frequently observed in dcSSc patients. Sensitivity and specificity of anti-Scl70 antibody using LBA was 90% and 92% respectively. Sensitivity and specificity of anti-centromere antibody using line assay was 87.5 % and 95.5% respectively. Sensitivity against both auto antibodies was much higher in LBA than DID method. Anti U3 RNP antibody, Anti NOR90 antibody and anti Ku antibody was also detected by LBA. Previous reports describe anti Th/To antibody were detected in 5–10 % of SSc patients by immunoprecipitation (IP) method. However, anti Th/To antibody was not detected in this screening using LBA.

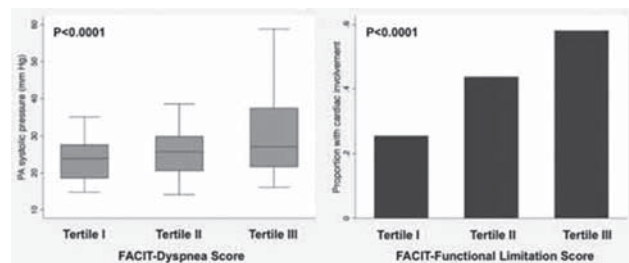
We also investigated the relationship between appearance of auto antibody and clinical phenotypes. It is known anti RNA polymerase III antibody positivity correlates with rapid skin sclerosis and higher MRSS points. This correlation was also identical with our cohort study. Anti Ku antibody positivity is known to correlate with myositis and pulmonary hypertension. However, our analysis indicated anti Ku antibody positivity was only correlated with myositis not with pulmonary hypertension.

Conclusion: Although the specificity of LBA was not better than conventional DID method, sensitivity was much higher than conventional DID assay. In case of anti Th/To antibody, none of sera showed positivity. Even though we have not evaluated anti Th/To antibody positivity by IP method, the frequency of anti Th/To antibody by LBA is much lower than previous report. Affinity to anti Th/To antibody by in this LBA may be affected by peptide design interfere conformation. Anti U3 RNP antibody, anti NOR90 and anti Ku antibody are usually detected by IP and western blot assay. These methods are complicated and not widely manipulated by commercial base laboratory. The LBA method provides more easy detection of auto antibody, and gives more beneficial information by measuring multiple parameters at once for characterization of SSc.

Disclosure: K. Takagi, None; **Y. Kawaguchi**, None; **S. Kataoka**, None; **Y. Ota**, None; **Y. Okamoto**, None; **M. Hanaoka**, None; **H. Ichida**, None; **T. Gono**, None; **Y. Katsumata**, None; **H. Yamanaka**, None.

surement Information System 29-item Health Profile (PROMIS-29) and the Functional Assessment of Chronic Illness Therapy-Dyspnea short form (FACIT-Dyspnea) in assessing general health and dyspnea in patients with SSc. No studies to date have assessed the utility of PROMIS-29 and FACIT-Dyspnea in predicting cardiac involvement in SSc as assessed by comprehensive echocardiography. We hypothesized that PROMIS-29 and FACIT-Dyspnea would be comparable to legacy patient-reported outcome instruments such as the Medical Research Council Dyspnea Index (MRC), the Short-Form-36 (SF-36), the Scleroderma Health Assessment Questionnaire (s-HAQ), and the St. George's Respiratory Questionnaire (SGRQ) in predicting cardiac involvement in patients with SSc.

Methods: Comprehensive 2D/Doppler echocardiography + tissue Doppler imaging was performed to screen for cardiac involvement and pulmonary hypertension at the initial clinic visit to a tertiary referral program. All patients fulfilled ACR criteria for SSc. A battery of legacy patient-reported outcome instruments including the MRC, SF-36, s-HAQ, and SGRQ as well as two novel instruments including the PROMIS-29 and FACIT-Dyspnea were administered.

Results: 185 patients underwent echocardiography and completed patient-reported outcome questionnaires at the baseline visit. The mean age of subjects was $53 \pm 12y$, 88% were women, and 60% had limited cutaneous SSc; median modified Rodnan skin score was 6 (interquartile range 4–17). There was echocardiographic evidence for pericardial effusion in 17%, pulmonary artery systolic pressure >40 mmHg in 16%, right ventricular dysfunction in 8%, left ventricular (LV) systolic dysfunction in in 5%, LV diastolic dysfunction in 26% and any of the above in 43% of subjects. FACIT-Dyspnea and FACIT-Functional Limitation scores were highly associated with PASP on echo and overall cardiac involvement (Figure). Area under the ROC curve for FACIT-Dyspnea (c-statistic > 0.8 for PASP) were comparable to legacy instruments (MRC, s-HAQ, and SGRQ) and superior to SF-36 (P<0.01). For overall cardiac involvement, FACIT-Dyspnea and PROMIS-29 were equivalent to legacy instruments (P=NS).


Conclusion: PROMIS-29 and FACIT-Dyspnea are comparable to legacy patient-reported outcome instruments in predicting cardiac involvement and pulmonary hypertension in SSc and may be preferable to legacy instruments because they are freely available in many languages, are readily administered electronically, and are simple to score and interpret.

Results From a Multi-Tiered Item Collection On Linking Systemic Sclerosis to the International Classification of Functioning, Disability and Health: A EULAR Scleroderma Trials and Research Initiative. Lesley Ann Saketkoo[1], Reuben Escorpizo[2], Kevin J. Keen[3], Kim Fligelstone[4] and Oliver Distler[5]. [1]Louisiana State University Health Science Center, New Orleans, LA, [2]ICF Research Branch in cooperation with the WHO Collaborating Centre for the Family of International Classifications Department of Health Sciences; and Health Policy, University of Lucerne, Switzerland, [3]University of Northern British Columbia, Prince George, BC, [4]Royal Free Hospital, Scleroderma Unit and Scleroderma Society, London, United Kingdom, [5]Department of Rheumatology and Center of Experimental Rheumatology, University Hospital Zurich, Zurich, Switzerland

Background/Purpose: Systemic Sclerosis (SSc) affects multiple organs with complex combinations of disability. Skin fibrosis, ischemic pain, ulceration, arthritis, joint contractures, myopathy and cardiopulmonary, renal as well as gastrointestinal involvement affect emotional, social and physical functioning.

International Classification of Functioning, Disability, and Health (ICF), introduced by the World Health Organization (WHO), is a universal frame-

Utility of Novel Patient-Reported Outcome Instruments in Predicting Cardiac Involvement and Pulmonary Hypertension in Patients with Systemic Sclerosis. Monique E. Hinchcliff, Mary A. Carns, Sofia Podlusky, John Varga and Sanjiv J. Shah. Northwestern University Feinberg School of Medicine, Chicago, IL

Background/Purpose: Heart involvement in systemic sclerosis (SSc) includes left ventricular systolic and diastolic dysfunction, right ventricular dysfunction, pericardial disease, and pulmonary hypertension. We recently demonstrated the construct validity for discriminative purposes of 2 new patient-reported outcome instruments: the Patient-Reported Outcomes Mea-

work that describes the disabilities associate with a health condition in terms of the bio-psycho-social model with consideration of environmental and personal factors.

Methods: Comprehensive literature review identified all validated outcome measures in SSc. Five instruments were selected to represent the broadest range of SSc manifestations (OD, LAS), deconstructed to concepts and linked separately by 2 health professionals familiar with updated ICF linkage rules (RE, LAS). Inter-reviewer agreement was analyzed (KK). Remaining instruments were deconstructed and linked. Five formal meetings with 27 patients (4 males) and 24 SSc specialists (physicians, therapists and nurses) from 16 countries provided data which were deconstructed, confirmed by participants and then linked to the ICF.

Results: 27 validated instruments were identified. 5 validated SSc instruments were linked to ICF codes and tested inter-linker agreement. The proportion of agreement ranged from 0.8611 (95% CI: 0.7500, 0.9444) to 0.9647 (0.9175, 1.000) (Table 1) with the overall proportion of agreement 0.9359 (0.9172, 0.9506). 228 and 618 categories were linked in instrument and group data respectively. All instrument linkages were captured within the expert group data collection (Table 2).

Table 1. Point and interval estimates of proportion of agreement with and without correction for chance.

Questionnaire	No. of Concepts	No. of ICF Codes	Proportion of Agreement			Proportion of Agreement Corrected for Chance		
			Estimate	Lower Limit	Upper Limit	Estimate	Lower Limit	Upper Limit
HAMIS	9	4	0.8611	0.7500	0.9444	0.7097	0.5291	0.8835
mRSS	17	5	0.9647	0.9176	1.0000	0.8964	0.7631	1.0000
RCS	7	10	0.9082	0.8367	0.9388	0.6736	0.3879	0.7726
SHAQ	7	11	0.9048	0.8477	0.9524	0.6650	0.4848	0.8279
SSc GIT	25	16	0.9506	0.9318	0.9718	0.6599	0.5306	0.7912
Overall	65		0.9359	0.9172	0.9506	0.7230	0.6453	0.7797

HAMIS: Hand Mobility in Scleroderma Test, **mRSS**: Modified Rodnan Skin Score, **RCS**: Raynaud Condition Score, **SHAQ**: Scleroderma Health Assessment Questionnaire, **SSc GIT**: SSc Gastrointestinal Tract Instrument

Table 2. ICF Linkage of Validated SSc Instruments and Expert Data

ICF Domain	Patient & Medical Experts	Validated Instruments	Common to Both	Total Identified
Body Structure	126	16	16	126
Body Function	149	108	107	150
Activities and Participation	265	96	96	265
Environmental Factors	78	9	9	78
Total	**618**	**229**	**228**	**619**

Conclusion: SSc is the most complex disease linked to the ICF. Important challenges exist in ICF Core Set development for SSc. Occurrences in the data suggest ICF level of specificity was insufficient to describe the SSc experience, e.g. Raynaud's and specific aspects of pain. 618 linkages are unusually high for ICF item collection, SSc is likely to require the development of an advanced ICF Core Set model to accommodate its complexity and ensure utility.

Further face, content and construct validation strategies with item reduction are now underway. Very importantly, the weight of these results implies that the global, regional and personal impact of SSc across cultures, age and socioeconomic status is likely to be severely under-estimated. Efforts to establish fair assessment for use in policy making and provision of services and funding are essential towards optimal health and functioning in SSc.

718

Worsening Carbon Monoxide Diffusing Capacity Predicts Mortality in Patient with Systemic Sclerosis and Pulmonary Arterial Hypertension Enrolled in the Pulmonary Hypertension Assessment and Recognition of Outcomes in Scleroderma Registry.
Elena Schiopu[1], Dinesh Khanna[1], Virginia D. Steen[2] and PHAROS Investigators[3]. [1]University of Michigan, Ann Arbor, MI, [2]Georgetown Univ Medical Center, Washington, DC, [3]Washington DC

Background/Purpose: Isolated decreases in carbon monoxide diffusing capacity (DLco) has been a well described risk factor for the development of pulmonary arterial hypertension (PAH) in Systemic Sclerosis (SSc). We used the Pulmonary Hypertension Assessment and Recognition of Outcomes in Scleroderma (PHAROS) prospective registry to determine whether the changes in the DLco were associated with mortality in patients with SSc-PAH.

Methods: Patients with Group 1 PAH as diagnosed by right heart catheterization with a mean pulmonary pressure (mPAP) $\geq$ 25mmHg, and a wedge pressure $\leq$ 15 who have been entered into PHAROS were eligible for this analysis. Patients had to have repeat pulmonary function tests, including a DLco during the course of follow up. We defined patients who had a decrease in the DLco of 5% or more as "worsening", and those who had less than 5% or who had an improvement in their DLco as "stable" DLco. We compared the patients who had "worsening" DLco to those with "stable" DLco by survival analyses using Kaplan Meyer curves.

Results: 160 patients with Group 1 PAH have been entered into PHAROS. 89 of these patients have had at least 2 DLco measurements after entry. 58 (65%) had limited SSc, 81 (90%) were females, mean/SD age at study entry was 60.2/9.7 years, and mean/SD duration of Raynaud's was 13.4/11.6 years. The mean/SD baseline of the percent predicted DLco (%DLco), last %DLco, mPAP and pulmonary vascular resistance (PVR) were 44.9/16.2, 41.5/16, 35.3/9.1 mmHg and 434/320 dyn·s/cm[5], respectively. 35 patients had a decreasing DLco (>5%, mean 6.7%), 36 had no change in DLco (mean 2.3%) and 18 had an improved DLco (mean 13.2%). Patients with a worsening DLco had a 3 year survival of 75% compared to 90% in those with stable or improved DLco. The Kaplan Meyer curves revealed a statistically different survival rate based on the worsening %DLco (P=.03).

Conclusion: In this multicenter prospective cohort of patients with SSc with PAH, worsening of the diffusion capacity in the course of the disease was associated with increased mortality. Rate of worsening of the DLco should be considered when evaluating the prognosis of patients with SSc-PAH.

719

Biomarkers of Pulmonary Hypertension in Patients with Scleroderma: A Case-Control Study.
Zsuzsanna H. McMahan[1], Florian Schoenhoff[2], Jennifer van Eyk[1], Fredrick M. Wigley[1] and Laura K. Hummers[1]. [1]Johns Hopkins University, Baltimore, MD, [2]Berne, Switzerland

Background/Purpose: The objective of this study was to evaluate for an association between various biomarkers and the presence or absence of pulmonary hypertension (PH) in scleroderma

Methods: Proteomic analysis was used to retrospectively compare growth factor and cytokine levels in 48 patients with scleroderma and PH and 48 patients with scleroderma without clinical or ECHO evidence of PH. PH was defined as either an mPAP $\geq$ 25mmHg by right heart catheterization (n = 44) or an RVSP of > 45 mmHg by Echo with strong clinical evidence supporting a diagnosis (n= 4). An additional proteomic analysis was performed on a subset of 24 patients from each group using samples that had been drawn at least 6 months prior to the first sample to determine if changes in candidate biomarker levels were associated with PH. A multiplex proteomic assay was subsequently performed to look at growth factors (bFGF, PIGF, VEGF, HGF, sFLT-1) and cytokine levels (IL 1B, IL-2, IL-4, IL-5, IL-8, IL-10, IL-12 p70, IL-13, TNF-alpha, and INF-gamma) (MesoScale Discovery, Gaithersburg, MD). Univariate and multivariable logistic regression were used to examine the association of growth factor and cytokine levels with the presence of pulmonary hypertension.

Results: The mean age in the PH group was 66 yrs (range 34–89) compared to 56 (range 27–83) in the non-PH group. Seventy-three percent (n=35) in the PH group had limited scleroderma compared to 65% (n=31) in the control group. Average disease duration was 17.3 years in the PH group and 12.2 years in the non-PH group. Differences in gender and scleroderma subtype were not significant between the two groups. We

found levels of IL-12 p70 (9.0 vs. 4.0; p=0.04), PlGF (26.7 vs. 21.3, p = 0.01), and sFLT-1(122.1 vs. 99.1, p=0.02) were significantly higher in the48 patients with PH compared with the 48 without PH at the latest blood sampling time point. When comparing biomarker levels at the earlier time point (17/24 with sample prior to PH diagnosis in the PH group) in the 24 patients with and 24 patients without pulmonary hypertension, sFLT-1 (122.2 vs. 100.5; p= 0.0062; CI −36.87, −6.52), HGF (451.6 vs. 202.1; p =0.003; CI −403.79, −95.28), and IL-10 (12.6 vs. 4.4; p= 0.03; CI −15.67, −.85), were significantly higher in the PH group. In a multivariable model adjusted for age, race, disease duration, and ILD, PlGF remained higher among those with PH (OR 1.06, p=0.16) although this was no longer statistically significant. In examining the stability of markers over time, all biomarkers were stable between the two samples except for VEGF (260.8 vs. 546.1; p=0.001) and bFGF (19.8 vs. 11.1; p= 0.01) which showed wide variability in levels between patients and at the 2 time points. IL-12p70 (−0.24, p = 0.05, CI −0.48, −0.00) and IL-5 (−0.51, p= 0.03, CI −0.952, −0.059) were negatively associated with severity of pulmonary hypertension as measured by mean pulmonary artery pressures (mPAP) among those with PH.

Conclusion: We found that PlGF (and possibly sFLT-1 and IL-12) may be associated with PH in scleroderma. This study confirms prior associations of PlGF with scleroderma vascular disease and suggests that this factor should be further explored as possible biomarkers of development of PH.

Left-Heart Disease Is a Frequent Cause of Pulmonary Hypertension in Systemic Sclerosis, Is Associated with Increased Levels of MR-ProANP and MR-ProADM but Is Unrelated to Elevated NT-ProBNP Levels: A Retrospective Cohort Analysis. Lada Miller[1], Sandra Chartrand[1], Martial Koenig[2], Jean-Richard Goulet[2], Eric Rich[1], Michal Abrahamowicz[3], Jean-Luc Senécal[1] and Tamara Grodzicky[1]. [1]Hôpital Notre-Dame du CHUM, Montreal, QC, [2]Hôpital Notre-Dame du CHUM, Montréal, QC, [3]Centre Universitaire de Santé McGill (CUSM), Montreal, QC

Background/Purpose: Pulmonary hypertension (PH) is a significant cause of morbidity and mortality in systemic sclerosis (SSc). Pulmonary arterial hypertension (PAH) is reportedly the most frequent cause of PH in SSc, affecting 8–12% of patients. We observed that a significant proportion of our SSc patients with PH as diagnosed by right heart catheterization (RHC) had PH due to causes other than PAH. The frequency of other causes of PH in SSc has not been accurately determined to date. The aim of the present study was therefore to determine the frequency of different causes of PH in our SSc cohort and to identify associated clinical, serological and radiologic variables.

Methods: A retrospective analysis of 432 SSc patients was done. All patients routinely underwent screening for PH. Clinical, serological and radiographic data from patients with PH confirmed by RHC (n=26) were analyzed. Living SSc PH patients (n=21) and 19 control SSc patients without clinical PH were prospectively re-evaluated with serial measurements of NT-proBNP and the hemodynamic biomarkers MR-proANP and MR-proADM.

Results: The most frequent cause of PH was left heart disease (LHD) (15/26, 58%). PAH was seen in 9/26 patients (34%). Other causes of PH were veno-occlusive disease and multifactorial PH. No association was found between the type of PH and the autoantibody profile. LHD-related PH was associated with significantly lower NT-proBNP levels than PAH at the time of established PH (137 ± 137 pg/ml vs 484 ± 248 pg/ml, p=0.024), and all SSc patients without PH had normal levels of NT-proBNP. MR-proANP and MR-proADM levels were significantly higher in SSc patients with PH than those without PH (105 [81–151] pmol/L vs 78 [32–91] pmol/L, respectively, p = 0.004, and 0.7 [0.42–0.87] nmol/L vs 0.5 [0.4–0.6] nmol/L, p = 0.018,). Similarly, MR-proANP and MR-proADM levels were significantly higher in SSc patients with LHD-PH as compared to those without PH (105 [87–137] pmol/L vs 78 [32–91] pmol/L, respectively, p = 0.014, and 0.75 [0.47–0.92] nmol/l vs 0.5 [0.4–0.6] nmol/L, p= 0.012). However, there was no significant difference between the LHD-PH and the PAH groups.

Conclusion: SSc-associated PH is heterogeneous. RHC is essential to determine the underlying cause. The most frequent cause of PH is LHD, not PAH. Levels of MR-proANP and MR-proADM, but not NT-proBNP, were increased in LHD-PH, and may be more reliable markers than NT-proBNP in this subgroup of patients. This study is the first to identify such a high frequency of LHD-PH correlating with normal NT-proBNP levels but increased MR-proANP and MR-proADM in SSc.

Background/Purpose: Pulmonary hypertension (PH) is a major complication of systemic sclerosis (SSc). We observed that a significant proportion of our SSc patients with PH as diagnosed by right heart catheterization (RHC) had PH due to causes other than pulmonary arterial hypertension (PAH), notably left heart disease (LHD) (15/26, 58%). We hypothesized that LHD in these patients could be explained by cardiomyopathy secondary to microvascular disease and/or fibrosis. The aim of our study was to detect microvascular perfusion defects and/or fibrosis, as well as useful parameters for PH diagnosis, by cardiac magnetic resonance imaging (MRI) in SSc patients with and without PH.

Methods: A retrospective analysis of our cohort of 432 SSc patients was performed. All patients routinely underwent screening for PH, and diagnosis of PH was proven by RHC in all suspected cases. Data from clinical, cardiopulmonary and serological investigations were analyzed. All living patients with PH (n=18) as well as a control group of 19 consecutive SSc patients without clinical suspicion of PH underwent a cardiac MRI (a morphologic and functional study with steady state free precession technique in static and cine imaging, and a T2 short-term inversion recovery (STIR) study, followed by a delayed contrast-enhanced imaging acquisition).

Results: Twenty-six SSc patients (26/432; 6%) had PH diagnosed by RHC. Eighteen of these patients (11 with PH due to LHD [61%], 4 with PAH [22%], 3 from other causes) and 19 without clinical suspicion of PH (control group) underwent cardiac MRI. Age, disease duration, gender, ethnicity, disease subtypes and autoantibody profiles were similar between the two groups. Systolic pulmonary artery pressure by transthoracic echocardiography (48,3±7,5 mmHg vs 30,3±5,7 mmHg, p<0,001) as well as the carbon monoxide transfer factor (TLCO) (54,3±15,4% of predicted value vs 69,1±22,8% of predicted value, p=0,043) were statistically significantly different between SSc patients with and without PH, respectively. Cardiac MRI showed statistically significant differences between SSc patients with and without PH, respectively, for the measurement of the diameter of the main pulmonary artery (PA) (30,90±5,03 mm vs 26,30±3,86 mm, p=0,006), the right PA (23,50±4,11 vs 18,60±2,90 mm, p=0,001), and the ratio of the main PA to the ascending aorta (0,97±0,10 vs 0,84±0,10, p=0,002). There was a trend toward significance for the measurement of the left PA (21,60±3,52 mm vs 19,80±1,98 mm, p=0,07). None of the 37 patients had significant myocardial hypersignal in T2 STIR nor delayed gadolinium enhancement.

Conclusion: Cardiac MRI investigation did not show overt evidence of myocardial perfusion defects nor fibrosis to explain PH secondary to LHD in our SSc cohort. Newer more sensitive cardiac MRI modalities may be more useful and should be evaluated in future studies. However, cardiac MRI measurement of the diameter of the main PA, the right PA and possibly of the left PA, as well as the ratio of the main PA to the ascending aorta, seem to be simple and reliable methods for PH diagnosis in SSc patients, and may prove to be useful noninvasive tools in the investigation of PH.

Systemic Sclerosis Associated Pulmonary Hypertension - Is Pulmonary Veno-Occlusive Disease As Common As They Say? Benjamin E. Schreiber[1], Greg Keir[2], D. Dobarro[3], Clive Handler[1], Svetlana Nihtyanova[4], Jay Suntharaligam[5], Nicola Sverzelatti[6], Graham Robinson[5], David Hansell[7], Athol U. Wells[2], Christopher P. Denton[8] and John G. Coghlan[1]. [1]Royal Free Hospital, London, London, United Kingdom, [2]Royal Brompton Hospital, United Kingdom, [3]Royal Free Hospital, London, United Kingdom, [4]Royal Free Hospital, Medical School, London, England, [5]Royal United Hospital, Bath, United Kingdom, [6]University of Parma, Parma, Italy, [7]Royal Brompton Hospital, London, United Kingdom, [8]UCL, London, United Kingdom

Background/Purpose: Recent reviews have suggested a high prevalence of pulmonary veno-occlusive disease (PVOD) amongst patients with systemic sclerosis (SSc) associated pulmonary hypertension (PH). Interlobular septal thickening (IST) and centrilobular nodules (CLN) are reported to correlate with presence of PVOD, which is associated with worse outcomes in small series. We tested this hypothesis on a large series of systemic sclerosis patients who underwent evaluation for pulmonary hypertension.

Methods: A retrospective study of patients with systemic sclerosis who underwent CT of the chest within six months of a diagnostic right heart catheterisation. The CTs were blindly scored by two independent radiologists including detailed assessment for extent of interstitial lung disease (using the Goh et al. AJRCCM 2008 staging system), IST and CLN. Each lung quadrant was scored separately for interlobular septal thickening (IST) with score 0–5 and centrilobular nodules (CLN), score 0–3. Survival data were collected on all patients.

Results: Mean age was 57.8 (range 22–85). 78% were female. 84 patients had LcSSc, 32 had DcSSc and 1 had MCTD. CT scans were performed a mean of 2.7 months from the RHC.

There was limited or no ILD extent (<20%) in 46 patients (43%), 20% in 28% and extensive (>20%) in 30%. On right heart catheterisation 53% had precapillary PH while 47% did not.

95 scans were reported independently in a blinded fashion by two radiologists. Of the remaining 95 patients, 49 had PAH and 46 did not. Of those with PH, 18 had <20% ILD, 18 had 20% ILD and 13 had >20% ILD. Amongst patients with PH, there was a weak trend towards worse survival in patients with more lung disease (HR 1.5, 95% CI 0.89,2.52, p=0.13).

IST of any degree was observed in 15% of patients and CLN in 18%. Mean IST score was 1 (on a scale of 0–4) and mean CLN score was 0.63 (scale of 0–2). IST was not associated with extent of ILD (p=0.19 by chi-square), and nor was CLN (p=0.74, by chi-square). IST did not correlate with PVR (R2=2%) whereas CLN did correlate with PVR (R2=15.7%).

By Cox proportional hazards analysis, PVR was a strong predictor of death (p=0.001). Increasing IST was associated with worse survival on univariate analysis (p=0.038) however statistical significance is lost (p=0.11) after adjustment for age.

Increasing CLN is strongly associated with higher mortality (p=0.013) even after adjustment for age, gender, extent of interstitial lung disease and mean pulmonary artery pressure (p=0.047). This is particularly observed in patients without PH (p=0.004 on this multivariate analysis) rather than in patients with PH (where p=0.19 on multivariate analysis). However, CLN is not a significant predictor for PVR after adjustment for age (p=0.18).

Conclusion: Interlobular septal thickening and centrilobular nodules are frequently seen in patients with systemic sclerosis and are each associated with worse survival. However, IST increases with age and CLN increases with worsening pulmonary vascular resistance. In our study they were not independent predictors of worse outcome in systemic sclerosis. It is therefore possible that the significance of these radiological findings is primarily as markers of known prognostic risk factors.

Renal Dysfunction and Disease Severity in Scleroderma-Associated Pulmonary Arterial Hypertension. Stephen C. Mathai[1], Laura K. Hummers[1] and Virginia D. Steen[2]. [1]Johns Hopkins University, Baltimore, MD, [2]Georgetown Univ Medical Center, Washington, DC

Background/Purpose: Renal disease is a common complication of scleroderma (SSc). Isolated reduction in glomerular filtration rate (GFR), a marker of impaired renal function, can occur in patients with normal serum creatinine. A recent single-center study of patients with SSc and pulmonary arterial hypertension (SSc-PAH) suggests that an estimated GFR (eGFR) < 60 ml/min/1.73m^{2}at baseline occurs in over 40% of patients and portends a three-fold increased risk of death in this population. Therefore, we sought to determine the prevalence and clinical correlates of renal dysfunction in a large, multi-center observational cohort using the PHAROS (Pulmonary Hypertension Assessment and Recognition of Outcomes in Scleroderma) registry.

Methods:: We identified patients with SSc-PAH, defined according to the Dana Point criteria. eGFR was calculated using the 4-variable Modified Diet in Renal Disease equation (MDRD); eGFR< 60 ml/min/1.73m^{2}was considered abnormal. Demographic, serologic, physiologic, and hemodynamic parameters were compared between groups using t-tests or chi-squared analyses where appropriate.

Results: 133 SSc-PAH patients were included in this study (Table 1). Overall, 33% (44/133) of subjects had an eGFR<60 ml/min/1.73m^2(low eGFR group). In general, the low eGFR group was older and was more likely to have diffuse disease, but there was no difference in gender, race, duration of SSc, or antibody profiles between groups. Pulmonary function and New York Heart Association functional class were similar between groups, however, six minute walk distance was significantly lower in the low eGFR group. Patients in the low eGFR group were more likely to have had a renal crisis and to have worse hemodynamics (higher mean pulmonary artery pressure, lower cardiac output, and higher pulmonary vascular resistance).

Table 1. Patient Population

Parameter	Overall (n=133)	eGFR<60 (n=44)	eGFR>60 (n=89)	p-value
Age (years)	60 (11)	64 (9)	59 (11)	<0.01
Gender (n,%women)	109 (83)	38 (86)	71 (82)	0.49
Race (n,% Caucasian)	120 (90)	42 (95)	78 (88)	0.15
Limited vs. Diffuse (n,% limited)*	54 (60)	13 (40)	41 (71)	<0.01
Duration of SSc (yrs)	8.2 (9.5)	7.7 (9.5)	8.9 (9.4)	0.68
First Raynaud's symptom (yrs)	14.3 (12.0)	14.9 (13.3)	13.9 (11.4)	0.69
History of renal crisis (n,%)	6 (5)	5 (13)	1 (1)	<0.01
FVC (% predicted)	81.7 (15.7)	84.9 (15.4)	79.9 (15.7)	0.10
FEV1/FVC (% predicted)	81.7 (9.9)	82.0 (11.1)	80.7 (9.9)	0.51
TLC (%predicted)	79.0 (18.5)	79.3 (19.3)	78.9 (18.2)	0.90
DLCO (%predicted)	40.1 (17.5)	37.5 (19.9)	41.5 (16.1)	0.22
FVC/DLCO (% predicted)	2.2 (0.9)	2.2 (0.7)	2.2 (0.9)	0.86
Home oxygen use (n,%)	39 (32)	13 (33)	26 (32)	0.86
6MWT (m)	332 (127)	291 (134)	355 (119)	0.02
NYHA class (I/II vs III/IV)	62/57	20/23	42/34	0.52
Mean PAP (mmHg)	37 (19)	40 (11)	36 (9)	0.02
CO (L/min)	5.0 (1.6)	4.4 (1.2)	5.4 (1.6)	<0.001
PCWP (mmHg)	10 (3)	9 (3)	11 (3)	0.03
PVR (Wood units)	5.8 (3.9)	7.2 (3.5)	5.1 (3.9)	<0.01

Conclusion: In this large cohort of patients with SSc-PAH, renal dysfunction was common and associated with more severe functional and hemodynamic impairments. Interestingly, there was no association between antibody profiles or race and prevalence of renal dysfunction. The determinants of renal disease and the relationship between renal dysfunction and mortality in this cohort will be the focus of future studies in the PHAROS registry.

Survival, Hospitalization or Need for Combination Therapy At One Year in Patients with Scleroderma-Associated Pulmonary Arterial Hypertension. Robyn T. Domsic[1], Lorinda Chung[2], Jessica K. Gordon[3], Yona Cloonan[1], Virginia D. Steen[4] and PHAROS Investigators[5]. [1]University of Pittsburgh, Pittsburgh, PA, [2]Stanford Univ Medical Center, Palo Alto, CA, [3]Hospital for Special Surgery, New York, NY, [4]Georgetown Univ Medical Center, Washington, DC, [5]Washington, DC

Background/Purpose: Pulmonary arterial hypertension (PAH) is a leading cause of death in patients with systemic sclerosis (SSc). Although survival has improved with PAH-specific medications in the last decade, the optimal

therapy remains unknown. We sought to compare the one year outcome of SSc-PAH patients with different therapeutic classes of PAH-specific medications.

Methods: Pulmonary Hypertension Assessment and Recognition of Outcomes in Scleroderma (PHAROS) is a multi-center prospective registry of SSc patients at high risk for PAH or with definite PH diagnosed by right heart catheterization (RHC) within 6 months of enrollment. To be included in this analysis, patients had to have World Health Organization (WHO) Group I PAH, and have received a PAH-specific medication for > 3 months duration. We assessed patient outcomes for four therapeutic classes: endothelin receptor antagonists (ERA), phosphdiesterase type 5 inhibitors (PDE-5), prostacyclins (PCA) and those started immediately on combination therapy ($\geq$2 of the other classes). A Kaplan-Meier curve was estimated for 1 year survival from the time the PAH treatment was started, and differences between the drug classes were assessed by the log-rank test. Rates of hospitalizations at one year were compared by chi-square tests.

Results: In the PHAROS registry 160 individuals have PAH, of whom 120 either had$\geq$ 1 year of follow-up or had died prior to 1year of follow-up. Of these, 101 had been treated with a PAH medication for > 3 months and comprised the analysis population. The mean age was 59.0 $\pm$ 10.4 years, 85% were female, 80% Caucasian and 11% African-American. 67% were classified as limited cutaneous SSc. Overall, initial therapy was a PDE-5 in 47%, ERA in 30%, PCA in 13% and combination therapy in 10%. In the PCA group 85% started inhaled, and 15% started parental therapy. With those with a baseline NYHA class within two months of therapy initiation, 25% of the PCA group were class IV, as compared to 20% in the combination, 0% ERA and 7% PDE5. At one year 7% (n=7) on medications had died, whereas 10% had died at one year in the entire PHAROS cohort. There was a statistically significant difference between the drug classes with 98% of PDE-5, 97% of ERA, 69% of PCA and 90% of combination therapy alive at one year (p=0.002). At one year 28% of patients had been hospitalized, but there was no difference in rate of all-cause hospitalization (p=0.78) or PAH-related hospitalizations (p=0.91) between the drug classes. Similarly, there was no difference in progression to combination therapy with 27% of PDE5, 23% of ERA and 13% of PCA (p=0.67).

Conclusion: At one year there is no difference in rates of hospitalization or progression to combination drug therapy among the PAH-specific drug classes. However, there was a difference in one-year survival between the drug classes, with those started on PCAs clearly having the lowest survival. This may reflect that those patients had more severe pulmonary vascular disease at baseline. Further follow-up is needed to determine whether long-term outcomes differ between the PAH therapeutic drug classes.

The Role of Interleukin-23 in Spondyloarthropathy. Jonathan Sherlock[1], Barbara Joyce-Shaikh[1], Scott Turner[1], Cheng-Chi Chao[1], Manjiri Sathe[1], Jeff Grein[1], Dan Gorman[1], Eddie P. Bowman[2], Terrill McClanahan[1], Jennifer Yearley[1], Gerard Eberl[3], Christopher D. Buckley[4], Robert Kastelein[1], Robert Pierce[1], Drake LaFace[1] and Daniel Cua[5]. [1]Merck, Palo Alto, CA, [2]Merck, Palo Alto, [3]Institut Pasteur, Paris, France, [4]School of Immunity and Infection, MRC Center for Immune Regulation, Birmingham, United Kingdom, [5]Merck Research Laboratory, Palo Alto, CA

Background/Purpose: Spondyloarthropathy is characterized by inflammation and bony pathology at the entheseal insertion of tendons to bone. Recent investigations have converged upon interleukin(IL)-23, demonstrating firstly that genetic variants in its receptor are associated with disease and secondly that HLA-B27, which is present in 90% of patients with ankylosing spondylitis, has a tendency to misfold and form cell surface homodimers resulting, respectively, in production of IL-23 and stimulation of IL-23R+ cells. However why such dysregulation of IL-23 should result in inflammation primarily at the enthesis has remained deeply enigmatic.

We have hypothesized that tissue resident cells fundamentally determine disease localization (Cua and Sherlock, Nature Medicine 17(9): 1055–6) and herein extend our previous observations (Sherlock *et al.* in press) to demonstrate the presence of IL-23R+ cells in the uvea and to further characterize these cells and their effects.

Methods: We used GFP reporter mice to investigate the tissue distribution of IL-23R+ cells in the main tissues inflamed in spondyloarthropathy: the enthesis, aortic valve and uvea. Flow cytometric analysis and multiphoton microscopy was employed to characterize the location of such cells and the reactivity of this tissue to IL-23 was determined in vitro and in vivo.

Results: Entheses, the aortic root and the uvea all contain a novel tissue resident IL-23R+ T lymphocyte, negative for both CD4 and CD8, which allows the tissue to respond to IL-23. Multiphoton microscopy confirms an extremely precise entheseal localization of the IL-23R+ cell type. These cells are RAG dependent, but express the PLZF transcription factor which confers an 'innate like' responsiveness on T cells, allowing them to immediately respond to cytokines. Entheses can respond within hours to IL-23 *in vitro* in the absence of further cellular recruitment. Moreover, IL-23 expression in mice is sufficient by itself to induce hallmark features of spondyloarthropathy, with severe inflammation developing very specifically at the enthesis and aortic root. Entheseal bone erosion, new bone formation and periostitis are likewise present.

Conclusion: The highly restricted anatomical distribution of IL-23R+ cells explains both the exquisitely precise tissue localization of disease in spondyloarthropathy, as well as the known genetic associations with IL-23, and gives a very clear mechanism whereby HLA-B27 and its tendency to cause IL-23 elaboration may predispose to pathology. These IL-23R+ tissue resident cells thus form the point of integration between the specific immunological dysregulations known to be associated with disease, and the very precise anatomical sites affected. The importance of these tissue resident cells is emphasized by the ability of IL-23 to drive enthesitis despite depletion of the conventional IL-23 responsive Th17 cells. Neutralization of IL-23 therefore represents an excellent therapeutic strategy in spondyloarthropathy since it will inhibit a potent molecule associated with known genetic factors, and do so directly at the site of pathology.

Dynamic *in Vivo* Imaging of Th17-Mediated Osteoclastic Bone Resorption in Live Bones by Using Intravital Multiphoton Microscopy. Junichi Kikuta and Masaru Ishii. Immunology Frontier Research Center, Osaka University, Osaka, Japan

Background/Purpose: Rheumatoid arthritis (RA) is a chronic autoimmune disease characterized by joint synovial inflammation and progressive cartilage/bone destruction. Although various kinds of cell types, such as T/B lymphocytes, macrophages and synovial fibroblasts, are involved in the pathogenesis of chronic inflammation in RA, bone destruction is considered to be mainly mediated by enhanced activation of osteoclasts. Recently CD4+ T helper 17 (Th17) cells have been reported to express RANKL on the cell surface, which were suggested to be important for osteoclastic bone destruction in arthritic joints. However, the RANKL expressed on the surface of Th17 possesses little ability for inducing differentiation, and the practical function of RANKL and Th17 on bone erosion remained elusive. This study aimed to investigate how the bone-resorptive functions of osteoclasts are regulated *in situ* and how Th17 cells control the osteoclastic bone resorption *in vivo*.

Methods: To examine *in vivo* behaviors of mature osteoclasts and Th17 cells, we utilized advanced imaging system for visualizing live bone tissues with intravital multiphoton microscopy that we have originally established. To identify mature osteoclasts in fluorescent microscopy, we utilized the mice in which GFP is expressed under the promoter of a vacuolar type H+-ATPase a3 subunit, those are preferentially and abundantly expressed in mature osteoclasts (a3-GFP mice). Polyclonally differentiated Th17 cells were labeled with fluorescent dye and then

adoptively transferred into a3-GFP mice. We observed calvaria bone tissues of a3-GFP mice by using intravital multiphoton microscopy.

Results: We succeeded in visualizing live mature osteoclasts on the bone surface *in situ*. By using this imaging system, we could identify different populations of live mature osteoclasts in terms of their motility and function, i.e., 'static – bone resorptive (R)' and 'moving – non resorptive (N)'. Treatment with recombinant RANKL or bisphosphonate changed the composition of these populations as well as total number of mature osteoclasts. We also found that rapid RANKL injection converted the moving (N) osteoclasts to static (R) ones without any changes in total number of osteoclasts, suggesting a novel action of RANKL in controlling mature osteoclast function. Furthermore, we could demonstrate that Th17 cells had potency for inducing rapid N to R conversion of mature osteoclasts by RANKL expressed on their cell surface *in situ*.

Conclusion: By visualizing *in vivo* behaviors of mature osteoclasts, we for the first time identified different functional subsets of live osteoclasts on the bone surface, from 'static – bone resorptive' to 'moving – non resorptive'. Furthermore, RANKL turned out not only to promote the differentiation of osteoclasts but also to regulate the bone-resorptive function of fully differentiated mature osteoclasts. RANKL-bearing Th17 cells were shown to control bone resorption of mature osteoclasts, demonstrating novel actions of Th17 that may be a novel therapeutic target in RA.

727

Effects of Odanacatib On BMD and Overall Safety in the Treatment of Osteoporosis in Postmenopausal Women Previously Treated with Alendronate.

Roland Chapurlat[1], Sydney Bonnick[2], Tobias De Villiers[3], Alberto Odio[4], Santiago Palacios[5], Boyd Scott[6], Celine Le Bailly De Tilleghem[7], Carolyn DaSilva[6], Albert Leung[8] and Deborah Gurner[8]. [1]Hôpital Edouard Herriot, Lyon, France, [2]Cooper Clinic, Dallas, TX, [3]Mediclinic Panorama, Cape Town, South Africa, [4]Alta California Medical Group, Simi Valley, CA, [5]Instituto Palacios, Madrid, Spain, [6]Merck Sharp & Dohme Corp., Whitehouse Station, NJ, [7]Merck Sharp & Dohme Corp., Brussels, Belgium, [8]Whitehouse Station, NJ

Background/Purpose: Odanacatib (ODN) is a potent, orally-active cathepsin K inhibitor being developed for the treatment of postmenopausal osteoporosis. This study evaluated the effects of ODN 50mg once weekly (OW) on BMD and biochemical markers of bone turnover in patients previously treated with alendronate (ALN) (dosed daily or weekly) for ≥3years, as well as the safety and tolerability of ODN.

Methods: This was a randomized, double-blind, placebo-controlled, 24-month study. The primary endpoint was % change in femoral neck (FN) BMD from baseline at Month 24. 243 postmenopausal women ≥60 years of age with low BMD T-score (T-score range ≤−2.5 but >−3.5) at the total hip, FN or trochanter but no history of hip fracture and who had been treated with ALN for ≥3years were randomized in a 1:1 ratio to receive ODN 50mg OW or placebo OW for 24 months. All patients received vitamin D_3 5600 IU/wk and calcium supplementation (to 1200 mg/day). BMD was assessed by DXA at baseline, 6, 12 and 24 months. Biochemical markers of bone resorption (s-CTx, u-NTx) and bone formation (s-BSAP and s-P1NP) were measured at baseline and 3, 6, 12, 18 and 24 months. This study was not designed and did not have the power to evaluate the effect of ODN on fractures.

Results: In the placebo group, FN and trochanter BMD were not significantly different from baseline levels for the first 12 months, but declined significantly from baseline by Month 24 (−0.94% and −1.35%, respectively). BMD at the total hip declined in a linear manner from baseline to month 24 (−1.87% at 24 months). BMD at the lumbar spine (LS) was not significantly different from baseline for the entire 24 months of the study. BMD changes from baseline at 24 months in the ODN group were significant vs placebo at all 3 hip sites and the LS. The changes in BMD for the FN, trochanter, total hip and LS from baseline were 1.73%, 1.83%, 0.83% and 2.28%, respectively. ODN 50mg OW significantly decreased the biomarker of bone resorption, u-NTx/Cr, and significantly increased biomarkers of bone formation, s-P1NP and s-BSAP, compared to placebo. The increase observed for the bone resorption marker s-CTx with ODN treatment was unexpected. AEs were comparable between the 2 treatment arms. The overall safety profile appeared similar between ODN 50mg OW and placebo.

ODN effects on BMD

% Change from Baseline in BMD (Least Square Mean +/-SE) at 24 Months — Geometric Mean % Change from Baseline +/- SE at 24 Months
ODN effects on biomarkers

% Change from Baseline in BMD (Least Square Mean +/-SE) at 24 Months — Geometric Mean % Change from Baseline +/- SE at 24 Months
Conclusion: In this study osteoporotic women treated with ODN following ALN treatment show incremental gains in BMD. Biomarker results suggest that ODN decreases bone resorption while preserving bone formation.

728

Does the Use of Angiotensin Converting Enzyme Inhibitors Prior to Scleroderma Renal Crisis Affect Prognosis ? – Results of the International Scleroderma Renal Crisis Survey.

Marie Hudson[1], Murray Baron[2], Solene Tatibouet[1], De Furst[3], Dinesh Khanna[4] and International Scleroderma Renal Crisis Study Investigaots[5]. [1]McGill University, Montreal, QC, [2]Jewish General Hospital, Montreal, QC, [3]University of California at Los Angeles, Los Angeles, CA, [4]University of Michigan, Ann Arbor, MI, [5]Montreal

Background/Purpose: Scleroderma renal crisis (SRC) is an infrequent but life-threatening complication of systemic sclerosis (SSc). The outcome of SRC has improved considerably since the advent of angiotensin converting enzyme (ACE) inhibitors. The incidence of SRC has also appeared to have decreased, perhaps in part due to the more liberal use of ACE inhibitors in SSc. However, recent retrospective data suggests that patients with SRC exposed to ACE inhibitors prior to the onset of SRC may have worse outcomes. We undertook a prospective study to verify whether SSc patients with incident SRC on ACE inhibitors at the time of onset of SRC had worse outcomes compared to those who were not on these drugs at that time.

Methods: We designed a prospective, observational cohort study of incident SRC subjects identified through a web-based survey. Every second week, an e-mail was sent to 589 participating physicians from around the world to identify incident cases of SRC. Data on patient demographic and disease characteristics, as well as exposure to ACE inhibitors was collected. A one-year follow-up case report form was sent to all the physicians who identified a case. The primary outcome of interest was death or dialysis at one year after the onset of SRC, comparing patients exposed and unexposed to ACE inhibitors at the time of onset of SRC.

Results: We identified 88 incident cases of SRC, of which 12 were lost to follow up (86% follow up rate). Mean age was 52 years, 67% were women, 76% had diffuse SSc and median disease duration since the onset of the first non-Raynaud's symptom was 1.5 years. The majority of cases had a hypertensive SRC (n=71/76) and only 5 had a normotensive SRC. Eighteen patients (24%) were on an ACE inhibitor immediately prior to the onset of the SRC. At one year follow up, 27 (36%) SRC patients had died and an additional 13 (17%) remained on dialysis.

The crude one-year cumulative incidence of death in those exposed to ACE inhibitors at the time of onset of SRC compared to the unexposed was 1.56 (95% confidence interval [CI] 0.70–3.47) and the crude one-year cumulative incidence of dialysis was 0.61 (95% CI 0.18–2.09). The crude Cox proportional hazard ratio comparing the time to death of SRC patients exposed to ACE inhibitors prior to the onset of SRC to those unexposed was 1.95 (95% CI 0.87–4.35). After controlling for differences in prednisone exposure and history of systemic hypertension in the two groups, the adjusted Cox proportional hazard ratio comparing the time to death of SRC patients exposed to ACE inhibitors prior to the onset of SRC to those unexposed was 2.52 (95% CI 1.05–6.05, p=0.0394).

Conclusion: SRC was associated with poor one-year outcomes. Exposure to an ACE inhibitor prior to the onset of SRC was associated with an increased risk of death during the first year of follow up after SRC. Clinicians caring for patients with early SSc should use ACE inhibitors cautiously.

Background/Purpose: The G1 and G2 coding variants in the apolipoprotein L1 gene (*APOL1;* G1: a compound missense allele (glycine-342/methionine-384) and G2: an in-frame deletion (deletion of asparagine-388 and tyrosine-389)), are strongly and reproducibly associated with focal segmental glomerulosclerosis (FSGS), HIV-associated collapsing glomerulopathy, and hypertension-attributed end-stage renal disease (ESRD) in African Americans (AAs) [Genovese G et al. Science 329:841,2010; Tzur S et al. Hum Genet 128:345,2010]. The role of *APOL1* in lupus nephritis (LN) related ESRD is unexplored. We tested for association between *APOL1* risk variants and LN-ESRD in a national sample of unrelated AAs with systemic lupus erythematosus (SLE).

Methods: The study sample included 668 AA cases with LN-ESRD (456 with kidney biopsy documentation; 212 physician-reported) and 697 AA patients with longstanding SLE lacking LN (mean duration of disease: 10.1 years). Genotyping was performed on a Sequenom platform. Allele frequency differences between LN-ESRD cases and SLE non-nephropathy cases were analyzed using multivariable logistic regression models, adjusting for non-muscle myosin heavy chain 9 gene single nucleotide polymorphism rs4821480 using a recessive genetic model.

Results: In cases with LN-ESRD, 87.1% were female, 89% received cytotoxic therapy, mean + SD age at SLE onset was 26.6 + 0.4 years, and duration of SLE to ESRD was 7.2 + 0.3 years with median at 5 years. In non-nephritis SLE patients, 93.5% were female with age at SLE onset 35.2 + 0.8 years. Contrasting all cases with and without ESRD, *APOL1* risk variants were significantly associated with LN-ESRD (odds ratio 2.35 (1.77–3.3 95% CI); p=4.25E^{-9}); significant differences in association were not observed when comparing cases with or without kidney biopsy documentation to SLE patients without LN. The duration of SLE onset to ESRD for those with the G1/G2 variants was 5.49+/−0.54 (median=4) years, while that for those without the variants was 7.78+/−0.37 (median=6) years, p<0.05.

Conclusion: This study demonstrates strong association between both *APOL1* G1 and G2 variants and LN-associated ESRD in AAs. It appears likely that *APOL1* G1 and G2 coding variants, which are rare in European populations, contribute to nephropathy progression in LN-ESRD, as well as in FSGS and other non-diabetic etiologies of ESRD. These variants, and their higher prevalence in individuals with African ancestry, may explain, in part, disparities in clinical outcomes in LN with there being a higher prevalence of severe LN in AA.

Disease Modifying Effect of Strontium Ranelate in Experimental Dog Osteoarthritis: Inhibition of Major Catabolic Pathways. Jean-Pierre Pelletier, Mohit Kapoor, Daniel Lajeunesse, Hassan Fahmi and Johanne Martel-Pelletier. Osteoarthritis Research Unit, University of Montreal Hospital Research Centre (CRCHUM), Notre-Dame Hospital, Montreal, QC

Background/Purpose: To assess the disease modifying (DMOA) effect of strontium ranelate (SrRan) under therapeutic conditions on the progression of structural changes and on the major pathways involved in these changes in an experimental osteoarthritis (OA) dog model.

Methods: Dogs were divided into 4 therapeutic groups and underwent sectioning of the anterior cruciate ligament of the right knee and, 4 weeks after surgery, received oral treatment with SrRan 25, 50 or 75 mg/kg, or placebo for 12 weeks. Severity of cartilage lesions was scored macroscopically, and specimens of cartilage, subchondral bone and synovium were processed for histology, including picrosirius red staining and quantitative PCR (RT-PCR). Specific probes were used to quantify the messenger RNA of MMP-1, MMP-13, ADAMTS5, cathepsin K and interleukin-1β (IL-1β). Histomorphometry of the subchondral bone and a pharmacokinetic analysis of strontium (Sr) blood levels were also performed. The level of CTX-II in serum was quantified by ELISA.

Results: At steady state, Sr blood exposures were found to be within the clinical therapeutic range of OA patients treated with 1 or 2 g/day of SrRan, and Sr concentrations in synovial fluid correlated with Sr blood concentrations. SrRan treatment significantly reduced the progression of

OA cartilage lesions at all dosages tested (p<0.05). Picrosirius staining also showed a significantly better preservation of the collagen network in dogs treated with SrRan at 50 and 75 mg/kg/day (p<0.03). The thickening of the subchondral plate found in the OA placebo treated dogs was reduced by SrRan treatment (50 mg/kg/day, p<0.02). The increased gene expression levels of MMP-1, MMP-13, ADAMTS5 and cathepsin K found in OA cartilage were all reduced by SrRan treatment (75 mg/kg/day, p=0.02, p=0.03, p=0.06, p<0.0001, respectively). A significant suppression of the increased levels of IL-1β in OA synovium by SrRan was also found (50 and 75 mg/kg/day, p=0.05). The serum level of CTX-II was significantly reduced at sacrifice in dogs treated with 50 and 75 mg/kg SrRan.

Conclusion: This study is the first to demonstrate that SrRan globally reduced the progression of OA structural changes, both cartilage lesions and subchondral bone sclerosis, in an *in vivo* animal model. The inhibition of the synthesis of several key pathophysiological pathways may have contributed to the protective effect of SrRan.

731

A Systems Biology Approach to Elucidating Pathways Active During the Development of Osteoarthritis. Richard F. Loeser[1], Amy L. Olex[2], Brian Westwood[2], Margaret A. McNulty[3], Cathy S. Carlson[3], Michael Callahan[4], Cristin Ferguson[4] and Jacquelyn S. Fetrow[2]. [1]Wake Forest School of Medicine, Winston-Salem, NC, [2]Wake Forest University, Winston-Salem, NC, [3]University of Minnesota, St. Paul, MN, [4]Wake Forest School of Medicine, Winston-Salem

Background/Purpose: OA affects the entire joint but most studies have focused on the disease process in a single tissue. In this study, we identified genes regulated during different stages of the development of surgically-induced OA by microarray using RNA isolated from the joint "organ" and analyzed the data using an unbiased computational modeling approach to discover the pathways active in the disease process.

Methods: 12 week-old male C57/BL6 mice underwent surgical destabilization of the medial meniscus (DMM) to induce OA or sham surgery as control. Joint tissues were collected for isolation of RNA (n=9 mice per group per time point) pre-surgery (time 0) and at 2, 4, 8, and 16 weeks after surgery and for histological analysis of OA severity (n=6 mice per group per time point). RNA was isolated from joint tissue collected from the medial half of the joint, including cartilage, meniscus, subchondral bone, and joint capsule with synovium. RNA was pooled from 3 mice for each Affymetrix microarray and 3 arrays were performed for each group at each time point. Signal log ratios (SLR) of DMM/sham were calculated using normalized array data. Genes passing detection, SLR ($\geq$0.5 or $\leq$0.5 for at least one time point in all 3 pools), and consistency filters were used for computational modeling to identify patterns of gene expression by consensus clustering, network analysis using jActiveModules (JAM) and functional classification using DAVID and KEGG.

Results: Histological lesions of OA were present in the medial tibial plateaus (MTP) of the DMM knees beginning at the earliest (2 week) time point and became progressively more severe by 16 weeks. Osteophytes were cartilaginous at 2 weeks and became progressively ossified. A total of 427 genes passed the consistency and significance filters. There were more upregulated than downregulated genes at all time points except at 8 weeks (17 up, 53 down) with the most upregulated at 4 weeks (336 up,33 down) followed by 2 weeks (174 up,12 down) and 16 weeks (84 up,2 down). Clustering identified 27 clusters with 2 or more genes and DAVID analysis of clusters upregulated at 2 and 4 weeks included morphogenesis, differentiation, development, collagen, and ECM genes as well as transcription regulatory genes. Cell division and cytoskeleton genes were in a cluster highly down-regulated at 8 weeks while genes upregulated at 16 weeks included Prelp (involved in collagen binding), Col3a1 and fibromodulin. JAM analysis revealed 13 subnetworks with gene expression activity during the time course where the majority of up-regulated genes were up at 4 weeks. Prominent sub-networks included the TGF-β signaling pathway, ECM-receptor interactions (including thrombospondins, syndecans, and collagens) and Wnt and hedgehog signaling.

Conclusion: The results support a phasic development of OA. Early matrix remodeling was associated with activation of TGFβ and Wnt/hedgehog signaling which may be drivers of cartilage degradation and osteophyte formation. The quiescent stage at 8 weeks suggests a tempo-

rary stabilization of the joint followed by activation of a more fibrotic process at 16 weeks. The findings suggest that specific therapies intended to slow disease progression may be most effective at specific stages of the disease.

Changes in Subchondral Bone Provide a Sensitive Marker for Osteoarthritis and Its Progression: Results From a Large Osteoarthritis Initiative Cohort. Michael A. Bowes[1], Christopher B. Wolstenholme[1], Devan Hopkinson[1], Graham R. Vincent[1] and Philip G. Conaghan[2]. [1]Imorphics Ltd, Manchester, United Kingdom, [2]University of Leeds, Leeds, United Kingdom

Background/Purpose: Change in subchondral bone has been clinically associated with progression of osteoarthritis (OA). Modern image analysis techniques allow accurate, automated identification of bone in MR images, facilitating the use of 3D changes in the bone to characterise and monitor OA. Objective was to compare rate of change in bone area of all the knee bones from all subjects in the OAI dataset with definite medial OA with a control group absent of radiological OA over a 4 year period.

Methods: 933 subjects with medial OA and MR images at baseline, 12, 24, 36 and 48 month were selected from the Osteoarthritis Initiative dataset; medial OA was defined as KL$\geq$ 2 and presence of medial osteophytes. 904 control subjects with absence of radiographic OA were also identified, defined as KL=0 at all time-points. One index knee was analyzed per subject. Femur, tibia and patella bones were automatically segmented from MRIs using active appearance models[1]. Anatomical areas were automatically identified within the model[2] and were measured at each time-point. All regions of the articulating surface of the femur, tibia and patella were included in the analysis.

Results: Mean age (SD) of the case group was 62 years (8.8); control group 59 (8.9); mean (SD) BMI for case/control 29.7 (4.9)/ 26.9 (4.3); %females for case/control 35%/47%. Rate of change of bone area in the medial compartments was typically 0.5% per annum in the case group with significantly lower change in the controls. Lateral compartments exhibited around half this amount of change, and showed less difference in the rates of change between cases and controls (though still highly significant). ANCOVA analysis demonstrated that age, BMI and gender could explain only a small amount of the variance in bone change.
Conclusion: Change in bone area within all knee compartments discriminated significantly between OA and control subjects. Discrimination was strongest in medial compartments, and particularly in the femur. The patella-femoral joint is an important component of OA disease, and discriminates between the groups as strongly as the femorotibial joint. Measurement of bone change provides a valuable tool for monitoring OA progression.

Intra-Articular Injection of Adipose-Derived Stem Cells Inhibits Activation of the Synovium and Protects Against Cartilage Damage and Enthesophyte Formation in Murine Experimental Osteoarthritis. Peter L.E.M. van Lent[1], Menno C. ter Huurne[1], Arjen B. Blom[1], Rik Schelbergen[1], Louis Casteilla[2], Thomas Vogl[3], Johannes Roth[3], Roxane Blattes[2], Christian Jorgensen[4] and Wim B. van den Berg[1]. [1]Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands, [2]INSERM U1031, Toulouse, France, [3]University of Muenster, Munster, Germany, [4]Hospital Lapeyronie, Montpellier, France

Background/Purpose: OA lesions are treated with mesenchymal stem cells aiming to enhance tissue repair by transformation to eg. chondrocytes. Recently it has been shown that adipose derived stem cells (ADSC) express strong immunosuppressive characteristics which might impair the activated phenotype of synovial OA macrophages. Previous studies have shown that synovial macrophages are crucial in mediating cartilage destruction and enthesophyte formation in murine collagenase-induced osteoarthritis (CiOA). In the present study we explored the effect of intra-articular injection of ADSCs on synovium, cartilage destruction and enthesophyte formation during murine CiOA.

Methods: Adipose derived stem cells (ADSCs) were isolated from fat surrounding the popliteal lymph nodes and were injected into knee joints at day 7 after induction of CiOA. CiOA was induced by injection of collagenase into murine knee joints, which causes instability and joint destruction and is characterized by synovial lining thickening. Mediators present in washouts of synovium were measured using Luminex. OA phenotypes were measured within 8 weeks after induction. Total knee joints were isolated and performed for histology. Synovial activation was measured using an arbitrary scale of 0–3, cartilage destruction according to the scorings method of Pritzker et al (2006) and enthesophyte formation in cruciate and medial collateral ligaments using image analysis.

Results: A single dose of ADSCs (20×10^3 in mouse serum) was injected into the knee joint of mice, 7 days after induction of collagenase-induced osteoarthritis. Histology showed that thickness of the synovial lining layer, which is characteristic for this model, was significantly inhibited by ADSCs treatment at day 14 (9%) and day 42 (35%) when compared to control (serum) treated OA joints. This was in line with significant lower levels of IL-1β (53%) and S100A8/A9 (51%) (no effect on TNFα and IL-6) in synovial washouts measured at day 14 after treatment. Destruction of cartilage was significantly lower both at day 14 (55%) and day 42 (35%) and was particularly found in the medial tibia. Strikingly, ADSCs treatment had a protective effect on enthesophyte formation assiocated with ligaments. At day 42, the formation of enthesophytes in medial collateral and cruciate ligaments was inhibited by 92% and 43% respectively. Intra-articular injection of GFP-labeled ADSCs into day 7 OA knee joints, showed that stem cells were clearly detected within the synovial intima in close interaction with macrophages.

Conclusion: Our study indicates that a single injection of ADSCs into the knee joints of mice with CiOA gives protection of synovial activation, cartilage destruction and enthesophyte formation when given at day 7 after onset probably by inhibiting the activated phenotype of synovial macrophages.

734

Chemokine (C-C Motif) Receptor 2 Signaling Mediates Persistent Pain in Experimental Osteoarthritis. Rachel E. Miller[1], Phuong Tran[1], Rosalina Das[1], Nayereh Ghoreishi-Haack[1], Richard J. Miller[2] and Anne-Marie Malfait[1]. [1]Rush University Medical Center, Chicago, IL, [2]Northwestern University, Evanston, IL

Background/Purpose: To investigate the role of MCP-1/CCR2 in the development of pain in osteoarthritis (OA) using a mouse model, destabilization of the medial meniscus (DMM). The protracted nature of this model enables longitudinal analysis of pain-dependent behaviors and concomitant molecular changes in the innervating dorsal root ganglia (DRG).

Methods: DMM or sham surgery was performed in the right knee of 10-week old male C57BL/6 or *Ccr2* null mice (Taconic) (total number used = 225). Pain-dependent behaviors were assessed at 0, 4, 8, and 16 weeks post surgery. Mechanical allodynia in the hind paw was assessed with von Frey fibers. Locomotion was assessed using a LABORAS platform. At the same time points, innervating dorsal DRG, L3-L5, from DMM or sham-operated and age-matched naïve mice were collected for qRT-PCR of monocyte chemoattractant protein (MCP)-1 and its receptor, CCR2. The response of DRG neurons to MCP-1 was recorded through intracellular Ca^{2+}-imaging. In brief, neurons were isolated, cultured for 3 days, and loaded with a calcium indicator dye. The number of cells responding to MCP-1 was counted. Cell culture supernatants were analyzed for MCP-1 protein via ELISA. For immunohistochemistry of DRG, mice were perfused transcardially with paraformaldehyde and DRG were collected for staining with anti-F4/80 (macrophage marker). Histopathology of the knees was evaluated according to OARSI recommendations.

Results: Joint pathology after DMM progresses slowly over 16 weeks. We documented pain-dependent behaviors longitudinally over this period, and found two stages of OA-associated pain: early-onset mechanical allodynia progressed to week 4, and was maintained for 16 weeks. Locomotive changes indicative of chronic pain (decreases in distance traveled and climbing) were first apparent 8 weeks after DMM, and maintained up to week 16. These changes were reversible with buprenorphine; DRG mRNA levels of MCP-1 and CCR2 were increased compared to naïve and sham controls, peaking at week 8 post DMM (p<0.01); Exposure of DRG neurons isolated 8 weeks post DMM to MCP-1 resulted in an increased calcium mobilization response compared to naïve and sham controls, indicating a functional role for MCP-1/CCR2 signaling in DRG neurons (p<0.0001); Protein levels of MCP-1 were increased in the supernatants of these cultured DRG cells compared to naïve and sham (p<0.0001); DRG may be infiltrated by immune cells, particularly macrophages, which may contribute to pain signaling. Therefore, we examined changes in the DRG macrophage population following DMM and found that by week 8, macrophages infiltrated the DRG and this was maintained through week 16; *Ccr2* null mice developed comparable joint damage 8 weeks post DMM to wild types, but showed altered pain behavior: i) Similar levels of mechanical allodynia developed up to week 8, but the allodynia completely resolved by week 16 weeks; ii) *Ccr2* null mice were protected from decreases in locomotion at 8 and 16 weeks. Macrophage infiltration was not noted in *Ccr2* null DRG at 8 weeks post DMM.

Conclusion: These data support a role for MCP-1/CCR2 in the persistence of experimental OA-associated pain. This pathway merits further exploration as a target for pain in OA.

735

Mass Spectrometry Assays of Plasma Biomarkers to Predict Radiographic Progression of Knee Osteoarthritis. Susan Y. Ritter[1], William M. Reichmann[1], Jamie E. Collins[1], Alejandra Garces[2], Bryan Krastins[2], David Sarracino[2], Mary Lopez[2], Elena Losina[1] and Antonios O. Aliprantis[1]. [1]Brigham and Women's Hospital, Boston, MA, [2]Thermo Fisher Scientific BRIMS Center, Cambridge, MA

Background/Purpose: Biomarkers to identify osteoarthritis (OA) patients at risk for disease progression are needed. Recently, we performed a proteomic analysis of knee synovial fluid from normal and OA patients to identify differentially expressed proteins that could represent biomarkers of disease activity. Mass spectrometry assays were developed to identify representative peptides from several of these proteins in both synovial fluid and peripheral blood. We tested a panel of these putative biomarkers in a cohort of OA patients followed prospectively for 30 months to identify those peptides that correlate with radiographic progression.

Methods: Multiplexed high throughput selected reaction monitoring (SRM) assays were developed to measure multiple peptides representative of the following 9 proteins identified in previous discovery experiments: afamin, clusterin, insulin-like growth factor binding protein, acid labile subunit, lumican, pigment epithelium-derived factor, lubricin, hepatocyte growth factor, kallistatin, cartilage oligomeric matrix protein. Plasma samples obtained from baseline visit of 173 subjects in an observational OA progression cohort were trypsin digested and SRM assays were performed. Linear regression was used to determine association between each biomarker level at the baseline and maximal joint space narrowing from baseline to 30 months. Correlation matrixes and linear regression models were then performed for the biomarkers, adjusting for age and sex. Finally, a biomarker score was developed for 2 peptides to examine the amount of progression explained by a combination of biomarkers.

Results: For this progression cohort, average age was 61 and average joint space narrowing over 30 months was 0.68 mm. A good correlation between multiple peptides for each individual protein was observed, indicating our assays were correctly measuring their target proteins. From our panel of putative biomarkers, peptides representative of clusterin, lumican and lubricin showed statistically significant associations with joint space narrowing after adjustment for age and sex. Partial R^2 values from these linear regression models show the clusterin FMETVAEK peptide and lubricin LVEVNPK peptide biomarker explains about 2–3% of the variability of JSN, values similar to the amount explained by age **(Table)**. A biomarker score was developed combining normalized data for both lubricin and clusterin peptides, which increased the model R^2 to 0.079.

Table. Linear regression models adjusting for age and sex

Model #	Model R^2	Parameter	Parameter Estimate	Partial R^2	p-value
1	0.063	Clusterin(F)	−1.64	0.022	0.05
		Age	−0.01	0.028	0.03
		Sex	0.26	0.026	0.03
2	0.075	PRG4(L)	−20.96	0.033	0.01
		Age	−0.01	0.030	0.02
		Sex	0.24	0.024	0.04
3	0.079	Biomarker score*	−0.13	0.038	0.01
		Age	−0.01	0.031	0.02
		Sex	0.28	0.030	0.02

*Normalized values for Clusterin(F) and PRG4(L) using beta estimates from models 1 and 2

Conclusion: Targeted mass spectrometry assays provide a rapid means to validate novel biomarkers in human samples. Our results suggest that when combined, clusterin and lubricin levels in plasma are as predictive of OA progression as age. Replication of these findings in other prospective OA cohorts is planned.

Inhibition of Interleukin-17 Signaling Via De-Ubiquitinatio. Sarah L. Gaffen and Abhishek Garg. University of Pittsburgh, Pittsburgh, PA

Background/Purpose: IL-17A (IL-17) is a proinflammatory cytokine that contributes to the pathogenesis of various autoimmune diseases, including rheumatoid arthritis (RA), multiple sclerosis (MS) and psoriasis. Despite limited homology with the toll-like receptors, IL-17 receptor subunits (IL-17RA and IL-17RC) do not recruit TLR-associated adaptors such as MyD88, but instead associate with the adaptor protein Act1/CIKS. Upon recruitment, Act1 activates pro-inflammatory signaling pathways including TRAF6/NF-kappaB, MAPK and CCAAT Enhancer Binding Proteins (C/EBP) Despite advances in identifying molecular events downstream of IL-17 signal transduction, mechanisms by which IL-17 signaling is constrained remain poorly understood. Ubiquitination is a central post-translational signaling mechanism involved in activation of inflammation, particularly the NF-kappaB pathway. Notably, both Act1 and Traf6 exhibit E3 ubiquitin ligase activity. Genome analysis has identified over 100 deubiquitinases (DUBs) in humans but their role in IL-17 signaling is unknown. Polymorphisms in the gene encoding the DUB A20 (Tnfaip3) are associated with autoimmune diseases including RA and psoriasis. A20 was originally defined as an inhibitor of the TNF signaling pathway. Here, we show that A20 also participates in downregulating the IL-17 signaling pathway.

Methods: IL-17 signaling was assessed in the stromal cell line ST2. Regulation of IL-17-induced genes was assessed by combinations of siRNA silencing, quantitative real-time RT-PCR (qPCR), immunoblotting and luciferase analyses. Association of receptor-associated proteins was determined by co-immunoprecipitation.

Results: IL-17 induced A20 expression, and transient knockdown of A20 resulted in increased IL-17-dependent proinflammatory target gene expression. Consistently, overexpression of A20 inhibits IL-17 target gene expression, which was associated with reduced NF-κB activity. Interestingly, A20 associated with IL-17RA at a motif that was previously linked to negative regulation of the IL-17 signaling pathway.

Conclusion: We show for the first time that A20 is an inhibitor of the IL-17 signaling pathway. This provides a new mechanistic explanation for the role of A20 in regulating autoimmune disease. Moreover, regulation of A20 could serve as a potential target for pharmacologic manipulation of inflammatory signaling in autoimmunity.

Citrullination of ENA-78/CXCL5 Results in Conversion From a Non-Monocyte Recruiting to a Monocyte Recruiting Chemokine. Ken Yoshida[1], Olex Korchynskyi[2], Paul P. Tak[3], Takeo Isozaki[1], Jeffrey H. Ruth[1], Phillip Campbell[1], Dominique L. Baeten[4], Danielle M. Gerlag[4], M. Asif Amin[1] and Alisa E. Koch[5]. [1]University of Michigan, Ann Arbor, MI, [2]Institute of Cell Biology, Lviv, Ukraine, [3]GlaxoSmithKline U.K. and Academic Medical Center/University of Amsterdam, Amsterdam, Netherlands, [4]Academic Medical Center/University of Amsterdam, Amsterdam, Netherlands, [5]University of Michigan Medical School, Ann Arbor, MI

Background/Purpose: Citrullination is a post-translational modification that is the conversion of arginine to citrulline in proteins mediated by peptidylarginine deiminase (PAD). Antibodies directed towards the citrullinated proteins are highly specific for rheumatoid arthritis (RA). We and others have shown that some chemokines including ENA-78/CXCL5 play important roles in the development of RA. We undertook this study to examine whether citrullinated ENA-78/CXCL5 (citENA-78/CXCL5) is detected in RA biological fluids, and if so, what its biological activity is.

Methods: An expression plasmid containing polyhistidine tagged human ENA-78/CXCL5 was transfected into the human embryonic kidney 293T cell line for ENA-78/CXCL5 production. After citrullination of the ENA-78/CXCL5 with rabbit PAD, citENA-78/CXCL5 was used as standard for enzyme linked immunosorbent assay (ELISA). The concentrations of citENA-78/CXCL5 in synovial fluids (SFs) or sera were measured by ELISA using anti-modified citrulline antibody. The citENA-78/CXCL5 levels in RA were compared with osteoarthritis (OA) and other inflammatory rheumatic diseases, and the correlation between the citENA-78/CXCL5 levels and clinical data was analyzed. Monocyte and polymorphonuclear neutrophil (PMN) chemotaxis assays were performed using a 48-well Boyden chamber system to examine the biological activity of citENA-78/CXCL5 compared to ENA-78/CXCL5. C57BL/6 mice were injected intra-articularly with ENA-78/CXCL5 or citENA-78/CXCL5 to induce inflammation and the severity of inflammation was evaluated to compare the biological activity of citENA-78/CXCL5 to ENA-78/CXCL5.

Results: CitENA-78/CXCL5 was significantly higher in RA (n=11, mean±SE; 286.3±68.0 pg/ml) than NL sera (n=15, 1.2±2.6 pg/ml) and higher in RA (n=20, 1126.4±296.6 pg/ml) compared to other inflammatory diseases (n=14, 14.1±8.2 pg/ml) and OA (n=15, 2.3±1.0 pg/ml) SFs. There was no significant correlation between ENA-78/CXCL5 levels and clinical data. On the other hand, there were significant positive correlations between citENA-78/CXCL5 and C-reactive protein (CRP) levels (RA; n=14, r=0.69, p<0.05, RF positive RA; n=10, r=0.86, p<0.05), citENA-78/CXCL5 and erythrocyte sedimentation rate (ESR) (RA; n=15, r=0.77, p<0.05, RF positive RA; n=11, r=0.71, p<0.05). Chemotaxis assays showed that PMN migration in response to citENA-78/CXCL5 was similar to that induced by ENA-78/CXCL5. However, citENA-78/CXCL5 induced monocyte migration, but ENA-78/CXCL5 did not. *In vivo*, citENA-78/CXCL5 induced more intraarticular inflammation compared to ENA-78/CXCL5.

Conclusion: CitENA-78/CXCL5 was detected in RA biological fluids and the concentrations were significantly higher in RA than OA or other diseases, and correlated with the inflammatory markers CRP and ESR. CitENA-78/CXCL5 induced monocyte migration while ENA-78/CXCL5 did not. CitENA-78/CXCL5 induced more severe joint inflammation compared to ENA-78/CXCL5. This may be attributed to the fact that citENA-78/CXCL5 acquired a monocyte recruiting function that ENA-78/CXCL5 does not have. These results indicate that citENA-78/CXCL5 may have novel inflammatory properties compared to ENA-78/CXCL5 in RA pathogenesis.

A Novel Orally Active Phosphatidylinositol 3-Phosphate 5-Kinase (PIK-fyve) Inhibitor Ameliorates Mouse Psoriasis-Like Model by Inhibition of Interleukin-12 and Interleukin-23 Production From Macrophages. Ayatoshi Andou, Eviryanti Agung, Yukie Seki, Yoichiro Shima, Sen Takeshita, Takashi Yamamoto and Hiroyuki Eda. Ajinomoto Pharmaceuticals Co., Ltd., Kanagawa, Japan

Background/Purpose: Phosphatidylinositol (3,5)-bisphosphate $(PI(3,5)P_2)$ is the most recently-identified phospholipid component of cellular membrane. Phosphatidylinositol 3-phosphate 5-kinase (PIKfyve) is a critical enzyme for the synthesis of $PI(3,5)P_2$ from phosphatidylinositol 3-monophosphate (PI3P), which has been implicated in intracellular trafficking events, but little is known about its biological function. We discovered a lead-compound APY0201 which is a potent, highly selective PIKfyve kinase inhibitor. In this study, we characterized anti-inflammatory properties of APY0201 *in vitro* and *in vivo*.

Methods: *In vitro* study: Mouse macrophages (thioglycolate-induced peritoneal exudate cells) and human peripheral blood mononuclear cells (PBMCs) stimulated by IFN-γ and heat-killed whole bacteria (*Staphylococcus aureus*Cowan strain I (SAC)) were used in this assay.

In vivo study: The imiquimod (IMQ)-induced psoriasis model was used. Female Balb/c mice received daily topical application of approx. 16 mg 0.5% IMQ cream & Vaseline mix (1:1, equivalent to 0.4 mg IMQ) on the right ear for 4 days. APY0201 or vehicle was orally or topically administered once daily. The severity of inflammation was assessed by daily ear thickness and ear weight after 4 days of IMQ-treatment.

Results: APY0201 inhibited the conversion of PI3P to $PI(3,5)P_2$ in the presence of recombinant human PIKfyve with an IC_{50} value of 8.9 nM. It is highly selective for PIKfyve compared to various receptors, channels and enzymes including 25 lipid kinases and 83 protein kinases. Interestingly, APY0201 demonstrated potent *in vitro* inhibitory activity against interleukin(IL)-12p70 production from mouse macrophages and human PBMCs with an IC_{50} value of 8.4 nM and 9.9 nM, respectively. Furthermore, IL-12/23 production but not other inflammatory mediators, such as TNF-α and MCP-1 from these cells were inhibited by APY0201. Downregulation of PIKfyve using siRNA of PIKfyve inhibited expression of IL-12 subunit mRNA in IFN-γ/SAC-activated mouse macrophages. These results indicate APY0201 exerts its inhibitory activity of IL-12/23 production *via* PIKfyve inhibition. In *ex vivo*study, IL-12p70 production was significantly inhibited in IFN-γ/SAC-activated whole blood from mice orally administered with APY0201. Finally, daily oral or topical administration of APY0201 significantly ameliorated skin inflammation in mouse psoriasis-like model.

Conclusion: The therapeutic potential of IL-12/23 inhibition in Th1/Th17-mediated immunological disorders, such as psoriasis has been clinically validated on the efficacy of ustekinumab, anti-IL-12/23 antibody. Our results clearly indicate that PIKfyve inhibition contribute to the suppression of inflammation in both *in vitro* and *in vivo*. Consequently APY0201, highly selective PIKfyve kinase inhibitor might be a promising medication for the treatment of patients with psoriasis.

The Serine Arginine Protein SF2/ASF Is a Novel Regulator of IL-2 Transcription and Restores IL-2 Production in T Lymphocytes From SLE Patients. Vaishali R. Moulton, Alexandros P. Grammatikos and George C. Tsokos. Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA

Background/Purpose: Systemic lupus erythematosus (SLE) is a complex autoimmune disease which afflicts mainly women in the reproductive years, and causes painful arthritis, skin disease and complications in the kidneys and brain. Abnormal T lymphocytes in SLE not only regulate autoantibody-producing B cells, but are also responsible for target organ infiltration. Currently, no specific therapies target T cell defects. Moreover, there are no known molecular markers to predict disease activity. Aberrant molecular mechanisms responsible for SLE T cell defects are thus promising targets for therapy, as well as potential biomarkers for disease. A key defect of T cells from lupus patients is that they produce insufficient amounts of the vital cytokine interleukin (IL)-2. Reduced IL-2 production is linked to reduced cytotoxicity, defective regulatory T cell function, and impaired activation-induced cell death leading to persistence of autoreactive T cells. We previously showed that T cells from SLE patients express decreased levels of the T cell receptor (TCR) - associated CD3 zeta (ζ) chain, a feature directly linked to their poor IL-2 production. We recently showed that the serine arginine (SR) protein splicing factor 2/alternative splicing factor (SF2/ASF) enhances the expression of CD3ζ chain by limiting the production of an unstable mRNA splice variant. In this study we asked whether the expression of SF2/ASF is aberrant in T cells from SLE patients and if SF2/ASF regulates T cell function, specifically IL-2 production.

Methods: T cells were isolated by negative selection from peripheral blood of SLE patients and healthy controls. SF2/ASF mRNA and protein expression was assessed using real time pcr and immunoblotting respectively. T cells were transiently transfected with siRNA or plasmids using electroporation. T cells were activated with anti-CD3 and anti-CD28 antibodies. Transcriptional activity was studied using the dual luciferase reporter assay system. IL-2 production was measured in supernatants by enzyme linked immunosorbent assay (ELISA). Chromatin immunoprecipitation assays were used to assess transcription factor binding to the IL-2 promoter.

Results: We show that SF2/ASF expression levels are decreased in T cells from SLE patients, and correlate inversely with patients' SLE disease activity index (SLEDAI). Importantly, overexpression of SF2/ASF in SLE T cells enhances their IL-2 production. In parallel, silencing SF2/ASF expression in normal T cells reduces their IL-2 secretion. Using reporter assays, we show that SF2/ASF increases transcriptional activity of the IL-2 promoter. Further, SF2/ASF induces the expression of the nuclear factor of activated T cells (NFAT) and c-fos transcription factors, and induces increased binding of NFAT and c-fos to the IL-2 promoter. Finally, we show recruitment of SF2/ASF to the IL2 promoter indicating its direct role in IL-2 transcription.

Conclusion: Our results identify SF2/ASF as a novel regulator of IL-2 expression in human T cells and a potential molecular mechanism underlying the altered T cell defect in SLE.

Select Soluble Inflammatory Mediators Are Detected Prior to and Increase At Systemic Lupus Erythematosus Classification. Melissa E. Munroe[1], Jourdan R. Anderson[1], Julie M. Robertson[1], Timothy B. Niewold[2], George C. Tsokos[3], Michael P. Keith[4], John B. Harley[5] and Judith A. James[6]. [1]Oklahoma Medical Research Foundation, Oklahoma City, OK, [2]University of Chicago, Chicago, IL, [3]Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA, [4]Walter Reed National Military Medical Center, Bethesda, MD, [5]Cincinnati Children's Hospital Medical Center; US Department of Veterans Affairs Medical Center, Cincinnati, OH, [6]Oklahoma Medical Research Foundation; Oklahoma University Health Sciences Center, Oklahoma City, OK

Background/Purpose: The processes that lead to clinical illness in systemic lupus erythematosus (SLE) years before diagnosis are not well characterized. Several cytokines have been associated with increased activity in established disease after diagnosis. This study evaluates the temporal relationship between autoantibody production, cytokine levels and the onset of SLE clinical disease.

Methods: Serial sera from 60 SLE cases before diagnosis with no ACR criteria to SLE classification (average timespan= 4.4 years) were obtained from the Department of Defense Serum Repository (DODSR). Sera samples were tested for C-reactive protein (hs-CRP), Von Willebrand's Factor (VWF) and 32 soluble inflammatory mediators, including cytokines, chemokines, and soluble receptors using xMAP multiplex bead-based assays or sandwich ELISA (BLyS, APRIL, hs-CRP, and VWF). In addition, samples were assessed for the presence of SLE-associated autoantibodies, including Ro, La, nRNP, Sm, Ribosomal P, dsDNA, and ANA by ELISA and immunofluorescence. Interferon (IFN) activity was assessed by a cell reporter assay measuring interferon responsive gene expression (MX1, PKR, and IFIT1) by serum.

Results: Patient samples before ACR classification had significant ($p \leq 0.01$) alterations in 16 soluble mediators of inflammation, as well as VWF and hs-CRP. Levels of particular TNF Receptor (TNFR) family members, TNFRI, TNFRII, BLyS, and APRIL, dramatically increased as lupus classification approached (levels at clinical symptoms versus pre-clinical sera, $p \leq 0.001$). The increase in these TNFR mediators affecting B-lymphocyte activation parallels the accumulation of autoantibodies seen leading up to diagnosis in SLE cases. Interferon (IFN)-associated mediators of inflammation are also of particular interest and were assessed. An initial evaluation of 20 SLE cases from this study revealed a significant increase in IFN activity leading up to diagnosis ($p = 0.0279$). We find a similar pattern of increased IFN-γ, IP-10, MIG, and MIP-1α ($p \leq 0.01$) leading up to diagnosis. Mediators such as VWF, hs-CRP, stem cell factor and resistin also increase over the pre-clinical course to SLE transition ($p \leq 0.01$). Inflammatory mediators IL-12 and IL-17 were significantly elevated ($p \leq 0.01$) in pre-clinical samples compared with first ACR criterion and lupus classification.

Conclusion: Before SLE patients transition to clinical disease, they have significantly elevated levels of soluble inflammatory mediators. Further elevation of select markers occurs between early clinical symptoms and classified disease. That these alterations are present prior to the transition to active SLE suggests that multiple perturbations in immune-mediated inflammatory processes occur long before clinical classification and suggest that high-risk, pre-clinical individuals, destined to become SLE patients, can be identified before their illness is clinically manifested and damaging.

Increased Risk of Recurrent Gout Attacks During Hospitalization.
Yuqing Zhang[1], Clara Chen[2], Hyon K. Choi[3], Christine E. Chaisson[2], David J. Hunter[4] and Tuhina Neogi[5]. [1]Boston University, Boston, MA, [2]Boston University School of Public Health, Boston, MA, [3]Boston University School of Medicine, University of British Columbia, Arthritis Research Centre of Canada, Boston, MA, [4]University of Sydney, Sydney, Australia, [5]Boston Univ Schl of Med, Boston, MA

Background/Purpose: While anecdotal evidence suggests that risk of recurrent gout attack increases during hospitalization and gout is one of the most common reasons for in-patient rheumatology consultations, to our knowledge no study has formally tested this hypothesis. Understanding the magnitude of risk conferred by hospitalization on recurrent gout attacks would provide clinical guidance as to whether prophylactic therapy should be provided to prevent gout attacks in patients with existing gout during hospitalization, particularly since such attacks contribute to increased length of hospital stay.

Methods: We conducted an online case-crossover study to assess putative risk factors, including hospitalization, for recurrent gout attacks among persons with pre-existing gout. Those who had experienced at least one gout attack within the previous year were recruited online and underwent verification of gout diagnosis through medical records review. Participants logged onto the study website when they experienced a gout attack and provided exposure information (including hospitalization) over the two-day period prior to an acute gout attack (case period) using an online questionnaire. The same questionnaire was collected for a two-day period during an intercritical period (control period) in a 3-month interval for up to four times. We examined the relation of hospitalization and reasons for hospitalization over a 2-day period to the risk of recurrent gout attacks using conditional logistic regression.

Results: Our analysis included 724 subjects who experienced recurrent gout attacks during the study period (mean age 54.5, mean BMI 32.1, 78.5% male). Over the one-year follow-up period, 35 hospitalizations occurred. Of these, 3 hospitalizations were due to gout-related conditions and were excluded from the analysis. Of the remaining, 10 were for surgery, 9 for acute infections, and 13 for other conditions. The proportion of hospitalization was 5.2 and 15.4 per 1000 person-periods during the control and case periods, respectively. Adjusting for alcohol consumption, purine intake, and use of diuretics, allopurinol, colchicine, and NSAIDs, the odds of recurrent gout attacks during hospitalization increased by more than 3-fold (odds ratio=3.86, 95% confidence interval: 1.69–8.84) compared with periods without hospitalization (Table).

Table. Hospitalization and Risk of Recurrent Gout Attacks

Hospitalization Over 2 Days	No. Control Periods	No. Hazard Periods	Adjusted OR (95% CI)
No	1931	1402	1.00 (referent)
Yes	10	22	3.86 (1.69–8.84)

Conclusion: Our study confirmed that the risk of gout attacks increases during hospitalization. These data support the consideration of the provision of appropriate prophylaxis to patients with pre-existing gout during hospitalization.

Utility of HLA-B5801 Genotyping and Renal Dosing of the Starting Dose of Allopurinol in Preventing Allopurinol Hypersensitivity Syndrome: A Cost-Effectiveness Analysis. Yanyan Zhu[1], Ada Man[2], Tuhina Neogi[3] and Hyon K. Choi[4]. [1]Boston University School of Medicine, Boston, MA, [2]Boston University, Boston, MA, [3]Boston Univ School of Medicine, Boston, MA, [4]Boston University School of Medicine, University of British Columbia, Arthritis Research Centre of Canada, Boston, MA

Background/Purpose: Allopurinol is the leading choice of urate-lowering therapy (95%) for gout which affects 8.3 million US adults. However, allopurinol is associated with a rare but potentially fatal reaction: allopurinol hypersensitivity syndrome (AHS). Studies have shown that HLA-B5801 allele carriage and renal impairment are strongly associated with AHS, suggesting utility of considering these factors in treatment decisions to prevent AHS and AHS-related deaths. We examined the cost-effectiveness of HLA-B5801 genotyping and renal dosing in preventing AHS and AHS-related deaths.

Methods: We built a decision model to compare 4 treatment strategies for 1 million hypothetical patients starting allopurinol in the US. All key parameters and costs were derived from the literature, including the risk of AHS: 0.163%, the risk of death among AHS cases: 26%, the probabilities of HLA-B5801 allele carriage: 0.01 (Caucasians) and 0.07 (Asians), relative risk (RR) of AHS among HLA-B5801 positive patients: 96.6, sensitivity for predicting AHS by renal dosing: 90% [1], HLA-B5801 genotyping cost: $45.11 and the average AHS hospitalization cost: $50,152. Sensitivity analyses were conducted by varying the risk of AHS, RR of AHS among HLA-B5801 positive patients, sensitivity for predicting AHS by renal dosing, and AHS hospitalization cost.

Results: Initiating treatment in all patients with the standard dose resulted in 1630 AHS cases and 424 AHS related deaths. Compared with the standard dose strategy, the combined use of HLA-B5801 genotyping and renal dosing prevented 95% of AHS cases and AHS-related deaths, and saved $32,500,684. It led to incremental cost-effectiveness ratios (ICERs) of −$21,009 per AHS case avoided and −$80,647 per death avoided among Caucasians (i.e., cost-saving). Compared with renal dosing alone, the combined use of HLA-B5801 genotyping and renal dosing avoided 80 more AHS cases and 21 more AHS-related deaths at an incremental cost of $41,072,740, resulting in ICERs of $513,409 per AHS case avoided and $1,955,845 per death avoided among Caucasians. The corresponding effectiveness and ICERs were more favorable among Asians (**Table**). Sensitivity analyses suggested the results were robust to variation in these model parameters.

Table. Results of the Base Case Analysis*

Population	Strategy	Incremental cost (per million patients)	AHS Cases avoided	ICER (per case)	Deaths avoided	ICER (per death)
		Compared with the standard starting dose for all patients strategy				
US Caucasians	1. Standard starting dose (300mg/day) for all patients	–	–	–	–	–
	2. Renally-adjusted starting dose (1.5 mg allopurinol per unit eGFR (mg/ml/min)) for all patients	–$73,573,424	1467	–$50,152	382	–$192,601
	3. Standard starting dose for HLA-B5801 negative patients	$4,737,399	805	$5,885	209	$22,667
	4. Renally-adjusted starting dose for HLA-B5801 negative patients	–$32,500,684	1547	–$21,009	403	–$80,647
US Asians	1. Standard starting dose for all patients	–	–	–	–	–
	2. Renally-adjusted starting dose for all patients	–$73,573,424	1467	–$50,152	382	–$192,601
	3. Standard starting dose for HLA-B5801 negative patients	–$26,754,490	1433	–$18,670	373	–$71,728
	4. Renally-adjusted starting dose for HLA-B5801 negative patients	–$35,649,873	1610	–$22,143	419	–$85,083
		Compared with the renally-adjusted starting dose for all patients strategy				
US Caucasians	2. Renally-adjusted starting dose for all patients	–	–	–	–	–
	4. Renally-adjusted starting dose for HLA-B5801 negative patients	$41,072,740	80	$513,409	21	$1,955,845
US Asians	2. Renally-adjusted starting dose for all patients	–	–	–	–	–
	4. Renally-adjusted starting dose for HLA-B5801 negative patients	$37,923,551	143	$265,200	37	$1,024,961

*Negative dollar amounts = cost-saving

Conclusion: The combined use of the HLA-B5801 genotyping and renal dosing of the starting dose of allopurinol was able to avert the majority of AHS cases and AHS-related deaths. The ICERs were especially favorable among Asians due to a higher probability of HLA-B5801 allele carriage. Since renal dosing was responsible for the majority of the reduction of AHS and AHS-related deaths at no incremental costs, this strategy alone was the most cost-effective. However, the combined use of the HLA-B5801 genotyping and renal dosing was considered cost-effective given that $7 million in the US is the median acceptable cost per life saved [2].

Anemia and the Onset of Gout in a Population-Based Cohort of Adults: Atherosclerosis Risk in Communities Study. Mara McAdams DeMarco[1], Janet W. Maynard[2], Josef Coresh[1] and Alan N. Baer[2]. [1]Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, [2]Johns Hopkins University School of Medicine, Division of Rheumatology, Baltimore, MD

Background/Purpose: There is a growing prevalence of gout in the US and worldwide. Gout is a recognized risk factor for cardiovascular disease (CVD). It is unclear whether other risk factors for CVD are also associated with increased risk of gout. Anemia is one such CVD risk factor. No studies have evaluated the relationship between anemia and gout. We tested whether anemia was associated with incident gout independent of comorbid conditions in Atherosclerosis Risk in Communities (ARIC).

Methods: ARIC is a prospective population-based cohort recruited in 1987–1989 from 4 US communities, consisting of 4 visits over 9 years. Participants were included in this analysis if they answered the gout query and were free of gout at baseline. Incident gout was defined as self-reported onset after baseline. Anemia was defined as hemoglobin <13.5 g/dL for men and <12 g/dL for women. Using a Cox Proportional Hazards model (age as time scale), we estimated the hazard ratio (HR) and confidence intervals (CI) of incident gout by baseline anemia, adjusted for confounders (sex, race, eGFR, BMI, and alcohol intake) and clinical factors (coronary heart disease, CHF, diabetes, hypertension, diuretic use, and serum urate level).

Results: A total of 10,791 ARIC participants met the study criteria. The study population was 43% male, 21% African American and the mean age at cohort entry was 54 years (SD=5.7). The mean hemoglobin level was 13.9 g/dL (SD=1.37); for men 14.9 g/dL (SD=1.1) and for women 13.1 g/dL (SD=1.1). At baseline, 1,084 (10%) participants were classified as having anemia; 66% of the participants with anemia were women. There were 271 cases of incident gout. The results are presented in the table. Patients with anemia had a 2-fold increased risk of developing gout (HR=2.01, 95% CI: 1.46, 2.76). Anemia was associated with incident gout independent of known gout risk factors, confounders and clinical risk factors (HR=1.73, 95% CI: 1.24, 2.41) and after additionally adjusting for serum urate level (HR=1.83, 95% CI: 1.30, 2.57). There was no evidence of effect measure modification by race (p=0.83) or kidney function (p-value=0.29) and limited support for an interaction by sex (p=0.06). Among female participants, the HR of incident gout by baseline anemia status was 2.38 (95% CI: 1.47, 3.84) compared to 1.43 (95% CI: 0.88, 2.30) for male participants.

Table. HR of incident gout by baseline anemia in ARIC

Model	HR (95% CI)
Unadjusted	2.01 (1.46, 2.76)*
Sex and race adjusted	1.52 (1.10, 2.12)*
Sex, race and eGFR adjusted	1.54 (1.11, 2.14)*
Adjusted for confounders[1]	1.64 (1.18, 2.28)*
Additionally adjusted for clinical factors[2]	1.73 (1.24, 2.41)*
Additionally adjusted for serum urate	1.83 (1.30, 2.57)**

[1] Confounders: Sex, race, categorical eGFR, BMI and alcohol intake.
[2] Clinical factors: Baseline hypertension, diuretic use, CHD, and CHF.
* p< 0.05
** p<0.001

Conclusion: We identified anemia as a novel risk factor for gout. Anemia was associated with an approximately 2-fold increased risk of gout independent of kidney function and serum urate. These findings suggest that anemia is a risk factor for gout on par with other chronic conditions such as obesity and diabetes. The biological mechanism linking anemia to gout remains unclear.

Racial Differences in Reported Knee Pain Severity Persist Even After Adjustment for Knee Examination and Radiographic Findings: Data From the Osteoarthritis Initiative. Paige Luneburg[1], Laura Yerges-Armstrong[2], Braxton D. Mitchell[2] and Marc C. Hochberg[1]. [1]University of Maryland, Baltimore, MD, [2]University of Maryland School of Medicine, Baltimore, MD

Background/Purpose: African Americans have a higher prevalence of both radiographic and symptomatic radiographic knee osteoarthritis (OA) than Caucasians. In addition, African Americans with knee OA report more pain than Caucasians. While the reasons for these disparities are poorly understood, differences in risk factor patterns and/or pathoanatomic characteristics have been suggested. We hypothesized that these racial differences might be explained by differences in findings found upon physical examinations, even while stratifying by radiographic severity.

Methods: Racial differences in pain reporting and severity as well as radiographic and physical examination findings of the knees were assessed using baseline data from subjects enrolled in the Osteoarthritis Initiative (OAI), a multicenter, longitudinal observational study initiated in 2004 to

examine biomarkers and risk factors for clinically significant knee OA. This analysis was limited to 690 African Americans and 3,337 Caucasians with complete data from the baseline visit for knee pain, clinical knee exam features, covariates of interest and bilateral fixed-flexion knee radiographs that had been centrally read for OA using the Kellgren-Lawrence (KL) scale. Three measures of pain severity (KOOS, WOMAC and NRS) were analyzed for each knee. We first evaluated racial differences in clinical exam findings using logistic regression models. We next used ANCOVA to determine if race was associated with pain severity while adjusting for anthropometric and demographic variables (body mass index, age, gender, income, depression score, and education level). Analyses were stratified into two groups by radiographic severity (KL=0 or 1 and KL ≥ 2). Finally, we additionally adjusted for clinical exam features that were significantly different between the racial groups.

Results: Patellar quadriceps tendinitis, lateral and medial tibiofemoral joint line tenderness, patellofemoral crepitus and grind, and pain on knee flexion were more common in blacks than whites (p<0.008 for all). No significant differences between racial groups were observed for static alignment, anserine bursa pain or presence of effusion. Blacks reported more knee pain for all three measures of pain severity (p<0.0001) regardless of radiographic severity. After adjusting for differences in knee examination, blacks still reported more knee pain for all three measures of pain severity: adjusted means and P-values are reported in Table 1.

Table.

Dependent	KL Grade	Right Knee Whites N	Right Knee Whites Adj. Mean	Right Knee Blacks N	Right Knee Blacks Adj. Mean	P-value	Left Knee Whites N	Left Knee Whites Adj. Mean	Left Knee Blacks N	Left Knee Blacks Adj. Mean	P-value
Knee Pain Severity in Past 7 Days	0–1	1885	2.0	282	2.5	<0.0001	1942	1.8	305	2.3	0.0001
	2–4	1398	2.9	392	3.5	<0.0001	1349	3.0	363	3.4	0.0138
KOOS Pain Score	0–1	1885	88.6	282	83.5	<0.0001	1942	90.2	305	85.7	<0.0001
	2–4	1398	81.1	392	76.3	<0.0001	1349	81.0	363	75.6	<0.0001
WOMAC Pain Score	0–1	1885	1.7	282	2.7	<0.0001	1942	1.4	305	2.4	<0.0001
	2–4	1398	2.9	392	4.0	<0.0001	1349	3.0	363	4.2	<0.0001

Adjusted for for body mass index, age, gender, income, depression score, and education level and clinical exam features.

Conclusion: These results demonstrate that African Americans report more knee pain than Caucasians and that this finding cannot be explained by features found upon knee examination or differences in radiographic severity. Further analyses will examine the potential role of coping mechanisms, psychosocial health and findings on magnetic resonance imaging of the knees.

Soft Drink Intake and Progression of Radiographic Knee Osteoarthritis: Data From the Osteoarthritis Initiative.
Bing Lu[1], Jeffrey Driban[2], Tim McAlindon[3] and Charles Eaton[4]. [1]Brigham and Women's Hospital, Boston, MA, [2]Tufts Medical Center, MA, [3]Tufts Medical Center, Boston, MA, [4]Warren Alpert Medical School at Brown University, RI

Background/Purpose: Soft drink consumption has been associated with weight gain and obesity which is a significant risk factor of osteoarthritis (OA), but its role in the progression of OA is unclear. We examine the prospective association of soft drink consumption with radiographic progression of OA.

Methods: In the Osteoarthritis Initiative (OAI), 2149 participants (3066 knees) with radiographic knee OA and having dietary data at baseline were followed up to 12, 24, 36 and 48 months. The frequency of soft drink (not including diet drinks) consumption was assessed with a Block Brief Food Frequency Questionnaire that was completed at baseline. To measure the OA progression, we used the change of a precise quantitative joint space width (JSW) in medial compartment over time between the adjacent bones of the knee based on plain radiographs. The multivariate linear models for repeated measures were used to test the independent association between soft drink

intake and the change in JSW over time, while adjusting for Body Mass Index (BMI) and baseline disease severity and potential confounding factors.

Results: In stratified analyses by gender, we observed a significant dose-response relationship between soft drink intake and adjusted mean changes of JSW in men (p trend<0.001) after controlling for BMI and potential confounding factors. With increasing levels of soft drink intake, the mean changes in JSW were 0.29mm, 0.39mm, 0.36mm and 0.59mm respectively. When we further stratified by BMI tertiles, stronger dose-response relationship was found (changes in JSW were 0.21mm, 0.38mm, 0.40mm, 0.75mm respectively) in the lowest BMI tertile (BMI<27.5 kg/m^2). In men with BMI ≥27.5 kg/m^2, only highest soft drink level (≥5 times/week) was associated with increased JSW compared to no use. By contrast in women, a significant association and dose-response relationship was only observed with the lowest BMI tertile (BMI<27.3 kg/m^2, p trend <0.001).

Table. Adjusted mean (SE) changes of Joint Space Width (JSW) by soft drink intake*

BMI tertiles†	Soft drinks, times/week	Men N	Men ΔJSW, mm*	Men P value	Men P trend	Women N	Women ΔJSW, mm*	Women P value	Women P trend

	≤1	133	0.39 (0.04)	0.789		176	0.40 (0.04)	0.516	
	2–4	51	0.38 (0.07)	0.923		64	0.34 (0.06)	0.721	
	≥5	39	**0.62 (0.08)**	0.007	0.022	50	0.35 (0.07)	0.876	0.766

* Adjusted for age, race, education, marital status, household income, employment, follow-up time, depression, knee injury and knee surgery, smoking, milk intake, total energy intake, baseline K-L grade and JSW, weight change, the changes of rim distance and beam angle.
** Adjusted for BMI as well
† BMI tertiles: Man: T1: <27.5, T2: 27.5–30.8, T3 30.9+; Women: T1: <27.3, T2: 27.3–32.0, T3 32.1+

Conclusion: Our results suggest that frequent consumption of soft drinks may be associated with increased OA progression in men. Replication of these novel findings in other prospective studies demonstrating the reduction in soft drink consumption leads to delay in OA progression are needed to test this hypothesis.

746

Increased Risk of Acute and Chronic Renal Comorbidity in Ankylosing Spondylitis: Results From a Population-Based Study.
Walter P. Maksymowych[1], Shelagh Szabo[2], Sumati Rao[3], Mary A. Cifaldi[3] and Adrian R. Levy[4]. [1]University of Alberta, Edmonton, AB, [2]Oxford Outcomes, Vancouver, BC, [3]Abbott Laboratories, Abbott Park, IL, [4]Oxford Outcomes Ltd, Vancouver, BC

Background/Purpose: Clinical evidence points to an increased risk of renal comorbidity in ankylosing spondylitis (AS) compared to the general population. However, there are no population-based estimates available in the literature. An increased risk of renal comorbidity would have substantial implications for the monitoring and treatment of AS because the mainstay of pharmacological treatment is the use of non-steroidal anti-inflammatory agents (NSAIDs). We estimated the prevalence and age- and sex-standardized increased risk of renal comorbidity, including acute and chronic kidney disease and amyloidosis in a population-based cohort of persons diagnosed with AS in Québec between 1996 and 2006, compared to the general population.

Methods: A retrospective cohort study was conducted using the administrative physician-billing database of the Régie de l'Assurance Maladie du Québec. The cohort included individuals with at least one International Classification of Diseases, 9th Revision (ICD-9) billing code for AS between 1996 and 2006. A comparison cohort was generated using a 1% random sample of individuals without AS. Renal complications were identified by ICD-9 codes for amyloidosis, hypertensive chronic renal disease, acute and chronic renal disease. Age- and sex-stratified prevalence, and standardized prevalence ratios with 95% confidence intervals (CI), of renal complications

in AS compared with the general population were calculated. Sensitivity analysis was conducted using two ICD-9 codes for AS.

Results: There were 8,616 individuals identified with AS; 56% were male and the median age at diagnosis was 42 years. Overall, renal complications were diagnosed among 3.4% and 2.1% of males and females with AS, compared to 2.0% and 1.6% of males and females in the general population cohort, respectively. Prevalence of renal complications increased with age in both the AS and general population cohort. Age- and sex-stratified prevalence ratios, comparing the risk of renal complications among those with AS to the general population, demonstrated a significantly excess risk of renal complications that was highest among younger individuals with AS. Overall, individuals with AS were at a significantly increased risk of renal complications compared to members of the general population (irrespective of a coding for hypertension), with a standardized prevalence ratio of 1.7 (1.5–2.0). Standardized prevalence ratios were 6.0 (2.0–18.0) for amyloidosis, 1.7 (1.4–2.0) for chronic kidney disease, 3.2 (0.8 – 12.4) for hypertensive kidney disease, and 1.9 (1.5 – 2.3) for acute kidney disease. The excess risk was highest among younger individuals with AS, and results were similar when two ICD-9 codes were used to identify AS.

Conclusion: This population-based analysis shows that individuals with AS are at increased risk of many types of renal complications, including acute kidney disease, with the excess risk being greatest among younger individuals. These data highlight the importance of careful monitoring for renal complications among those with AS, particularly during long-term continuous use of NSAIDs.

Familial Mediterranean Fever: Inhibition of IL-6 Signalling As a New Therapeutic Option in a Frequent Autoinflammatory Syndrome.
Nicola Stein[1], Matthias Witt[1], Michael Baeuerle[2], Fabian Proft[1], Hendrik Schulze-Koops[3] and Mathias Gruenke[1]. [1]Medizinische Klinik und Poliklinik IV, Klinikum der Universität München, Munich, Germany, [2]Klinikum Nürnberg, Nuernberg, Germany, [3]University of Munich, Munich, Germany

Background/Purpose: Familial Mediterranean Fever (FMF) is the most prevalent episodic fever syndrome with more than 100.000 affected individuals worldwide. Colchicine is the established first-line therapy to control disease activity, to achieve remission and to prevent secondary amyloidosis, a significant complication of an inadequately controlled disease and the major cause of mortality in FMF patients. One third of patients with FMF are non- or only partial responders to colchicine and therewith call for experience with other immunosuppressive agents in FMF. Here, we present the first case series of five patients with Familial Mediterranean Fever (FMF) refractory to treatment with colchicine and/or anakinra, who have been switched to monthly treatment with tocilizumab.

Methods: Up to date, eight FMF-patients have been screened for receiving tocilizumab because of inadequate clinical and/or serological response to colchicine and inadequate response or intolerance of anakinra. Treatment has been started in five FMF-patients and is administered with 8 mg/kg bodyweight tocilizumab every 28 days. Colchicine was continued in four patients and discontinued in one patient. Treatment with anakinra, previously given in two patients, was discontinued.

Results: Three patients showed a good clinical and serological response to tocilizumab. In these patients remission of FMF symptoms was achieved with the first application of tocilizumab. A normalization of SAA- and CRP-level was documented after the first application of tocilizumab in one patient and after the third application in another patient. The therapy was well tolerated in four patients with no relevant side effects (one uncomplicated urinary tract infection). In one patient with no acute FMF-attack after the first application of tocilizumab, the therapy had to be discontinued because of an anaphylactic reaction during the second infusion. The first treated patient achieved prolonged remission with tocilizumab-treatment and has been switched back to colchicine alone for maintenance therapy after the ninth

infusion. He still is in remission, now 18 months after initiation of tocilizumab therapy. Patient 2 is still on tocilizumab. The request for a self-administerable drug led to a switch back to anakinra after the third infusion of tocilizumab in patient 3. Only patient 4 did not respond to tocilizumab and showed persistent arthralgia and a relapse with abdominal pain after the third infusion. The non-responding patient and the patient with the anaphylactic reaction were switched to anakinra. Three additional patients have currently been scheduled for start of tocilizumab therapy in the nearest future.

Conclusion: This is the first documentation of a case series of successful treatment of FMF with tocilizumab. Of note, interference with IL-6 activity did not only result in complete clinical remission in three of the five patients previously resistant to immunosuppressive therapy, but also in complete serological remission as indicated by normalization of SAA in two individuals. These data strongly argue in favour of IL-6 as a main inflammatory cytokine in FMF and, thus, as a promising target in this disease.

Efficacy and Safety of Canakinumab in Patients with Cryopyrin Associated Periodic Syndrome: Results From Meta-Analysis of 5 Studies.
Helen J. Lachmann[1], Jasmin B. Kuemmerle-Deschner[2], Toshio Heike[3], Toshiro Hara[4], Shumpei Yokota[5], Phil Mckernan[6], Albert Widmer[6], Nicole Davis[7] and Eric Hachulla[8]. [1]University College London Medical School, London, United Kingdom, [2]Division of Pediatric Rheumatology, Department of Pediatrics, University Hospital Tuebingen, Tuebingen, Germany, [3]Department of Pediatrics, Graduate School of Medicine, Kyoto University, Kyoto, Japan, [4]Department of Pediatrics, Graduate School of Medical Science, Kyushu University, Fukuoka, Japan, [5]Department of Pediatrics, Yokohama City University, Graduate School of Medicine, Yokohama, Japan, [6]Novartis Pharma AG, Basel, Switzerland, [7]Novartis Pharmaceuticals Corporation, East Hanover, NJ, [8]Department of Internal Medicine, Claude Huriez Hospital, University of Lille, Lille CEDEX, France

Background/Purpose: Canakinumab (CAN) is approved in over 60 countries for the treatment of CAPS. This meta-analysis evaluated the efficacy and safety of CAN and assessed potential differences across age and the 3 CAPS phenotypes (FCAS, MWS and NOMID).

Methods: This meta-analysis pooled data from 5 studies (1 phase II and 4 phase III). Data from 2 of the 4 phase III, open-label, uncontrolled studies with similar efficacy endpoints (n=185, including 128 CAN-naïve patients) were pooled for efficacy analysis (the other studies were of a different design and not included). Patients previously treated with CAN could "roll over" into one of these phase III studies. Step-wise dose escalations from 150 mg or 2 mg/kg (if weight 15–40 kg) every 8 weeks (q8w) up to 600 mg or 8 mg/kg q8w were allowed in patients who did not achieve/remain in complete response (CR; defined as physician global assessment [PGA] ≤ minimal, assessment of skin disease ≤ minimal, serum C-reactive protein and/or serum amyloid A protein < 10 mg/L) in the 2 studies pooled for efficacy. The primary efficacy endpoint, CR was assessed in CAN-naïve patients (n=128). Percentage of patients with relapse assessment and PGA were evaluated in CAN-naïve plus roll-over patients [n=185]). For safety analysis, data from all 5 studies were pooled (n=194).

Results: 85.2% (109/128) of CAN-naïve patients achieved CR; 65.6% (84/128) with 150 mg or 2 mg/kg. 42 patients (32.8%) required dose escalation to 300 or 600 mg (4–8mg/kg) q8w of whom 25 achieved CR at a higher dose, including 7 patients at the highest dose. Of 159 patients assessed for relapse, 142 (89.3%) did not relapse at any dose. CR and relapse data by phenotype and age are shown in Table.

Patients treated with 150mg or 2mg/kg q8w had greater reduction in disease activity (PGA; absent/minimal symptoms) than patients who required dose escalation (91.4% vs 60% to 77.8%) at the End of Study (EOS) (or Week 48). FCAS patients (92%) showed lowest disease activity score at EOS compared to MWS (85.1%) and NOMID (81.8%). Patients as young as 2–<4 yrs had a reduction in disease activity score by Day 8 and EOS (57.1% and 71.4%, respectively, with absent/minimal symptoms). 94.3% (183/194) patients had at least 1 adverse event (AE). Most frequently reported AEs were nasopharyngitis (36.1%), headache (23.7%), rhinitis (17.5%) and upper respiratory tract infection (17.0%). Serious AEs (SAEs) occurred in 13.4% (26/194) patients (infections and infestations; 13 [6.7%]), and no deaths were reported. Incidence of AEs and SAEs was comparable between NOMID and MWS with lower incidence in FCAS (AEs: 98.1% and 96.4% vs 80.6%; SAEs: 13.5% and 16.4% vs 3.2%).

Table. Complete response and relapse assessment to treatment with canakinumab

Parameters	Number of Patients	Phenotype NOMID % (n/N)	MWS % (n/N)	FCAS % (n/N)	Age 2-<4 years % (n/N)	4–11 years % (n/N)	12–17 years % (n/N)	18–59 years % (n/N)	≥60 years %(n/N)
Achieving complete response	N=128[a]	73.7 (28/38[a])*	88.3 (53/60[a])	96.6 (28/29[a])	57.1 (4/7[a])	86.4 (19/22[a])	70.8 (17/24[a])	92.2 (59/64[a])	90.9 (10/11[a])
Patients without relapse	N=159[b]	78.1 (25/32[b])	91.9 (91/99[b])	92.9 (26/28[b])	50.0 (2/4[b])#	87.0 (20/23[b])	94.7 (18/19[b])	90.2 (92/102[b])	90.9 (10/11[b])

[a]Only CAPS-naïve patients; [b]CAPS-naïve and roll-over patients who achieved complete response and had a relapse assessment; *Of the 38 NOMID patients, 21 (55.3%) required dose escalation, 11 of whom later achieved complete response; #3/4 patients were NOMID.

Conclusion: This meta-analysis confirms the efficacy of CAN in CAPS across all phenotypes and also for the youngest patients (2–<4 yrs). Dose escalation was most frequent in younger and NOMID patients who did not respond to initial dose. It did not appear that there was an increase in AEs and SAEs with an increase in dose or decrease in age.

749

Efficacy and Safety of Canakinumab in Patients with TNF Receptor Associated Periodic Syndrome. Marco Gattorno[1], Laura Obici[2], Antonella Meini[3], Vincent Tormey[4], Ken Abrams[5], Nicole Davis[6], Christopher Andrews[7] and Helen J. Lachmann[8]. [1]Istituto Giannina Gaslini, Genova, Italy, [2]IRCCS Policlinico San Matteo, Pavia, Italy, [3]Pediatric Immunology and Rheumatology, Brescia, Italy, [4]Galway University Hospitals, Galway, Ireland, [5]Novartis Pharmaceutical Corporation, East Hanover, NJ, [6]Novartis Pharmaceuticals Corporation, East Hanover, NJ, [7]Novartis Pharmaceuticals UK Limited, Surrey, United Kingdom, [8]University College London Medical School, London, United Kingdom

Background/Purpose: TNF-receptor associated periodic syndrome (TRAPS) is a rare dominantly inherited periodic fever syndrome due to mutations of the *TNFRSF1A* gene. It is characterized by recurrent fever attacks associated with rash, musculoskeletal and abdominal pain, conjunctivitis, and periorbital edema. Approximately 10–20% of pts develop renal amyloidosis. The IL-1 receptor antagonist anakinra has been reported to be an efficacious treatment. Canakinumab (CAN) is a fully human monoclonal selective anti-IL-1β antibody with a $T_{1/2}$ of 4 wks. Interim data of open label 4-months CAN therapy and 5-months follow-up in active TRAPS pts is presented.

Methods: 14 adults and 6 children (7 to 78 yrs, median 39 yrs) with active TRAPS entered a 3-part trial: 4 months open-label 150 mg (or 300 mg) CAN every 4 wks followed by up to 5 months treatment withdrawal, and then 24 months open-label CAN. Disease activity was evaluated by a 5-point physician's global assessment (PGA) score and by CRP and SAA levels. Primary endpoint was complete or almost complete response at Day 15. Complete response was defined as clinical remission (PGA of 0 or 1 [absent or minimal signs/symptoms]) and normal CRP and/or SAA. Almost complete response was defined as clinical remission and elevated but ≥70% reduced from baseline CRP and/or SAA. Quality of life was assessed by the SF-36 in adults. Those without response by Day 8 were eligible for another 150 mg dose and then 300 mg thereafter. Pts were observed after last dose until relapse (5 month max) before restarting CAN.

Results: On Day 8, 16 (80%) achieved complete/almost complete response and 18 (90%) achieved clinical remission. Two pts without clinical remission were dose up-titrated to 300 mg. At Day 15, 19 (95%) achieved complete/almost complete response, including all 4 without it at Day 8. Clinical remission was maintained by all from Day 15 onwards except 1 who relapsed at Day 85, responding to that visit's CAN dose. Median time to clinical remission was 4 days (95% CI: 3,8). Median baseline CRP (125 mg/L) and SAA (198 mg/L) both reduced to <5 mg/L from Day 15 onwards. All relapsed after stopping CAN at a median 91.5 days. The relapse graded by the PGA was mild in 11, moderate in 7, and severe in 2. Upon redose, 18 regained complete/almost complete response 8–27 days later and 2 relapsed at final visit with no follow-up available for this analysis. Baseline SF-36 components improved after CAN therapy. All pts reported ≥1 adverse event (AE). Infections, mostly of the upper respiratory tract (URI), was the most common (n=15, 75%) AE category. Headache (n=9) followed by abdominal pain (n=7) were the most common specific AEs reported. Two serious AEs, a URI and a TRAPS relapse, were reported. All pts are active in the 24-month open-label period.

Conclusion: Canakinumab produced a rapid and effective clinical and serological benefit which was maintained with continued dosing. Relapse occurred at a median of 3 months after last dose, was usually mild or moderate, and resolved upon re-dosing. Canakinumab demonstrated a favorable safety and tolerability profile in this small study. Data support IL-1β's pivotal role in TRAPS and further study is needed to better define canakinumab treatment.

750

Efficacy and Safety of Canakinumab in Adults with Colchicine Resistant Familial Mediterranean Fever. A. Gul[1], H. Ozdogan[2], B. Erer[1], S. Ugurlu[2], Nicole Davis[3], S. Sevgi[4] and O. Kasapcopur[2]. [1]Istanbul University, Istanbul Faculty of Medicine, Istanbul, Turkey, [2]Istanbul University, Cerrahpasa Faculty of Medicine, Istanbul, Turkey, [3]Novartis Pharma Corp, East Hannover, [4]Novartis Pharma, Istanbul, Turkey

Background/Purpose: Familial Mediterranean fever (FMF) is associated with variations in the MEFV gene resulting in proteolytic activation of IL-1β through the inflammasome complex. FMF is characterized by recurrent attacks of fever, peritonitis, pleuritis, arthritis, and/or erysipelas-like rash. Colchicine is the standard of care to prevent attacks and development of secondary amyloidosis, but there is no established treatment available for those resistant or intolerant to it. Canakinumab, a fully humanized selective anti-IL-1β monoclonal antibody with a half-life of 4-weeks binds to human IL-1β and neutralizes its proinflammatory effects. The aim of this study is to evaluate the efficacy and safety of canakinumab by documenting the FMF attack rate and adverse events (AE) in adolescents and adults with FMF who are resistant or intolerant to colchicine.

Methods: FMF patients describing >1 attack/month in the preceding 3-months despite the highest tolerated colchicine dose were eligible to enter a 30-day run-in period. Those with an attack in the run-in period advanced to a 3-month treatment period to receive canakinumab 150mg sc every 4-weeks starting at the next attack in the following month. Patients then followed-up for up to 2months or until the next attack. Attacks were confirmed by presence of fever, serositis, and elevated CRP. Primary efficacy outcome was the proportion of patients with >50% reduction in time-adjusted attack frequency in the treatment vs pre-treatment periods. Secondary objectives included the percent of patients with no attacks in the treatment period, time to next attack after the last canakinumab dose, and changes in the quality of life by SF-36. Safety was assessed by AEs and laboratory values at each visit.

Results: Thirteen patients entered the run-in period and 9 (median age 22 yrs, range 12–34 yrs) advanced to the treatment period. Only 1 patient had an attack (peritonitis) in the treatment period and all had a ≥50% reduction in their time-adjusted pre-treatment attack rate. Median baseline elevated CRP (58mg/L) and serum AA (162mg/L) levels normalized (CRP, 2.5mg/L; SAA, 5.8mg/L) by Day 8 and remained low throughout the study. The Physical and Mental Component scores of the SF-36 improved from a median baseline of 32 and 38 to 81 and 78 at Day 8 respectively, and continued to improve throughout the treatment period. Five patients had an attack in the follow-up period which occurred a median 71 days (31–78 days) from the last canakinumab dose. Compared to baseline, the physician and patient global assessment of FMF control improved with treatment with overall the response to treatment reported as Very Good by both physicians (9/9) and patients (7/9) at study end. Eight patients reported at least 1 adverse event (AE) with headache (n=4) and upper respiratory tract infection (n=2) being the only AEs reported in more than 1 patient. No one discontinued early from the trial.

Conclusion: In this pilot study, canakinumab was found to be effective at controlling the attack recurrence in FMF patients resistant or intolerant to colchicine. AEs were similar to previous canakinumab trials and were managable. Further studies are warranted to explore the role of canakinumab in the treatment of FMF.

Whole Transcriptome Analysis in Erdheim-Chester Disease: A Multi-center Collaborative Study of 58 Patients. Laurent Arnaud[1], Julien Haroche[1], Lorenzo Dagna[2], Augusto Vaglio[3], Bruno Faivre[4], Karim Dorgham[4], Baptiste Hervier[1], Fleur Cohen-Aubart[1], Guy Gorochov[4] and Zahir Amoura[1]. [1]Hopital Pitié-Salpêtrière, AP-HP & UPMC Univ Paris 06, Paris, France, [2]Vita-Salute San Raffaele University School of Medicine and San Raffaele Scientific Institute, Milano, Italy, [3]University of Parma, Parma, Italy, [4]Institut National de la Santé et de la Recherche Médicale, INSERM UMR-S 945, Paris, France

Background/Purpose: To date, gene expression profiling has not been performed in Erdheim-Chester disease (ECD), a rare, non-Langerhans form of histiocytosis. The aim of this study was to analyze the transcriptome of ECD compared to healthy individuals, as a manner to identify new pathways involved in the pathogenesis of the disease as well as new therapeutic targets.

Methods: Total RNA was extracted from peripheral blood mononuclear cell (PBMC) obtained in 58 patients with biopsy-proven ECD and 36 healthy individuals. Complementary DNA (cDNA) was hybridized in Illumina Human HT-12® v4 Expression Bead Chips. Statistical analysis of Microarray (SAM) algorithm with Benjamini and Hochberg multiple testing correction was used to determine the statistical significance of the differences in gene expression while controlling the false-discovery rate. Cluster analysis was also performed with JMP8 software. Differentially expressed genes were analyzed to identify potential functional pathways using Ingenuity® Pathway Analysis (IPA).

Results: Gene expression analysis using SAM showed 265 significantly down- or up-regulated transcripts between ECD patients and controls. Cluster analysis of these transcripts by similarity on gene expression patterns identified several clusters containing only ECD patients, healthy individuals, or both, underlining the strong heterogeneity of the disease. The set of genes statistically different between ECD and healthy individuals was further analyzed with IPA Analysis, which revealed a role for genes related to growth factor and cytokine activities, cyclin-dependant cell-cycle genes, regulation of phosphate homeostasis, DNA packaging, transcription regulation, and mRNA stability.

Conclusion: This large multicenter collaborative transcriptome analysis of 58 patients with Erdheim-Chester disease reveals that complex gene expression patterns are involved in the pathogenesis of the disease. This may be seen as a significant advance in this rare disease with poor prognosis and non-formally codified therapeutic management.

IFNg Production Is Intimately Associated with Clinical and Laboratory Features of CpG-Induced Secondary Hemophagocytic Lymphohistiocytosis (sHLH)/Macrophage Activating Syndrome (MAS) in Mice. Vanessa Buatois, Laurence Chatel, Laura Cons, Maureen Deehan, Cristina de Min, Marie Kosco-Vilbois and Walter Ferlin. NovImmune S.A., Geneva, Switzerland

Background/Purpose: Repeated TLR9 stimulation with CpG DNA has been found to result in a sHLH/MAS-like disease in mice (1). CpG-administered mice present with cytopenia, anemia, thrombocytopenia, splenomegaly, hepatitis and hyperferritemia. The use of IFNg deficient mice as well as treatment of wild type mice with the anti-IFNg monoclonal antibody (mAb), XMG1.2, suggested an important role for IFNg in the pathogenesis of sHLH/MAS. Our aim was to extend these findings and perform biomarker studies to correlate the kinetics of IFNg production to sHLH/MAS disease endpoints.

Methods: C57BL/6 mice (n=10) were administered $5 \times 50\mu g$ injections of CpG-1826 over a 10-day period (day 0, 2, 4, 7 and 9). XMG1.2 was administered i.v. at 30mg/kg 24hrs preceding each CpG injection. Quantitative Real-time PCR was used to analyze inflammatory gene expression. Luminex multiplex technology was used to detect serum inflammatory cytokines. Whole blood cell count, red blood cells and haemoglobin were assessed using a haematological counter.

Results: We observe a multi-phasic production of IFNg in serum with peak levels reaching 600pg/ml at day 7. Cytokine mRNA level expression confirms the multi-phasic production of IFNg in the liver and spleen following each exposure to CpG. The initial peak of IFNg production correlates with the rapid appearance of cytopenia and thrombocytopenia, while each additional injection of CpG sustains these symptoms and generates new features such as anemia, hemoglobinemia, splenomegaly, hypercytokinemia and ferritinemia, culminating in induction of acute phase protein SAA and severe disease. IFNg-induced gene signature biomarkers, e.g., CTIIA (MHC class II trans-activator gene) and CXCL10, are upregulated in spleen and liver as too inflammatory cytokines IL-6 and TNFα. Neutralization of IFNg by XMG1.2 reduces body weight loss and splenomegaly, normalizes white blood cell counts, significantly reverses the decrease in other laboratory parameters (e.g., platelets, haemoglobin and red blood cells) and controls hyperferritinemia.

Conclusion: Thus, IFNg production is intimately associated with the clinical and laboratory features in the CpG-induced sHLH/MAS model suggesting the inhibition of this cytokine as a therapeutic target for patients afflicted with this life-threatening disease.

ACR Concurrent Abstract Session
Muscle Biology, Myositis and Myopathies: Classification, Treatment and Outcome in Idiopathic Inflammatory Myopathies
Sunday, November 11, 2012, 2:30 PM–4:00 PM

753

Progress Report On Development of Classification Criteria for Adult and Juvenile Idiopathic Inflammatory Myopathies. Anna Tjärnlund[1], Matteo Bottai[2], Lisa G. Rider[3], Victoria P. Werth[4], Clarissa A. Pilkington[5], Marianne de Visser[6], Lars Alfredsson[7], Anthony A. Amato[8], Richard J. Barohn[9], Matthew H. Liang[10], Jasvinder A. Singh[11], Frederick W. Miller[3], Ingrid E. Lundberg[12] and the International Myositis Classification Criteria Project[13]. [1]Rheumatology Unit, Department of Medicine, Karolinska University Hospital, Solna, Karolinska Institutet, Stockholm, Sweden, Stockholm, Sweden, [2]Institute for Environmental Medicine, Karolinska Institutet, Stockholm, Sweden, Stockholm, Sweden, [3]NIEHS, NIH, Bethesda, MD, [4]University of Pennsylvania and Philadelphia V.A. Medical Center, Philadelphia, PA, [5]Great Ormond Street Hospital for Children NHS Trust, London, United Kingdom, [6]Department of Neurology, Academic Medical Centre, Amsterdam, Netherlands, Amsterdam, Netherlands, [7]Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden, [8]Brigham and Women's Hospital and Harvard Medical School, Boston, MA, [9]Department of Neurology, University of Kansas Medical Center, Kansas City, USA, Kansas City, MO, [10]Brigham & Womens Hospital, Boston, MA, [11]University of Alabama at Birmingham, Birmingham, AL, [12]Karolinska Institutet, Stockholm, Sweden, [13]Stockholm

Background/Purpose: In patients with idiopathic inflammatory myopathies (IIM) persisting muscle impairment after treatment underscores the need for improved management. Inadequate classification criteria for IIM are a fundamental limitation in clinical studies of myositis. An international, multidisciplinary collaboration, the International Myositis Classification Criteria Project (IMCCP), with support from ACR and EULAR, seeks to develop and validate new classification criteria for adult and juvenile IIM and its major subgroups.

Methods: *Identification and definition of potential criterion* Candidate variables to be included in classification criteria were assembled from published criteria and inclusion criteria in controlled trials of myositis and refined using Nominal Group Technique. Effort was made to assure content validity. Comparator groups confused with IIM were defined.

Data collection Within this retrospective case control study, clinical and laboratory data from IIM and comparator patients were collected from 47 rheumatology, dermatology, neurology and pediatrics clinics worldwide from 2008–2011.

Analysis Crude pair-wise associations among all variables measured and between each variable and clinician's diagnosis were assessed. Three approaches for derivation of classification criteria were explored:

1. Traditional: case defined by specified number of items from a set

2. Risk score: patient assigned a probability risk score by summing score-points associated with the variables (Model 1)

3. Classification tree: case defined by a decision tree (Model 2)

A random forest algorithm explored the most important variables. Results obtained with each approach were utilized to improve others iteratively.

Validation Internal validation using bootstrap methods was performed.

Results: Data from 973 IIM (74% adults; 26% children) patients and 629 comparators (81% adults; 19% children) were obtained, representing subgroups of IIM (245 polymyositis, 239 dermatomyositis, 176 inclusion body myositis and 246 juvenile dermatomyositis cases). The comparators include other myopathies and systemic rheumatic diseases.

Two models were developed (Table). Model 1 performs better than Model 2 although both models perform equally to, or better, than current published criteria.

Table. New models for classification criteria for IIM and performance of criteria

MODEL 1. RISK SCORE

Variable	Score points
$18 \leq$ Age of onset of first symptom < 40	1.6
Age of onset of first symptom ≥ 40	2.3
Clinical Muscle Variables	
Objective symmetric weakness, usually progressive, of the proximal upper extremities	0.7
Objective symmetric weakness, usually progressive, of the proximal lower extremities	0.6
Neck flexors are relatively weaker than neck extensors	1.6
In the legs proximal muscles are relatively weaker than distal muscles	1.5
Skin Variables	
Heliotrope rash	3.3
Gottronxs papules	2.3
Gottron's sign	3.4
Other Clinical Variables	
Dysphagia or esophageal dysmotility	0.7
Laboratory Variables	
Serum creatine kinase (CK) activity	1.2
Anti-Jo-1 (anti-His) antibodies	4.2
Score-sum from above items*	**0.9**
Muscle Biopsy Variables	
Endomysial infiltration of mononuclear cells surrounding, but not invading, myofibers	1.6
Perimysial and/or perivascular infiltration of mononuclear cells	1.1
Perifascicular atrophy	1.7

* When muscle biopsies are available, multiply the score-sum of all other variables by 0.9 and then add the scores of the positive biopsies.

MODEL 2. CLASSIFICATION TREE

(a) Heliotrope rash:

If yes then IIM; if no go to step (b)

(b) Objective symmetric weakness, usually progressive, of the proximal lower extremities:

If yes then go to step (c); if no go to step (h)

(c) Endomysial infiltration of mononuclear cells surrounding, but not invading, myofibers:

If yes then IIM; if no go to step (d)

(d) Perimysial and/or perivascual infiltration of mononuclear cells:

If yes then IIM; if no go to step (e)

(e) Serum alanine aminotransferase activity:

If yes then IIM; if no go to step (f)

(f) Interstitial lung disease:

If yes then IIM; if no go to step (g)

(g) Dysphagia or esophageal dysmotility:

If yes then IIM; if no then not IIM

(h) Mechanic's hands:

If yes then IIM; if no go to step (i)

(i) Endomysial infiltration of mononuclear cells surrounding, but not invading, myofibers:

If yes then IIM; if no then not IIM

PERFORMANCE OF NEW AND EXISITING CLASSIFICATION/ DIAGNOSTIC CRITERIA FOR IIM

Performance (%)	Model 1 Risk Score [a] Without muscle biopsy data	With muscle biopsy data	Model 2 Tree	Peter & Bohan [1][b]	Tanimoto et al. [2]	Targoff et al. [3][b]	Dalakas & Hohlfeld [4][b]	Hoogendijk et al. [5][b]
Sensitivity	91	94	93	98	96	93	6	51
Specificity	82	85	74	55	31	88	99	96
Positive predictive value	90	93	91	85	80	95	92	96
Negative predictive value	84	87	80	90	72	84	43	57
Correctly classified	88	91	88	86	79	91	45	70

[a] Cut point for probability: 50%
[b] Definite and probable polymyositis and dermatomyositis

Conclusion: New classification criteria for IIM with easy-to-access measurements and symptoms have been developed that generally have superior performance compared to existing criteria. External validation is in progress.

The Functional Index-3 in Adult Dermatomyositis and Polymyositis: Validity and Reliability of an Outcome Measure for Muscle Endurance. Christopher Chong[1], Orla Ni Mhuircheartaigh[1], Helene Alexanderson[2], Tanaz A. Kermani[3], Cynthia S. Crowson[4], Abigail B. Green[4], Ann M. Reed[4] and Floranne C. Ernste[5]. [1]Mayo Clinic, Rochester, [2]Karolinska Institutet, Stockholm, Sweden, [3]University of California Los Angeles, Los Angeles, [4]Mayo Clinic, Rochester, MN, [5]Mayo Clinic Rochester, Rochester, MN

Background/Purpose: Although muscle fatigue is a major source of functional impairment in dermatomyositis (DM) and polymyositis (PM), few valid and reliable methods for efficient evaluation of functional disability exist. The Functional Index (FI) was the first to specifically assess impairment in myositis, and consisted of 14 tasks to determine muscle endurance. The Functional Index-2 (FI-2) was a revision of FI, which decreased the tasks from 14 to 7. However, busy clinical practices may preclude feasibility of use. We developed a Functional Index-3 (FI-3) to streamline content for assessment of muscle endurance in DM and PM patients and tested its validity at a single, large academic center.

Methods: Twenty-eight patients with DM or PM diagnosis were recruited at our institution from 2010–2012. All patients participated in at least one of two sessions which included 3 tasks (shoulder flexion, head lift, hip flexion) performed bilaterally. After each task, participants completed the Borg CR-10 to rate perceived muscle exertion. Self-reported limitations in daily activities were assessed by the Myositis Activity Profile (MAP) and the Health Assessments Questionnaire (HAQ). Intra-class correlation (ICC) coefficients were calculated. Performance results from the tasks were correlated to the MAP, HAQ, and Borg CR-10 using Spearman's correlation coefficient to assess validity.

Results: Fifteen patients with DM, 7 patients with anti-synthetase syndrome, and 6 patients with PM participated. The mean (SD) age was 58 (11) years and mean (SD) disease duration was 6.5 (5.4) years. There were 19 (68%) females. Six patients (21%) had active disease as determined by creatine kinase level and clinician judgment. Twelve patients completed the second session for intra-rater reliability. Consistently high ICC values indicate high intra-rater reliability: ICC (95% confidence interval): shoulder flexion, right 0.90 (0.69, 0.97); shoulder flexion, left 0.88 (0.64, 0.96); head lift, 0.66 (0.19, 0.89); hip flexion, right 0.64 (0.15, 0.88); hip flexion, left 0.84 (0.56, 0.95). Ten patients completed the second session for inter-rater reliability, and the high ICC values show that the raters agreed: shoulder flexion, right 0.81 (0.43, 0.95); shoulder flexion, left 0.94 (0.78, 0.98); head lift, 0.92 (0.74, 0.98); hip flexion, right 0.46 (−0.16, 0.83); hip flexion, left 0.60 (0.03, 0.88). Two patients had large decreases in repetitions in hip flexion during the second session (>8 repetitions). Correlations were significant between MAP, HAQ, and Borg CR-10 in all tasks as shown in the table.

Table. Spearman correlations of disease activity and Borg CR-10 scores with FI-3 task scores in session one

	MAP score (n=28)		HAQ score (n=27)		Borg CR-10 scores (n=28)	
	correlation	p-value	correlation	p-value	correlation	p-value
Shoulder flexion right	-0.62	<0.001	-0.69	<0.001	-0.57	0.002
Shoulder flexion left	-0.54	0.003	-0.54	0.003	-0.45	0.016
Head lift	-0.50	0.006	-0.55	0.003	-0.38	0.046
Hip flexion right	-0.69	<0.001	-0.77	<0.001	-0.46	0.015
Hip flexion left	-0.56	0.002	-0.65	<0.001	-0.40	0.036

Conclusion: The FI-3 is an efficient and valid method for assessment of muscle endurance in DM and PM patients. FI-3's validity is supported by the significant correlations between functional tasks and the MAP, HAQ, and Borg CR-10 scores.

Sifalimumab, an Anti-IFN-Alpha Monoclonal Antibody Shows Target Suppression of a Type I IFN Signature in Blood and Muscle of Dermatomyositis and Polymyositis Patients. Brandon W. Higgs[1], Wei Zhu[1], Chris Morehouse[1], Wendy White[1], Philip Brohawn[1], Charles Le[1], Anthony A. Amato[2], David Fiorentino[3], Steven A. Greenberg[2], Laura Richman[1], Warren Greth[1], Bahija Jallal[1] and Yihong Yao[4]. [1]MedImmune, LLC, Gaithersburg, MD, [2]Brigham and Women's Hospital and Harvard Medical School, Boston, MA, [3]Stanford University School of Medicine, Redwood City, CA, [4]MedImmune, Gaithersburg, MD

Background/Purpose: To assess the pharmacodynamic effects of sifalimumab, an investigational anti-IFN-alpha monoclonal antibody, in the blood and muscle of adult dermatomyositis and polymyositis patients by measuring the suppression of a type I IFN signature following sifalimumab administration.

Methods: A phase 1b randomized, double-blinded, placebo-controlled, dose-escalation, multicenter clinical trial was conducted in adult patients with dermatomyositis or polymyositis. Blood and muscle biopsies were procured before and after administration with sifalimumab. Samples were transcript-profiled using microarray and qRT-PCR. The target modulation in patients following administration with either sifalimumab or placebo was measured by a 13-gene type I IFN signature.

Results: The type I IFN signature was suppressed by a median of 53–66% across the three times points (day 28, 56, and 98) in blood and 47% at day 98 in muscle specimens post sifalimumab administration, with the latter exhibiting dose-dependent target modulation. Patients with ≥15% improvement from baseline manual muscle testing scores showed a greater suppression of the gene signature than those with <15% improvement as measured in both blood and muscle. Pathway/functional analysis of transcripts suppressed by sifalimumab showed that leukocyte infiltration, antigen presentation, and immunoglobulin categories were most suppressed following administration with sifalimumab and were highly correlated with suppression of the type I IFN signature ($r=-0.93$; $p<0.001$ and $r=-0.84$; $p<0.001$, and $r=-0.64$, $p=0.001$, respectively) in muscle tissue.

Conclusion: Administration of sifalimumab resulted in suppression of the type I IFN signature in peripheral blood and muscle tissue in patients with myositis, consistent with this molecule's mechanism of action and a positive trend of correlation between this target suppression and clinical improvement. These observations will require confirmation in a larger trial powered to evaluate efficacy.

756

Effect of B Cell Depletion Therapy with Rituximab On Myositis Associated Autoantibody Levels in Idiopathic Inflammatory Myopathy. Rohit Aggarwal[1], Chester V. Oddis[1], Andriy Bandos[1], Danielle Goudeau[2], Diane Koontz[1], Qi Zengbiao[1], Ann M. Reed[3], Dana P. Ascherman[4] and Marc C. Levesque[1]. [1]University of Pittsburgh, Pittsburgh, PA, [2]Univ of Pittsburgh Med Ctr, Pittsburgh, PA, [3]Mayo Clinic, Rochester, MN, [4]University of Miami, Miami, FL

Background/Purpose: Myositis associated autoantibodies (MAA) in idiopathic inflammatory myopathy (IIM) demonstrate unique phenotypic features. In some autoimmune disorders, autoantibody levels correlate with disease activity and are reduced after B cell depletion (BCD). Our aim was to determine the effect of BCD on the serum levels of 3 common MAAs (anti-Jo-1, -TIF1g, -SRP) and to assess whether quantitative changes in MAA levels correlate with IIM core-set measures (CSM) [manual muscle testing (MMT), muscle enzyme, physician global, patient/parent global, extramuscular disease activity and HAQ].

Methods: Treatment-resistant IIM subjects (n=200) received rituximab in a 44-week clinical trial, the Rituximab in Myositis (RIM) Study. CSM were evaluated monthly and serial serum samples were collected. Anti-Jo-1 (n=25), -SRP (n=25) and -TIF1g (n=23) levels were measured using validated ELISAs. Temporal trends in MAA levels and longitudinal relationship between MAA levels and CSM within patients (adjusted for the total immunoglobulin (IgG) levels) was estimated using linear mixed models (SAS v. 9.2). Spearman correlation within each subject longitudinally and median MAA levels and CSM over time were evaluated.

Results: After start of the treatment autoAb levels in Jo-1 subjects decreased by approximately 9 units per week ($p<0.001$). Anti-Jo-1 levels longitudinally correlated with all CSM ($p<0.05$) univariately and after adjusting for IgG levels In contrast, anti-TIF1g and anti-SRP levels do not demonstrate systematic trends with time; there was no significant correlation between anti-TIF1g or anti-SRP levels and any CSM. Median (IQR) Anti-TIF1g levels were unchanged between baseline [34 (11–85)] and the last visit [38 (13–94)]. Post-hoc analysis of anti-SRP levels (n=25) revealed intermediate results as 13/25 (52%) anti-SRP subjects dropped their autoAb level while 9 were unchanged. The 13 subjects with a decrease in anti-SRP levels had significantly higher baseline anti-SRP levels compared to the remaining patients [median 81 (12–208) vs. 5(4–50); p=0.02]. Those 13 subjects demonstrated moderate to strong correlations (rho > 0.35) between anti-SRP levels and CSM except for the HAQ (median rho 0.26).

Longitudinal median Levels of anti-Jo1, muscle enzyme (x upper limit of normal) and IgG (x lower limit of normal) after rituximab
Conclusion: Anti-Jo-1 autoAb levels in IIM patients decreased after BCD with rituximab and longitudinally correlated with changes in all CSM. In contrast, anti-TIF-1g and anti-SRP levels did not change significantly over time and there were no significant correlations with CSM, except a subset of anti-SRP patients with higher baseline levels. The strong association of anti-Jo-1 levels with clinical outcomes suggests that these autoantibodies may have a direct pathogenic role in IIM that is mitigated by B cell depletion with rituximab and may be a good biomarker for disease activity.

757

Beneficial Role of Rapamycin in Experimental Autoimmune Myositis.
Nicolas Prevel[1], Yves Allenbach[2], David Klatzman[1], Benoit Salomon[1] and
Olivier Benveniste[2]. [1]UPMC Université Paris 06, UMR 7211, Paris, France,
[2]Pitie-Salpetriere Hospital, Paris, France

Background/Purpose: Idiopathic inflammatory myopathies are a hetero-
geneous group of different diseases, classified into four main categories:
dermatomyositis, polymyositis, immune-mediated necrotizing myopathy, and
sporadic inclusion body myositis. The treatment of polymyositis consists of
corticosteroids frequently associated to other immunosuppressive drugs. The
obligatory and often severe side effects of these drugs, which have to be taken
for several months or years, prompted us to propose alternative treatments,
which have to be tested first in experimental animal models. Rapamycin is a
known potent immunomodulator with less side effects compared to other
immunosuppressants (e.g. ciclosporin). Rapamycin has been used for a
decade in transplant patients to prevent graft rejection. In vivo, rapamycin has
been described to increase the percentage of regulatory T cells. Our objective
was to Study the role of rapamycin in an experimental autoimmune myositis
(EAM) model of polymyositis in mouse (Allenbach Y et al. Am J Pathol,
2009, 174, 989–998).

Methods: EAM is induced by 3 injections of myosin coupled with
complete Freund's adjuvant. Mice received rapamycin (1 mg or 3 mg/kg/day)
during 25 days starting before myosin immunization (preventive treatment),
or during 10 days following the last myosin immunization (curative treat-
ment). Muscle strength and histology, composition of lymphocyte subpopu-
lations, and KLF2 pathway, a transcription factor controlling lymphocyte
homing, were studied.

Results: Under preventive or curative treatment, an increase of muscle
strength was observed with in parallel a decrease of muscle inflammation,
both being well correlated ($R^2=-0.645$, $p<0.0001$). Rapamycin induced a
general decrease in frequency of effector T cells (lymphopenia in draining or
non draining lymph nodes and spleen, harmoniously distributed between
$CD4^+$ and $CD8^+$ T cells, but sparing B cells), and an increase in frequency
of regulatory T cells ($CD4^+CD25^+$) in draining lymph nodes (rapamycin 3
mg/kg/day preventively treated mice compared to controls: $16.9\pm2.2\%$ vs.
$9.3\pm1.4\%$, $p<0.001$), which were mostly activated regulatory T cells
($CD62L^{low}CD44^{high}$: $58.1\pm5.78\%$ vs. $33.1\pm7\%$, treated vs. untreated,
$p<0.001$). Furthermore, during preventive treatment, rapamycin increased the
levels of KLF2 transcript in $CD44^{low}$ $CD62L^{high}$ naive T cell ($2,1\pm0,14$ vs.
$1,05\pm0,09$, treated vs. untreated, $p<0.05$) and in $CD62L^{low}$ $CD44^{high}$
activated T cell ($1,02\pm0,18$ vs. $0,44\pm0,08$, treated vs. untreated, $p<0.05$).

Conclusion: Rapamycin is an effective treatment for EAM, resulting in a
decrease in effector T cells, an increase in regulatory T cells, and upregulation
of KFL2 in naive and activated T cells. Those observations suggest that
rapamycin may represent an effective new therapeutic approach in patients
with polymyositis. This approach may also be beneficial, since a deficiency in
regulatory T cells has been reported during polymyositis.

**Cutaneous Ulceration in Dermatomyositis: Association with MDA-5 and
Interstitial Lung Disease.** Neera Narang[1], Livia Casciola-Rosen[2], Antony
Rosen[3], David Fiorentino[4] and Lorinda Chung[5]. [1]Stanford Univ Medical
Center, Stanford, CA, [2]Johns Hopkins University, Baltimore, MD, [3]The
Johns Hopkins University, Baltimore, MD, [4]Stanford University School of
Medicine, Redwood City, CA, [5]Stanford Univ Medical Center, Palo Alto, CA

Background/Purpose: Dermatomyositis (DM) is a multisystem auto-
immune disease that affects the muscles and skin and can be associated with
malignancy or interstitial lung disease (ILD). Cutaneous ulceration can be
seen in patients with dermatomyositis, and this has classically been associated
with internal malignancy. We have recently described that ulceration can also
be associated with antibodies against melanoma differentiation-associated
gene 5 (MDA5), a DM-specific autoantigen that is associated with ILD, and
mild or no muscle disease. We sought to better describe cutaneous ulceration
in DM and to specifically identify clinical and serologic correlates of ulcers
and their anatomic location.

Methods: We retrospectively examined a cohort of 131 DM patients
followed in our interdisciplinary rheumatology-dermatology clinic. We col-
lected data on demographics, ANA and DM-associated auto-antibodies (Jo-1,
NXP2, Mi2, TIF-Gamma, SAE1, Ro52, MDA5) and clinical features includ-

ing presence and location of ulcers, ILD (evidence of fibrosis or alveolitis on
computed tomography), and malignancy within 3 years of symptom onset.
The cutaneous ulcer locations were subdivided into three categories: ulcer-
ations over joints (Gottron papules, knees, or elbows); ulcerations of the
digital pulp or periungual region; and ulcers elsewhere on the body including
those in sun-exposed areas. We compared the features of patients with ulcers
to those without ulcers using chi-squared tests. We used univariate and
multivariate logistic regression models to identify significant predictors for
the presence of ulcers and ILD.

Results: In the overall cohort, the mean age was 45 ± 19 years, 31% were
male, and the ethnic distribution was 66% Caucasian, 19% Asian, 5% African
American, and 10% Hispanic. 40 patients had cutaneous ulcers and 91
patients did not have ulcers. 50% of patients had ulcers over the Gottron
papules and extensor surfaces, 40% at the digital pulp or periungual areas, and
62.5% had ulcers located elsewhere. Patients with any cutaneous ulcers were
more likely to be Asian ($p=.006$) or anti-MDA5+ ($p<.0001$). We did not
find a significant association between ulcers and malignancy. In multivariate
analysis MDA5+ remained significant and increased the odds of ulcers by
10-fold (OR=10.1, 95%CI 2.0–51.8, $p=.006$). Examining only the ulcer+
patients, ulcers located at the digital pulp or periungual areas was associated
with a 20-fold increased odds of being MDA5+ (OR= 20.9, 95%CI
3.5–126.5, $p=.0009$). Consistent with previous reports, MDA5+ was asso-
ciated with an increased risk for ILD (OR=5.8, 95%CI 1.8–18.4, $p=.003$),
that was higher in the presence of ulcers (OR=8.3, 95%CI 2.5–28.3,
$p=.0007$), particularly if located at the digital pulp or periungual areas
(OR=14.2, 95%CI 3.4–58.3, $p=.0002$).

Conclusion: We confirmed the strong association between MDA5+ and
cutaneous ulcers, with the novel finding that ulcers located at the digital pulp
and periungual areas are highly predictive of the presence of ILD in these
patients. DM patients who display this cutaneous phenotype should undergo
appropriate evaluation for ILD.

Stancati[4], D. J. Lovell[6] and Alberto Martini[2]. [1]Pediatric Rheumatology
Collaborative Study Group (PRCSG), Cincinnati, OH, [2]Paediatric Rheuma-
tology International Trials Organisation (PRINTO)-Istituto Gaslini, Genova,
Italy, [3]Necker-Enfants Malades Hospital, Paris, France, [4]Novartis Pharma
AG, Basel, Switzerland, [5]Novartis Pharmaceutical Corporation, East Ha-
nover, NJ, [6]Cincinnati Children's Hospital, Cincinnati, OH

Background/Purpose: Systemic juvenile idiopathic arthritis (sJIA) is an
interleukin-1β (IL-1β)-mediated autoinflammatory disease. Canakinumab is
a selective, fully human, anti-IL-1β monoclonal antibody. Two pivotal phase
3 trials evaluated the efficacy and safety of canakinumab in patients (pts) with
active sJIA with fever.

Methods: Pts aged 2–19 yrs with active sJIA (fever, ≥2 active joints,
C-reactive protein >30 mg/L) with inadequate response to standard of care
treatments (NSAIDs, steroids, MTX) were enrolled. Trial 1 was a 4-wk,
double-blind, single-dose study of pts randomized to subcutaneous (SQ)
canakinumab 4 mg/kg or placebo. Trial 2 enrolled 177 pts, including eligible
pts rolling over from Trial 1. In Part I of Trial 2, pts received open-label (OL)
canakinumab 4 mg/kg/4wks SQ for up to 32 wks. Pts with an adapted ACR
Pediatric 30 criteria response (aACR-Ped30) at the end of Part I entered Part
II after randomization 1:1 to continue canakinumab or receive placebo until
37 flare events occurred. The primary endpoint of Trial 1 was the proportion
of aACR-Ped30 responders at Day 15. The primary endpoint of Trial 2 in Part
I was the proportion of steroid-treated pts at entry who successfully tapered
steroids, and in Part II the time to flare. Pts withdrawn due to protocol-driven

discontinuation rules were offered participation in the currently on-going OL long-term extension study.

Results: In Trial 1, 84 pts (canakinumab n=43; placebo, n=41) were enrolled. At Day 15, of the 84 pts, significantly more pts in the canakinumab group (83.7% [36/43]) vs. the placebo group (9.8% [4/41]) achieved an aACR-Ped30 response (P <0.0001). In Trial 2, 177 pts received canakinumab in Part I, 100 of whom were randomized in Part II (canakinumab, n=50; placebo, n=50) and 77 discontinued. During Part I of Trial 2, 44.5% (57/128) of the steroid-treated pts successfully tapered steroids (P <0.0001), with the mean steroid dose lowered to 0.05 mg/kg/d from 0.34 mg/kg/d. Of note, 32.8% (42/128) of the pts stopped steroids completely. In Part II, the median time to flare on placebo was 236 days vs. not observed with canakinumab, corresponding to a statistically significant 63% relative risk reduction of flares (HR 0.37; 95% CI 0.17–0.78; P=0.0043). Inactive disease was achieved by 30.9% (54/175) of the canakinumab-treated pts at the end of Part I and 62% (31/50) upon completion of Part II. 142 (80.2%) of the enrolled pts from Trial 2 entered the OL extension study, which included 48 pts who had withdrawn from the Part I due to efficacy related protocol-driven discontinuation. In both trials, infections were the most common type of adverse event (AE) reported. Most Serious AEs were associated with infections, disease flare, and macrophage activation syndrome (MAS, n=7, including 2 on placebo). Two deaths were reported (1 canakinumab, 1 placebo), both associated with MAS.

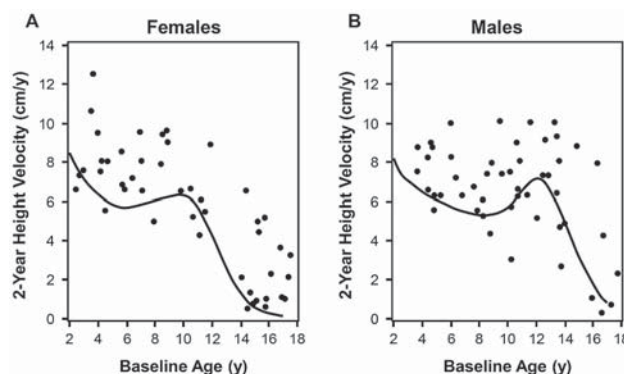
Conclusion: These data support that canakinumab is an effective treatment for active sJIA with fever. Canakinumab demonstrated superior efficacy vs. placebo, allowed successful reduction of steroid use, and significantly decreased the risk of sJIA flares, while demonstrating an acceptable safety profile.

760

Catch-up Growth During Tocilizumab Therapy for Systemic Juvenile Idiopathic Arthritis: 2-Year Data From a Phase 3 Clinical Trial.
Fabrizio De Benedetti[1], Nicolino Ruperto[2], Graciela Espada[3], Valeria Gerloni[3], Berit Flato[3], Gerd Horneff[4], Barry L. Myones[5], Karen Onel[5], James Frane[6], Andrew Kenwright[7], Terri H. Lipman[8], Kamal N. Bharucha[6], Alberto Martini[3] and D. J. Lovell[9]. [1]IRCCS Ospedale Pediatrico Bambino Gesù, Rome, Italy, [2]Paediatric Rheumatology International Trials Organisation [PRINTO], Genova, Italy, [3]Paediatric Rheumatology International Trials Organisation–IRCCS [PRINTO], Genova, Italy, [4]Centre of Pediatric Rheumatology, Sankt Augustin, Germany, [5]Pediatric Rheumatology Collaborative Study Group [PRSCG], Cincinnati, OH, [6]Genentech, South San Francisco, CA, [7]Roche, Welwyn Garden City, United Kingdom, [8]University of Pennsylvania School of Nursing, Philadelphia, PA, [9]Cincinnati Children's Hospital, Cincinnati, OH

Background/Purpose: Systemic juvenile idiopathic arthritis (sJIA), characterized by chronic arthritis associated with prominent systemic and laboratory features, also has a significant impact on the growing skeleton, resulting in impaired linear growth and systemic osteoporosis. A phase 3 trial (TENDER) demonstrated that the interleukin-6 (IL-6) receptor inhibitor tocilizumab (TCZ) is effective in the treatment of patients with sJIA. Long-term growth responses for children in the TENDER trial (up to week 104) are presented.

Methods: The TENDER trial enrolled 112 patients (ages 2–17 years) with active, refractory sJIA (≥6-month duration with inadequate response to previous nonsteroidal anti-inflammatory drugs and oral corticosteroids). After a 12-week, randomized, placebo-controlled phase, patients received open-label TCZ in the long-term extension. Height parameters, laboratory data, and clinical assessments of disease activity were compared at baseline and through year 2 of the study.

Results: At enrollment in the TENDER trial, the height measurements of study patients revealed profound growth failure (mean height standard deviation score [SDS] of –2.1; n = 107). During treatment, the majority of patients had greater than normal height velocities, with 85% of female patients and 73% of male patients demonstrating catch-up growth (Figure). The height SDS increased significantly from baseline to year 2 of the study, with a mean improvement of 0.61 ($p < 0.0001$, paired t-test). Although the mean corticosteroid dose was higher in the first year (0.13 mg/kg/day compared with 0.05 mg/kg/day in the second year), mean height velocities in the first and second years of the study were comparable at 5.8 and 6.3 cm/y, respectively ($p = 0.32$, paired t-test). During TCZ treatment, a significant increase in insulin-like growth factor 1 (IGF-1) levels was observed, suggesting a normalization of growth hormone axis function (mean baseline IGF-1 SDS of –1.1 [n = 95] compared with year 2 mean IGF-1 SDS of 0.0 [n = 91]; $p < 0.0001$, paired t-test). The osteocalcin/c-telopeptide of type 1 collagen (OC/CTX-1) ratio increased significantly ($p = 0.0045$, paired t-test), suggesting an increase in osteoblast activity relative to osteoclast activity. Patients with greater improvement in JADAS-71 scores during the first year had greater height velocities during that year ($r = -0.35$, $p = 0.0002$; mean decrease in JADAS-71 of 29.2 [n= 107]).


Conclusion: TCZ therapy for sJIA resulted in catch-up growth of study patients. Additionally, TCZ therapy resulted in increased IGF-1 levels and OC/CTX-1 ratios, suggesting beneficial effects on the growth hormone axis and on bone metabolism. Improvement in JADAS scores correlated with increased height velocity. Continued data collection (for a total of 5 years) will allow a comprehensive analysis of growth outcomes in the TENDER study.

761

Analysis of Biomarkers in Systemic Juvenile Idiopathic Arthritis Patients On Canakinumab Therapy. Nico Wulffraat[1], Hermine I. Brunner[2], Nicolino Ruperto[1], Pierre Quartier[3], Riva Brik[1], Liza McCann[1], Huri Ozdogan[1], Lidia Rutkowska-Sak[1], Rayfel Schneider[2], Valeria Gerloni[1], Liora Harel[1], Maria Hilário[2], Kristin Houghton[2], Rik Joos[1], Daniel Kingsbury[2], Arndt Brachat[4], Stephan Bek[4], Martin Schumacher[4], Marie-Anne Valentin[4], N.R Nirmala[5], Hermann Gram[4], Ken Abrams[6], Alberto Martini[1] and D. J. Lovell[7]. [1]Paediatric Rheumatology International Trials Organization (PRINTO), Genova, Italy, [2]Pediatric Rheumatology Collaborative Study Group (PRCSG), Cincinnati, OH, [3]Necker-Enfants Malades Hospital, Paris, France, [4]Novartis Institutes for Biomedical Research, Basel, Switzerland, [5]Novartis Institutes for Biomedical Research, Cambridge, MA, [6]Novartis Pharmaceuticals Corporation, New Jersey, [7]Cincinnati Children's Hospital, Cincinnati, OH

Background/Purpose: Systemic Juvenile Idiopathic Arthritis (SJIA) is a severe disabling subtype of Juvenile Idiopathic Arthritis characterized by arthritis plus systemic symptoms, such as high fever, rash, serositis, and lymphadenopathy. Among others, interleukin (IL)-1β is an inflammatory cytokine that plays a dominant role in SJIA and several other autoinflammatory conditions, with anti-IL-1β therapy showing good efficacy in many of these settings. Canakinumab (CAN) is a high-affinity selective human monoclonal antibody targeted against IL-1β. Levels of inflammatory biomarkers and gene expression profiles of patients with active SJIA before and during canakinumab treatment were studied from patients aged 2 to <20 years participating in 2 phase III trials.

Methods: Serial measurements of levels of cytokines and proteins involved in inflammation (IL6; IL18; S100A8, A9 and A12) were made at baseline and at Days 3 and 29 after initiation of CAN treatment. Whole blood samples and DNA microarrays were used to characterize the early (Day 3) transcriptional response to CAN treatment and to predict efficacy.

Results: Protein markers: The median levels of IL-6 were strongly reduced; 7.2 fold reduction in the first trial (*p=0.012*) and 4.9 fold in the second trial (*p=0.000046*) by Day 29, while IL-18 levels remained largely unchanged by Day 29. Among the S100 proteins, median S100A9 levels were reduced by 3.4 fold in the first trial (*p=0.0078)* and 4.3 fold in the second trial (*p=0.016*). S100A8 and S100A9 proteins did not show consistent behaviors across the two trials.

Gene Expression: For all comparisons, the number of down regulated genes was much larger than the number of upregulated genes upon treatment, suggesting that the active disease state was mainly characterized by transcriptional activation of "disease genes". Transcriptional changes upon CAN treatment at Day 3 were highly consistent between the two trials. Subjects who showed strong transcriptional changes (primarily down regulation, >2x, *p=0.05*) also showed a strong adapted pediatric ACR response (≥ACR50) at Day 15, while subjects that did not reach ACR50 by Day 15 showed a much weaker transcriptional response at Day 3. Strongly responsive genes included many known inflammation and neutrophil-related genes, including IL-1β, encoding the CAN target. A set of transcripts was identified for which baseline expression levels predicted a subgroup of strong (≥ACR70) responders at Day 15. However, another subgroup of strong responders was indistinguishable from weak responders (<ACR30) based on transcript levels at baseline.

Conclusion: CAN treatment resulted in a strong reduction of elevated baseline IL6 protein levels in patients with active SJIA, while IL18 protein levels remained largely unchanged until Day 29 of the treatment period. Many patients who showed a strong clinical benefit already at Day 15 were characterized by high baseline expression levels of inflammatory and neutrophil associated genes which were repressed after 3 days of CAN treatment. A second, smaller, group of patients showing good clinical response did, however, not show this pattern, suggesting the existence of mechanistically different subpopulations in this disease.

Background/Purpose: Systemic Juvenile Idiopathic Arthritis (sJIA) is characterized by fevers, rash and arthritis, for which IL1 and IL6 inhibitors appear to be effective. Pulmonary artery hypertension (PAH), interstitial lung disease (ILD) and alveolar proteinosis (AP) have been recently reported in sJIA patients with increased frequency and is associated with mortality. The purpose of our study was to identify and characterize these cases and compare them to a larger cohort of sJIA patients.

Methods: A retrospective review of sJIA patients who developed PAH, ILD and/or AP solicited through an electronic listserv was performed. Demographic, sJIA and pulmonary disease characteristics and medication exposure information were collected. These features were compared to a cohort of sJIA patients enrolled in the Childhood Arthritis and Rheumatology Research Alliance (CARRA) pediatric rheumatic diseases registry.

Results: Patients (N=25) were significantly more likely (p<0.05) than the CARRA registry cohort (N=389) to be female and have more systemic features. They were also significantly more likely to have been exposed to the following: an IL-1 inhibitor, tocilizumab, infliximab, corticosteroids, intravenous immunoglobulin, cyclosporine and cyclophosphamide. Eighty% were diagnosed after 2004. Twenty (80%) patients had MAS during their disease course and 16 (64%) had suspected/confirmed MAS at pulmonary diagnosis. Sixteen patients had PAH, 7 AP and 8 ILD. Dyspnea on exertion and shortness of breath were the most common symptoms. One patient was diagnosed at autopsy and did not have any known prior pulmonary symptoms. Pulmonary disease characteristics are shown in the Table. Seventeen (68%) patients were taking or recently (<1 month) discontinued a biologic agent at pulmonary symptom onset, and 12 (48%) were taking anti-IL1 therapy (primarily anakinra). Seventeen (68%) patients died at a mean of 10.2 months from pulmonary diagnosis.

Clinical features at pulmonary disease diagnosis

Total N: 25

Age at start of pulmonary symptoms (years)*	11.7 ± 5.2 (3.5–18.8)
Disease duration at pulmonary diagnosis (months [mos])*	50.6 ± 44.6 (8–160)
Time between pulmonary symptoms to diagnosis (mos)*	3.1 ± 3.2 (0–10)
Time between pulmonary diagnosis to death (mos) (N=17)*	10.2 ± 13 (0–44)
Disease features at pulmonary disease diagnosis	**N (%)**
sJIA manifestations	
Any systemic manifestation**	23 (92)
MAS (suspected or confirmed)	16 (64)
Pericarditis/serositis	11 (44)
Thrombotic thrombocytopenic purpura	1 (4)
Arthritis	16 (64)
Pulmonary symptoms	
Shortness of breath	16 (64)
Dyspnea on exertion	18 (72)
Cough	11 (44)
Clubbing	10 (40)
Chest pain	5 (20)
Pulmonary diagnosis	
Pulmonary artery hypertension	16 (64)
Alveolar proteinosis	7 (28)
Interstitial lung disease	7 (28)

* Mean ± SD (range)
**Includes patients with one or more of the following: fever, rash, lymphadenopathy, hepatomegaly, splenomegaly

Conclusion: Despite recent advances in therapy, sJIA remains a disease with significant morbidity and mortality. This is the first time that a large cohort of sJIA patients who developed PAH, AP and ILD has been described. These are important, largely fatal and under-recognized complications of sJIA which are likely to be the result of severe uncontrolled systemic disease activity and inflammation, but may be influenced by exposure to certain medications. Further prospective studies are needed to determine the factors associated with the development of these complications. Increased awareness regarding these complications in sJIA is needed, and screening for these complications should be considered in sJIA patients with significant and persistent systemic disease activity.

763

Incidence of Selected Opportunistic Infections Among Children with Juvenile Idiopathic Arthritis. Timothy Beukelman[1], Fenglong Xie[1], John Baddley[1], Lang Chen[1], Elizabeth S. Delzell[1], Carlos Grijalva[2], Melissa L. Mannion[1], Nivedita M. Patkar[1], Kenneth G. Saag[1], Kevin L. Winthrop[3] and Jeffrey R. Curtis[1]. [1]University of Alabama at Birmingham, Birmingham, AL, [2]Vanderbilt University, Nashville, TN, [3]Oregon Health & Science University, Portland, OR

Background/Purpose: There may be an increased risk of opportunistic infections among children with juvenile idiopathic arthritis (JIA), especially with exposure to immunosuppressant medications. No controlled studies to address this question have been published. We determined incidence rates of selected opportunistic infections among children with and without JIA and examined the effects of immunosuppressant medications.

Methods: Using U.S. national Medicaid claims data from 2000 through 2005 we identified a cohort of children with JIA based on physician diagnosis codes and dispensed medications. We defined a non-JIA comparator cohort of children diagnosed with attention deficit hyperactivity disorder. All subjects had a 3 month baseline period prior to study follow-up to assess for prevalent opportunistic infections (which excluded patients from analysis) and current medication exposures. All medication exposures to methotrexate (MTX), TNF inhibitors, and systemic glucocorticoids (GC) were considered current for 30 days past the days supplied by the last filled prescription. Hospitalized and outpatient incident opportunistic infections were identified using physician diagnosis or hospital discharge codes. Identification of some infections

(mycoses, tuberculosis, and herpes zoster) also required evidence of treatment with specific antimicrobials within 90 days. We calculated infection incidence rates (IR). The rates in the non-JIA comparator cohort were standardized to the age, sex, and race distribution of the JIA cohort. We calculated incidence rate ratios (IRR) to compare infection rates.

Results: The JIA cohort included 8,503 children with 14,370 person-years of follow-up; 1,392 used TNF inhibitors and 3,491 used MTX during follow-up. The non-JIA comparator cohort included 360,362 children with 490,939 person-years of follow-up. When all opportunistic infections were considered together as a single outcome, there were 42 infections in the JIA cohort (IR 300 [216–406] per 100,000; IRR 2.4 [1.7–3.3] versus non-JIA comparator). Among all children with JIA, there were no identified infections with *Aspergillus*, *Blastomyces*, *Histoplasma*, *Cryptococcus*, *Legionella*, *Listeria*, JC virus, or tuberculosis. We identified 1 infection each (IR 7 per 100,000) with *Nocardia*, non-tuberculous mycobacteria, *Toxoplasma*, and *Pneumocystis*. We identified 3 infections with *Coccidioides* (IR 21 per 100,000; IRR 101 [8.1–5319] versus non-JIA comparator); 5 infections with *Salmonella* (IR 35 per 100,000; IRR 3.8 [1.2–9.5]); and 32 cases of herpes zoster (IR 225 per 100,000; IRR 2.1 [1.4–3.0]). Among children with JIA, herpes zoster was not strongly associated with current use of GC (IRR 1.8 [0.6–4.5] versus no current GC use), MTX (IRR 1.4 [0.5–3.6] versus no current MTX or TNF inhibitor use), or TNF inhibitors (IRR 2.2 [0.7–6.9] versus current MTX use without current TNF inhibitor use).

Conclusion: Opportunistic infections are rare among children with JIA. Nevertheless, children with JIA had a higher rate of opportunistic infections, including *Coccidioides*, *Salmonella*, and herpes zoster, than children without JIA. Herpes zoster was not strongly associated with specific immunosuppressant medications used to treat JIA.

764

The Impact of Adalimumab On Growth in Patients with Juvenile Idiopathic Arthritis. D. J. Lovell[1], Nicolino Ruperto[2], Katerina Jarosova[2], Dana Nemcova[2], Veronika Vargova[2], Hartmut Michels[2], Elizabeth Chalom[3], Norman Ilowite[3], Carine Wouters[2], Hermine Brunner[2], Karolyn Kracht[4], Hartmut Kupper[5], Edward Giannini[3], Alberto Martini[2] and Neelufar Mozaffarian[4]. [1]Cincinnati Children's Hospital, Cincinnati, OH, [2]Paediatric Rheumatology International Trials Organisation–IRCCS [PRINTO], Genova, Italy, [3]Pediatric Rheumatology Collaborative Study Group [PRSCG], Cincinnati, OH, [4]Abbott, Abbott Park, IL, [5]Abbott GmbH and Co. KG, Ludwigshafen, Germany

Background/Purpose: Children with juvenile idiopathic arthritis (JIA) often exhibit growth impairments. Treatment with adalimumab (ADA) has been shown to be safe and effective in JIA patients (pts) when dosed every other week (eow) for up to 3 years,[1] but the effect of ADA on growth is not known. The purpose of this post hoc analysis is to describe growth parameters in pts with JIA treated with ADA in a clinical trial setting.

Methods: Pts aged 4–17 with polyarticular course JIA were enrolled in a phase 3, randomized-withdrawal, double-blind (DB), stratified, parallel-group study, which consisted of a 16-wk open-label (OL) lead-in phase, a 32-wk DB phase, and an OL extension (OLE) phase. In the OLE phase, pts were dosed based on body surface area (24 mg/m^2, max 40 mg dose), followed by a switch to 20 or 40 mg eow based on a body weight of ≤30 kg or >30 kg, respectively. To enter the DB phase, pts had to achieve an American College of Rheumatology Pediatric score ≥30% (ACR Pedi 30) during the OL lead-in. Pts could enter the OLE after 32 wks in the DB phase or at time of first flare (whichever came sooner). For this analysis, pts in the DB phase were grouped by baseline weight into 2 groups: ≤33rd percentile and >33rd percentile based on the US Centers for Disease Control and Prevention (CDC) growth charts. All pts who received ≥1 dose of ADA ± methotrexate (MTX) were included in the analysis. Mean CDC percentile changes in height, weight, and body mass index (BMI) percentiles were calculated through 104 weeks. Growth and efficacy data were analyzed using last observation carried forward (LOCF).

Results: Among the 171 pts enrolled in this study, 144 (84%) met ACR Pedi 30 response criteria at week 16, and 133 (78%) entered the DB phase. Of the 133 pts, 77% were female, with a mean age of 11.2 years, and a mean disease duration of 3.8 years; at baseline, 55 pts (41%) were in the ≤33rd percentile for weight and 78 pts (59%) were >33rd percentile. There were no differences between MTX and non-MTX groups in mean changes from baseline in weight, height, or BMI percentiles (*P*>.26). Pts in the lower 33rd percentile climbed to a higher mean growth rate through 104 weeks of ADA treatment (**Figure**). For those who started in the >33rd percentile, growth rates showed an initial increase that remained in the normal range throughout the study (**Figure**). Similar patterns were observed for height and BMI percentiles in these 2 groups. ACR Pedi 30/50/70/90 response rates improved over time in both groups, reaching 85%/76%/60%/36% for the ≤33rd percentile group and 83%/76%/51%/29% for the >33rd percentile group by the end of the DB phase with ADA treatment.

Figure. Mean Height Percentile Change from Baseline[a] (All Subjects Who Received ≥1 Dose of ADA)
[a]Baseline mean height percentile for pts in the lower 33rd and >33rd percentiles were 25.1 and 55.5, respectively; LOCF analyses.

Conclusion: Long-term ADA treatment ± MTX is associated with improvement and maintenance of growth in children with JIA who had experienced impaired development. ADA treatment improved JIA signs and symptoms in both groups, regardless of baseline growth status.

ACR Concurrent Abstract Session
Rheumatoid Arthritis - Clinical Aspects I: Risk Factors and Prediction of Rheumatoid Arthritis
Sunday, November 11, 2012, 2:30 PM–4:00 PM

765

A Prediction Rule for the Development of Rheumatoid Arthritis: A Prospective Cohort Study of Seropositive Arthralgia Patients. Lotte van de Stadt[1], B. I. Witte[2], W.H. Bos[1] and Dirkjan van Schaardenburg[1]. [1]Jan van Breemen Research Institute | Reade, Amsterdam, Netherlands, [2]VU University Medical Center, Amsterdam, Netherlands

Background/Purpose: Patients presenting with arthralgia and a positive test for anti-cyclic citrullinated peptide antibodies (aCCP) and/or IgM rheumatoid factor (IgM-RF) (seropositive) are at risk for developing RA. We aim to predict the development of arthritis in these patients using antibody characteristics and clinical variables.

Methods: A prediction rule was developed using a prospective cohort of 374 seropositive arthralgia patients. Patients were followed biannually in the first year and then annually for the development of arthritis, which was defined as presence of one or more swollen joints at clinical examination. 18 prediction variables were selected based on clinical applicability, biologic plausibility, previous research and expert opinion. Backward stepwise Cox regression was used to create a prediction model (p removal 0.1). Regression

coefficients were rounded to half points to make a prediction rule. Scores were multiplied by 2 for easier clinical applicability. The diagnostic performance of the prediction rule was evaluated using the area under the curve (AUC) of ROC curves.

Results: Patients were followed for a median of 32 months (IQR: 13–48). 131 arthralgia patients (35%) developed arthritis after a median of 12 months (IQR: 6–23), of whom 121 (92%) were diagnosed with RA according to the 2010 ACR/EULAR criteria. The prediction model consisted of 9 variables: antibody status (double positive, or high titer aCCP confers higher risk), RA in a first degree family member, VAS pain over 50, presence of morning stiffness, arthralgia in both upper and lower extremities, duration of symptoms shorter than 12 months, presence of intermittent complaints, history of swollen joints as reported by the patient and alcohol non-use. The variables age, sex, smoking, NSAID use, symmetric symptoms, symptoms in small joints, tender joint count, CRP and Shared Epitope were excluded. Patients scored 0 to 12 points on the prediction rule. The AUC value of the prediction rule was 0.82 (95% CI: 0.75–0.89). According to Cox regression analysis with the prediction rule as categorical variable, patients could be categorized in three risk groups: low risk (0–4 points), intermediate risk (5–6 points) and high risk (7–12 points). 155 (41%) patients had low, 102 (27%) intermediate and 117 (31%) had high risk. The percentages of arthritis development per risk group are depicted in the figure. With the low risk group as a reference, the intermediate risk group had a hazard ratio (HR; 95% CI) of 4.3 (2.3–8.1) and the high risk group had a HR of 14 (7.7–25).

Survival per risk group
Conclusion: In patients who present with seropositive arthralgia, the risk of developing arthritis and subsequent RA can be predicted. The prediction rule that was made in this patient group can help 1) to inform patients and 2) to select high-risk patients for intervention studies before clinical arthritis occurs.

766

Anemia May Provide Clinically Relevant Information Beyond Conventional Disease Activity Assessment to Predict Radiographic Damage Progression in Rheumatoid Arthritis. Burkhard Moller[1], Frauke Förger[2], Peter M. Villiger[3] and Axel Finckh[4]. [1]Inselspital University Hospital, Bern, Switzerland, [2]Inselspital University Hospital of Bern, Bern, Switzerland, [3]Inselspital-University Hospital of Bern, Bern, Switzerland, [4]Geneva University Hospitals, Geneva 14, Switzerland Burkhard Möller, Frauke Förger, Peter M. Villiger, Axel Finckh, on behalf of the Swiss Clinical Quality Management Program for Rheumatic Diseases.

Background/Purpose: Anemia in rheumatoid arthritis (RA) is prototypic for anemia of chronic disease (ACD) and often neglected in clinical practice. Previous studies have shown a relation between this extra-articular manifestation of RA and disease severity. Purpose: To study the relation between anemia and radiographic progression in RA.

Methods: This study is nested in a large prospective RA patient cohort. Data were collected between 1996 and 2007. Anemia was defined according to the WHO criteria (♀ Hb<12, ♂: Hb<13 g/dl). We also used one less (♀ Hb<12.2, ♂ 20–59y: Hb<13.7 g/dl, ♂ 60+y: Hb<13.2 g/dl) and one more severe definition of anemia (♀ Hb<11, ♂: Hb<12 g/dl) in sensitivity analyses. Erosions were assessed with a validated erosion score (Ratingen score) of 38 joints at hands and feet in 11255 radiograph sets from 4005 RA patients, over a mean follow-up of 2.2 years. Radiographic progression was

analyzed using longitudinal regression models for repeated data and adjusted for potential confounding factors, such as age, gender, rheumatoid factor, disease duration and erosion score at inclusion, baseline and time dependent DAS28$_{ESR}$, DMARD, glucocorticoid and anti-TNF therapy. Subgroup analyses were performed in patients starting on methotrexate (n=728) or anti-TNF-therapy (n=938), in patients achieving different stages of severe, moderate, mild disease activity or remission (DAS28$_{ESR}$<2.6, n=1253) at the final visit, and in 508 patients achieving remission after TNF blockade.

Results: Erosions progressed significantly (p<0.001) faster in patients with than without anemia, despite adjusting for clinical disease activity and other important predictors of joint damage. As an example, erosion had progressed by mean 1.36% (95% CI 1.21–1.51) in non-anemic versus 2.66% (2.17–3.14) in anemic patients after one year. Patients with less severe anemia had a less rapid and patients with more severe anemia displayed a more rapid joint damage progression, suggesting a 'dose response effect'. Effect modification by anemia went insignificant in subgroups of patients with persistent clinically detectable disease activity, but remained a significant factor for more rapid erosive progression in patients achieving remission upon any treatment (p<0.001) or upon anti-TNF-therapy (p<0.001).

Conclusion: Anemia appears to capture structural disease processes that remain unmeasured by conventional disease activity measures in patients with or without TNF blockade. Thus, anemia may help to identify patients with more rapid erosive disease.

Patients with Early Inflammatory Arthritis Who Fulfil the 2010 American College Rheumatology/European League Against Rheumatism Classification Criteria for Rheumatoid Arthritis Have Increased Mortality Compared to Those Who Do Not: Results From the Norfolk Arthritis Register.
Jh Humphreys[1], Suzanne Verstappen[2], Mark Lunt[3], Jackie Chipping[4], Kimme Hyrich[5], Tarnya Marshall[6] and Deborah Symmons[7]. [1]Arthritis Research UK Epidemiology Unit, Manchester, United Kingdom, [2]University of Manchester, Manchester Academic Health Sciences Centre, Manchester, United Kingdom, [3]Arthritis Research UK Epidemiology Unit, The University of Manchester, Manchester, United Kingdom, [4]Norfolk Arthritis Register, School of Medicine Health Policy and Practice Faculty of Health UEA, Norwich, United Kingdom, [5]Arthritis Research UK Epidemiology Unit, University of Manchester, Manchester, United Kingdom, [6]Norfolk and Norwich University Hospitals Trust, Norwich, United Kingdom, [7]University of Manchester, Manchester Academy of Health Sciences, Manchester, United Kingdom

Background/Purpose: Mortality is increased in rheumatoid arthritis (RA) in comparison with the general population. The majority of studies have used the 1987 ACR criteria to define RA when investigating mortality. The aims of this study were (i) to examine whether, in a cohort of patients with early inflammatory polyarthritis (IP), the 2010 ACR/EULAR classification criteria for RA identify those with decreased survival; and if this is the case (ii) to identify which components of these criteria are the strongest predictors of mortality.

Methods: Consecutive adults with ≥2 swollen joints for ≥4 weeks were recruited to the Norfolk Arthritis Register (NOAR) between 1990 and 2009. Patients included in this analysis had symptom duration ≤2 years and had not received any disease modifying therapy at initial assessment. Data on the components of the 2010 criteria, along with demographic details, were obtained at baseline visit through a nurse-administered questionnaire and joint examination. Patients also completed the health assessment questionnaire (HAQ). Bloods samples were taken for C-reactive protein (CRP), rheumatoid factor (RF) and anti-citrullinated protein antibody (ACPA) estimation. All patients registered with NOAR are flagged with the UK Office for National Statistics (ONS) who provide mortality data. Survival analyses were performed using Cox proportional hazards models univariately, then adjusting for age and sex. A multivariate model was then developed including all components of the 2010 criteria as well as baseline smoking status, age and gender.

Results: 1671 patients had complete data for analysis, with 20488 person-years follow up. 1092 (65%) patients were female and there were 471 (28%) deaths reported by the ONS by 31st December 2011. 905 (54%) patients fulfilled the 2010 criteria at baseline, and these patients had a significantly increased risk of death compared to those patients in NOAR who did not fulfil the 2010 criteria, both univariately and in the age and sex

adjusted model, hazard ratio(HR) 1.39 (95% CI 1.15–1.68). Results of the Cox regression models for the different parameters are shown in the table. High titre antibody positivity (more than three times the upper limit of normal) was the strongest predictor of mortality in the multivariate model adjusted for all components of the 2010 criteria, age, sex, and smoking status (HR 1.64 (95% CI 1.34 – 2.01)).

Table 1. Predictors of mortality in the 2010 ACR/EULAR classification criteria for RA

	n (%)	Univariate HR	Univariate 95% CI	Age & sex adjusted HR	Age & sex adjusted 95% CI	Multivariate HR	Multivariate 95% CI
Satisfy 2010 criteria: No	766 (46)	ref	–	ref	–	–	–
Yes	905 (54)	1.56	1.29–1.88	1.39	1.15–1.68	–	–
Joint score 0	173 (10)	ref	–	ref	–	ref	–
Joint score 1	77 (5)	1.09	0.63–1.91	1.31	0.75–2.31	1.55	0.88–2.75
Joint score 2	372 (22)	1.15	0.77–1.74	1.19	0.79–1.79	1.29	0.85–1.95
Joint score 3	357 (21)	1.62	1.09–2.40	1.33	0.90–1.98	1.36	0.92–2.03
Joint score 5	692 (41)	1.60	1.11–2.32	1.42	0.98–2.06	1.40	0.96–2.04
RF/ACPA negative	1086 (65)	ref	–	ref	–	ref	–
RF/ACPA low positive	171 (10)	1.02	0.72–1.45	0.93	0.66–1.33	0.90	0.64–1.28
RF/ACPA high positive	414 (25)	1.84	1.51–2.23	1.75	1.44–2.13	1.6	1.31–1.97
Normal CRP	743 (45)	ref	–	ref	–	ref	–
Abnormal CRP	928 (56)	2.04	1.68–2.46	1.39	1.15–1.69	1.25	1.02–1.52
Disease duration: 6 weeks	88 (5)	ref	–	ref	–	ref	–
≥6 weeks	1583 (95)	0.86	0.60–1.25	0.88	0.61–1.28	0.84	0.58–1.22

Conclusion: In patients presenting with early inflammatory polyarthritis, those who fulfil the 2010 criteria have significantly increased mortality compared to those who did not. The components of the 2010 criteria which appear to be important predictors of mortality are high titre RF or ACPA positivity, and abnormal CRP at baseline.

768

An Easy to Use Referral Model for Arthritis From the Rotterdam Early Arthritis Cohort.
C. Alves[1], Jolanda J. Luime[2], Darian P. Shackleton[3], P.J. Barendregt[4], A.H. Gerards[5] and Johanna M.W. Hazes[6]. [1]Erasmus MC, Rotterdam, Netherlands, [2]Erasmus MC - University Medical Center, Rotterdam, Netherlands, [3]Medisch Centrum Parklaan, Netherlands, [4]Maasstad Hospital, Rotterdam, Netherlands, [5]Vlietland Hospital, Schiedam, Netherlands, [6]Erasmus Medical Center, Rotterdam, Netherlands

Background/Purpose: The first hurdle general practitioners (GPs) face to identify Rheumatoid Arthritis(RA) is to recognize presence of arthritis. Due to the low incidence of arthritis in primary care it is challenging to differentiate between patients with inflammatory musculoskeletal disease and those without. We set out to create a referral model to aid early referral in primary care based on data from the REACH.

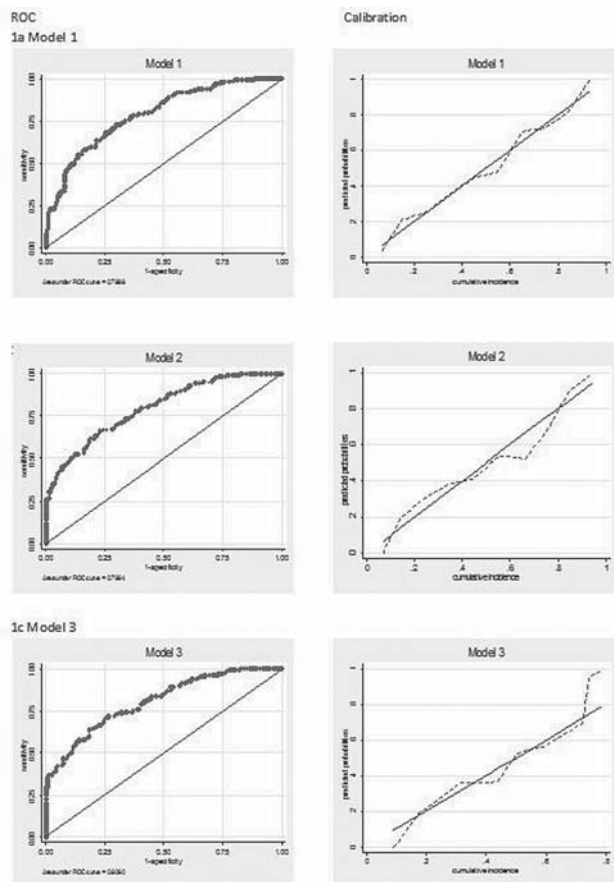
Methods: The REACH cohort includes patients with either arthritis or 2 painful joints with 2 additional inflammatory characteristics. Four hundred and one patients referred to REACH by their GPs were used in this analysis. A prediction model was build by selection of variables from the history, physical examination and laboratory values that were likely available to GPs. The presence of at least one joint with synovitis was used as outcome excluding patients with gout. Variable selection was performed by classifying variables in 8 categories: symptoms, duration of complaints, life style, family history, comorbidity, medication use and systemic complaints (fever, skin disorder) followed by logistic regression with backward selection in each category. A referral model was build with the variables with p<0.1 evaluated in a logistic regression model that was bootstrapped 200 times to elicit the for optimism corrected c-statistic. Performance was also evaluated using ROC-curves and calibration plots. The addition of blood markers to the simple model was also evaluated.

Results: Table 1 shows baseline characteristics for the 401 patients. Arthritis was present at baseline in 182 patients. The referral model based on the REACH data resulted in a model containing the following variables: age, female sex, problems with fitting shoes, self-reported limitation of joint movement, lower number of self-reported painful joints, higher number of self-reported swollen joints, self-reported redness or hot/warm joints, the presence of squeeze pain in hand or feet and delay in presenting to the GP. The AUC was 0.79 (corrected for optimism: 0.72), adding ESR resulted in an AUC of 0.80 and adding RF resulted in 0.81. The simplest model calibrated slightly better (fig 1).

Table 1. baseline characteristics

	case, n=182	non case, n=219		
age (mean, SD)	51 (15)	47 (12)	p<0.05	
gender (%)	69%	66%	p<0.05	
duration of complaints (median, range)	68 (4–370)	122 (1–416)	p<0.05	
delay patient (median, range)	21 (0–328)	43 (0–361)	p<0.05	
tender joint count (median, range)	7 (0–34)	6 (0–38)	ns	
rheumatoid factor positive (%)	25%	11%	p<0.05	
anti-CCP positive (%)	17%	6%	p<0.05	*
ESR (median, range)	18(2–100)	8(0–66)	p<0.05	@
C-reactive proteine (median, range)	6 (1–180)	3 (1–55)	p<0.05	#
Diagnosis RA	0%	29%	p<0.05	$

*n=30 missing, @ n=63 missing, # n=92 missing, $ n=47 missing.

ROC / Calibration
1a Model 1 — Model 1
Model 2
1c Model 3 — Model 3


Conclusion: We were able to create a referral model based on history taking and physical examination suitable for referral of patients with arthritis at risk for RA and perhaps other inflammatory diseases in primary care. Adding laboratory values did not improve performance and thus may be omitted based on the resources of the primary care facility.

2010 ACR/EULAR Rheumatoid Arthritis Classification Criteria Predicts Radiogical, but Not Clinical Outcomes At 18 Months Into Disease in a Canadian Early Arthritis Cohort. Ariel Masetto[1], Arthur J. Fernandes[2], Patrick Liang[3], Pierre Cossette[2] and Gilles Boire[4]. [1]CHUS, Fleurimont, QC, [2]Universite de Sherbrooke, Sherbrooke N, [3]CHUS, Sherbrooke, QC, [4]CHUS - Sherbrooke University, Sherbrooke, QC

Background/Purpose: The potential of the 2010 ACR/EULAR rheumatoid arthritis (RA) classification criteria to discriminate early arthritis patients according to their clinical and radiological outcomes needs to be confirmed.

Methods: Consecutive patients with at least 3 swollen joints (SJC≥ 3) were recruited; duration of disease was more than 1 and less than 12 months; microcrystalline arthritides and connective tissue diseases were actively excluded. All patients were treated with the target of SJC= 0, using whatever DMARDs was required. According to the 2010 RA criteria, our cohort was classified in two groups: RA and non-specific inflammatory arthritis (NSIA). Both groups were compared at baseline and at 18 months into disease according to radiological and clinical outcomes: Sharp erosion score (classified erosive if ≥ 3), Health Assessment Questionnaire (HAQ), Disease Activity Score in 28 joints (DAS28-CRP), and pain (0–100 mm VAS). Remission rates at 18 months were calculated based on DAS 28 and ACR 2011 remission criteria.

Results: A total of 422 patients were available at baseline. Of these, 319 (75.6%) were classified as RA. Based on clinical outcome measures, RA patients had more severe disease than NSA patients at baseline (higher DAS 28, HAQ and pain scores measures – p<0.001). At 18 months, this initial clinical discrepancy had now disappeared, but more RA patients had progressed to erosive status than NSIA patients (54% vs 33%; p<0.001). Using two different definitions of remission, there was no difference in remission rates.

	Rheumatoid arthritis (2010 ACR/EULAR criteria) mean (median)	Non specific inflammatory arthritis mean (median)	P value
Baseline			
HAQ	0.95 (0.875)	0.625 (0.5)	P<0.001
DAS 28 - CRP	5.53 (5.58)	4.61 (4.57)	P<0.001
Pain	59.2 (61)	47.3 (47)	P<0.001
18 months			
HAQ	0.38 (0.25)	0.38 (0.125)	P=0.717
DAS 28 - CRP	2.47 (2.84)	2.64 (2.33)	P=0.238
Pain	29.0 (24)	31.4 (23)	P=0.485
Sharp erosion score	5.67 (3.0)	3.14 (1.0)	P=0.002
Remission at 18 months			
DAS 28 – CRP	53%	58.6%	P=0.316
ACR 2011	16%	18.8%	P=0.964

Conclusion: In this early arthritis cohort actively treated to SJC= 0, there was no difference in the 18-month clinical outcomes (HAQ, DAS 28, Pain, Remission rates) between 2010 ACR/EULAR criteria-defined RA and NSIA patients. Patients with RA had a worse radiological outcome, but significant joint damage occurred in one third of NSIA patients. Early intensive treatment of NSIA patients, and not only of early RA patients, thus appears warranted.

Is Late Onset Rheumatoid Arthritis (LORA) Really a Distinct Entity of RA? Results From the Swiss Observational Cohort. Ruediger Mueller[1], Toni Kaegi[1], Axel Finckh[2] and Johannes von Kempis[1]. [1]MD, St. Gallen, Switzerland, [2]Geneva University Hospitals, Geneva 14, Switzerland

Background/Purpose: Rheumatoid arthritis (RA) is generally described as a disease with two peaks of onset, either late (late onset RA, LORA) or early (young onset RA, normal 30–55 years, YORA). Considering that the average age of the population is continuously rising, LORA will gain importance in the near future. Despite this growing importance LORA has not been the focus of much interest in the past. This study was set up to analyse disease activity and progression in LORA in comparison to YORA patients with early disease.

Methods: This is a cohort study within the Swiss RA registry SCQM. We included all patients with recent onset arthritis, either RA (disease duration ≤1 year) or undifferentiated, as diagnosed by the data-entering physician. Patients were followed up to 5 years. The cut off between YORA and LORA was operationally set at 60 years of age. Disease progression and activity was assessed based on DAS 28 and the progression of joint erosions using the Ratingen score.

Results: A total of 592 patients with early undifferentiated or RA was analysed. The age at disease onset had a Gaussian distribution, with a single peak at 60 years of age. 366 patients were 60 years or younger (YORA) and 226 patients were older (LORA) at disease onset. DAS 28

scores were significantly higher among LORA as compared to YORA patients (4.8 vs. 4.5, p = 0.049). Corticosteroids were used in 68% of LORA patients as a first line treatment, compared to 25.4% in YORA patients (X^2 test, p < 0.0001). DMARDs, on the other hand, were used in 100% of the YORA patients as first line treatment compared to 91.2% of the LORA patients. During follow up, new glucocorticoid, synthetic, or biologic DMARD were initiated in 32.8%/61.1%/14.1% of all decisions documented among YORA patients and 17.5%/54.6%/6.6% in LORA patients (X^2 test, all p < 0.0001). The DAS28 scores decreased in both groups over the observed time period, and the initial differences in disease activity vanished after 1/2 year and during the subsequent follow up. The Ratingen score was higher in LORA than in YORA patients at inclusion (12.7 vs. 5.6, p < 0.0001). The rate of radiological progression at 5 years was similar comparing LORA and YORA (3.3 vs. 2.6, resp., p=0.64). The level of Ratingen scores at onset and during follow up over 5 years did not clearly separate LORA and YORA into two groups), but rather increased linearly when comparing the patients in groups per decade from 20 to 92 years of age.

Conclusion: Our results do not support the existence of a separate LORA subgroup with a distinct peak of incidence and/or course of the disease.

Discontinuation of Adalimumab without Functional and Radiographic Damage Progression After Achieving Sustained Remission in Patients with Rheumatoid Arthritis (the HONOR study): 1-Year Results. Yoshiya Tanaka, Shintaro Hirata, Shunsuke Fukuyo, Masao Nawata, Satoshi Kubo, Kunihiro Yamaoka and Kazuyoshi Saito. University of Occupational and Environmental Health, Japan, Kitakyushu, Japan

Background/Purpose: Discontinuing anti-TNF therapy after achieving a stable low disease activity (LDA) or remission (REM) state in rheumatoid arthritis (RA) has become an important area of investigation in current rheumatology from the risk-benefit point of view including health-economic considerations. However, there is little information about characteristics of patients in which adalimumab (ADA) can be successfully discontinued in patients with long-standing RA. REM induction was aimed with ADA plus methotrexate (MTX) at patients with long-standing RA encountered during routine clinical practice. In the present HONOR study, we investigated whether the resultant remission was preserved for at least 12 months after discontinuing ADA.

Methods: Sustained REM was defined as persistent DAS28-ESR<2.6 achieved for at least 6 months. Patients with age >18 years who had attained the sustained REM with ADA plus MTX went on ADA discontinuation with their consent and those with follow-up of ≥12 months become subject to evaluation. The primary endpoint was a proportion of patients who maintained the sustained REM for at least another 12 months after the discontinuation. DAS28, SDAI, CDAI, HAQ-DI and DmTSS were analyzed before and after discontinuation of ADA. To predict retaining REM even after withdrawing ADA, a logistic regression/ROC analysis was conducted on clinical variables and cut-off values at the discontinuation were determined.

Results: Of the 197 patients who initiated ADA treatment between July 2008 and April 2011, 69 (35.0%) met the criteria of sustained REM. Fifty-one out of the 69 patients consented to enter the study. The mean age of the 51 patients was 59.5 years with the mean disease duration of 7.1 years. Thirty-six percent of evaluable 42 patients maintained ADA-free remission (DAS28-ESR<2.6) for 12 months. DAS28-ESR at discontinuation was found to be significantly predicting the retention of remission with a cut-off value of 1.98.

ADA-free remission as defined by SDAI ≤3.3 was also maintained for 12 months in 19 (49%) of the 42 patients. A vast majority of patients (94.9%) showed no evidence of radiographic progression at 12 months. Moreover, mean functional improvement observed at the time of ADA discontinuation was almost preserved for 12 months.

Conclusion: Although the sample size is limited, the results of the HONOR study indicated that after reaching REM with ADA plus MTX 36% (DAS28-ESR) and 49% (SDAI) patients could discontinue ADA for ≥12 months without functional impairment and radiographic damage progression. Deep remission at discontinuation was associated with successful biologic-free remission. Hence, "Treatment holiday" of biologics by discontinuing ADA is now feasible in patients with RA following sustained remission.

Tocilizumab Monotherapy Compared with Adalimumab Monotherapy in Patients with Rheumatoid Arthritis: Results of a 24-Week Study. Arthur Kavanaugh[1], Paul Emery[2], Ronald F. van Vollenhoven[3], Ara H. Dikranian[4], Rieke Alten[5], Micki Klearman[6], David Musselman[6], Sunil Agarwal[6], Jennifer Green[7] and Cem Gabay[8]. [1]UCSD School of Medicine, La Jolla, CA, [2]University of Leeds, Leeds, United Kingdom, [3]Karolinska Institute, Stockholm, Sweden, [4]San Diego Arthritis Medical Clinic, San Diego, CA, [5]Schlosspark Klinik, University Medicine Berlin, Berlin, Germany, [6]Genentech Inc, South San Francisco, CA, [7]Welwyn Garden City, United Kingdom, [8]Geneva University Hospitals, Geneva, Switzerland

Background/Purpose: Approximately one-third of RA pts treated with biologics receive them as monotherapy (ie, without other DMARDs).[1–3] Although tocilizumab (TCZ), an IL-6 receptor inhibitor, has been assessed as monotherapy in 6 trials,[4–9] direct comparison with an anti-TNF agent as monotherapy has not occurred. ADACTA is the first trial specifically designed to determine superiority of one approved biologic vs another (TCZ vs adalimumab [ADA]) as monotherapy for RA.

Methods: ADACTA was a phase 4 randomized, double-blind, 24-wk study in pts with RA of ≥6-mo duration and DAS28 >5.1 who were MTX intolerant or for whom continued treatment with MTX was considered ineffective or inappropriate. Pts received TCZ 8 mg/kg IV every 4 wks (+ placebo [PBO] ADA) or ADA 40 mg SC every 2 wks (+ PBO TCZ) for 24 wks. Primary endpoint was mean change from baseline (BL) in DAS28 at 24 wks.

Results: The ITT population included 325 pts (163, TCZ; 162, ADA). BL characteristics were similar between the TCZ and ADA arms: mean age (54.4 and 53.3 y), mean RA duration (7.3 and 6.3 y), and mean DAS28 (6.72 and 6.76). At wk 24, mean change from BL in DAS28 was significantly greater with TCZ than with ADA ($p<0.0001$; Table). Statistically significantly greater proportions of TCZ than ADA pts achieved DAS28 <2.6, DAS28 ≤3.2, and ACR20/50/70 responses ($p<0.005$; Table). A difference in favor of TCZ was observed in proportions of pts achieving Clinical Disease Activity (CDAI) and Simplified Disease Activity (SDAI) Index remission (≤2.8 and ≤3.3) at wk 24 (post hoc analysis; $p<0.05$; Table). From wk 16 onward, the proportion of pts achieving ACR/EULAR remission (Boolean: SJC ≤1, TJC ≤1, CRP ≤1 mg/dL, pt global VAS ≤10) was numerically greater with TCZ, and by wk 24 it reached 18% compared with 11% for ADA. For exploratory endpoints HAQ-DI, SF-36 MCS, SF-36 PCS, and FACIT Fatigue, differences in mean change from BL at wk 24 were numerically higher for TCZ than ADA. Incidences of AEs, serious AEs, and serious infection were similar between arms (TCZ, 82.1%/11.7%/3.1%; ADA, 82.7%/9.9%/3.1%). Transaminase and LDL elevations and neutrophil count reductions were more common with TCZ. Two deaths occurred in the TCZ arm: 1 due to sudden death, the other due to reported illicit drug overdose.

Table. Selected Endpoints at Week 24 (ITT population[a])

	TCZ, n = 163	ADA, n = 162	p[b]
Primary: change from BL in DAS28	−3.3[c]	−1.8 (diff:−1.5)	<0.0001
Secondary efficacy endpoints			
DAS28 <2.6, %	39.9	10.5	<0.0001
DAS28 ≤3.2, %	51.5	19.8	<0.0001
ACR20, %	65.0	49.4	0.0038
ACR50, %	47.2	27.8	0.0002
ACR70, %	32.5	17.9	0.0023
Exploratory and post hoc efficacy endpoints			
CDAI remission, %	17.2	9.3	0.0389[d]
SDAI remission, %	18.4	8.0	0.0067[d]
ACR/EULAR remission (Boolean), %	18.0	11.0	0.0569[d]
Change from BL in HAQ-DI	−0.7	−0.5 (diff:−0.2)	0.0653[d]

[a]Last-observation-carried-forward and nonresponder imputation were applied to primary and secondary continuous and categorical endpoints, respectively, to handle missing data and data after withdrawal and escape.
[b]p values were adjusted for region and duration of RA for all endpoints. In addition, when evaluating changes from baseline, p values were adjusted for baseline values of the analyzed parameter.
[c]Two pts in the TCZ arm with no post-baseline data were excluded from the primary endpoint analysis.
[d]p value was not adjusted for multiple testing and controlling of type 1 error; therefore, no statistical significance claims can be made.

Conclusion: TCZ as monotherapy was superior to ADA as monotherapy in reducing RA signs/symptoms in MTX-intolerant pts or pts for whom MTX was considered ineffective or inappropriate. The overall AE profiles of the two agents were similar, and lab changes were consistent with previous reports.

Remission Rates with Tofacitinib Treatment in Rheumatoid Arthritis: A Comparison of Various Remission Criteria.

J. S. Smolen[1], D. Aletaha[1], D. Gruben[2], J. D. Bradley[2], S. H. Zwillich[2], S. Krishnaswami[2], B. Benda[3] and C. Mebus[2]. [1]Medical University of Vienna, Vienna, Austria, [2]Pfizer Inc., Groton, CT, [3]Pfizer Inc., Collegeville, PA

Background/Purpose: Tofacitinib is a novel, oral Janus kinase inhibitor being investigated as a targeted immunomodulator and disease-modifying therapy for RA. This analysis evaluated the rates of remission across five tofacitinib Phase 3 RA trials based on various established and new remission criteria including the ACR/EULAR criteria.

Methods: We analyzed the data from five Phase 3 RA trials of tofacitinib monotherapy (ORAL Solo) or tofacitinib with background DMARD (ORAL Step, Scan, Sync and Standard) and compared remission rates as defined by various remission criteria: a) DAS28-4(ESR) <2.6 (co-primary endpoint in all five Phase 3 studies); b) DAS28-3(CRP) <2.6; c) CDAI ≤2.8; d) index-based ACR/EULAR criteria (SDAI ≤3.3); and e) Boolean-based ACR/EULAR criteria.[1] Remission rates were calculated under each set of criteria for each treatment sequence: tofacitinib 5 mg twice daily (BID), tofacitinib 10 mg BID, placebo (PBO) to 5 mg BID, and PBO to 10 mg BID; PBO sequences were pooled. ORAL Standard also included adalimumab 40 mg sc every 2 weeks as an active control. All trials had an initial PBO period of 3 or 6 months. Here, 3-month LOCF data are presented to illustrate results.

Results: Despite the short treatment duration, rates of remission were 5–30% with tofacitinib treatment (Table). Remission rates were numerically greater for both tofacitinib doses versus placebo, and rates for tofacitinib 10 mg BID were generally greater than with 5 mg BID. Across trials, the DAS28-3(CRP)-based criteria generated markedly higher remission rates compared with other remission criteria.

Table. Remission rates[a] across Phase 3 trials at Month 3

Phase 3 trial	Treatment (N)	DAS28-4(ESR) <2.6	DAS28-3(CRP) <2.6	CDAI ≤2.8	SDAI ≤3.3	Boolean ACR/EULAR
ORAL Solo	Tofacitinib 5 mg BID (241)	5.6	19.1	5.8	5.4	5.0
	Tofacitinib 10 mg BID (242)	9.0	24.8	8.3	9.1	7.4
	PBO (120)	4.5	6.7	1.7	1.7	1.7
ORAL Step	Tofacitinib 5 mg BID (132)	6.7	21.2	6.1	6.8	6.8
	Tofacitinib 10 mg BID (133)	10.4	27.8	7.5	9.0	5.3
	PBO (131)	1.7	4.6	0.8	0	0
ORAL Scan	Tofacitinib 5 mg BID (309)	5.3	21.4	5.8	5.8	4.5
	Tofacitinib 10 mg BID (309)	11.7	28.2	5.5	5.8	7.4
	PBO (154)	1.6	5.2	0	0	0
ORAL Sync	Tofacitinib 5 mg BID (311)	10.0	22.2	5.5	5.8	5.1
	Tofacitinib 10 mg BID (309)	11.2	25.6	7.1	7.1	5.8
	PBO (157)	1.4	5.1	0	0	1.3
ORAL Standard	Tofacitinib 5 mg BID (196)	5.6	15.3	4.6	4.1	2.0
	Tofacitinib 10 mg BID (196)	6.8	18.9	6.1	7.1	5.6
	Adalimumab 40 mg sc Q2W (199)	4.5	14.1	2.5	4.0	2.0
	PBO (106)	2.2	4.8	1.9	1.9	2.8

[a]Last observation carried forward; rates are percentages of patients achieving the respective outcome

Conclusion: Tofacitinib was effective in reaching treatment target[2–4] and inducing remission after 3 months of treatment using various established and new remission criteria including the ACR/EULAR index- and Boolean-based criteria. Remission rates were generally greater with tofacitinib 10 mg BID compared with 5 mg BID.

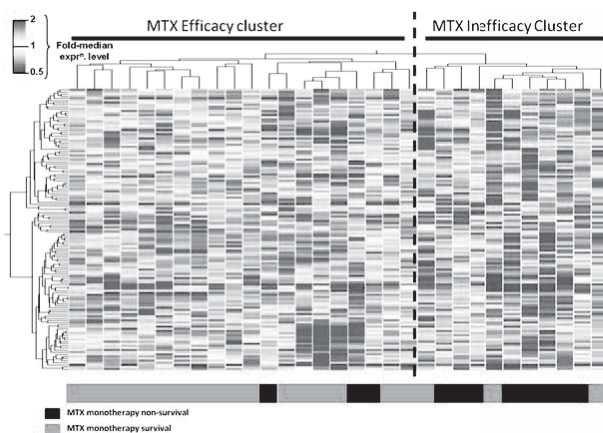
A CD4+ T-Cell Gene Expression Signature Predicts Drug Survival On Methotrexate Monotherapy in Early Rheumatoid Arthritis. Arthur G. Pratt[1], Philip M. Brown[1], Simon J. Cockell[2], Gillian Wilson[3] and John D. Isaacs[4]. [1]Newcastle University, Newcastle Upon Tyne, United Kingdom, [2]Newcastle University, Newcastle-upon-Tyne, United Kingdom, [3]Freeman Hospital, Newcastle-upon-Tyne, United Kingdom, [4]Musculoskeletal Research Group, Institute of Cellular Medicine, Newcastle University and Newcastle upon Tyne NHS Foundation Trust, Newcastle Upon Tyne, United Kingdom

Background/Purpose: The mechanism of action of methotrexate (MTX) in the management of rheumatoid arthritis (RA) remains incompletely understood. It is nonetheless capable of inducing clinical remission as a monotherapy in approximately 30% of cases, being the most cost-effective therapeutic choice in such individuals. We investigated the CD4+ T-cell transcriptome in early RA patients, seeking biomarkers for drug survival on MTX monotherapy and associated pharmacological insights.

Methods: RNA was extracted from highly purified peripheral blood CD4+ T-cells from consenting early RA patients within 4 hours of blood draw, at which time patients had been symptomatic for a median of 12 weeks, and were naïve to immunomodulatory treatments. All patients were subsequently treated with MTX monotherapy, which was continued for as long as this treatment was deemed successful between patient and consulting rheumatologist, over an 18 month follow-up period. Intramuscular steroid bolus administration (but not oral steroid therapy) was permitted during the study at the discretion of the consulting rheumatologist. Transcriptional profiling of baseline samples was undertaken using Illumina WG6v3 BeadChip oligonucleotide array technology and analysed using GeneSpring XI (Agilent).

Results: Of 37 recruited patients, 6 were excluded from analysis because of insufficient or defaulted follow-up. Amongst the remaining 31 patients, 19 (61%) remained on MTX monotherapy at the end of follow-up, but the treatment strategy was unsuccessful (and required modification) for the remaining 12 (39%). Baseline characteristics and final methotrexate doses were comparable between the two groups. 133 CD4+ T-cell transcripts were identified as being differentially expressed between comparator groups at baseline (>1.2 fold-change; p<0.05) and, amongst these, functional analysis identified an over-representation of genes involved in apoptosis (11/133 genes; hypergeometric p=0.000045).


Conclusion: Our pilot study has identified potential transcriptional biomarkers for drug survival on MTX monotherapy amongst early RA patients which, alongside their potential clinical applicability, suggest that the efficacy of this treatment may depend on its ability to regulate CD4+ T-cell survival pathways. Validation amongst a clinically well-characterised, independent early RA cohort is now on-going.

Long-Term Outcomes of Early Rheumatoid Arthritis Patients Initiated with Adalimumab Plus Methotrexate Compared with Methotrexate Alone Following a Targeted Treatment Approach. Roy Fleischmann[1], Ronald F. van Vollenhoven[2], Josef S. Smolen[3], Paul Emery[4], Stefan Florentinus[5], Suchitrita S. Rathmann[6], Hartmut Kupper[7] and Arthur Kavanaugh[8]. [1]University of Texas Southwestern Medical Center, Dallas, TX, [2]Karolinska Institute, Stockholm, Sweden, [3]Medical University of Vienna and Hietzing Hospital, Vienna, Austria, [4]Leeds Musculoskeletal Biomedical Research Unit, Leeds, United Kingdom, [5]Abbott, Rungis, France, [6]Abbott, Abbott Park, IL, [7]Abbott GmbH and Co. KG, Ludwigshafen, Germany, [8]UCSD School of Medicine, La Jolla, CA

Background/Purpose: In rheumatoid arthritis (RA), anti-TNF therapy is considered following 3–6 months of failed methotrexate (MTX) treatment. Some patients (pts), particularly those with many risk factors, may benefit from earlier intervention with anti-TNF+MTX, as this combination maximizes the likelihood of response. This analysis assessed, on a group level, whether there is a long-term advantage for early RA pts treated with initial and continued adalimumab (ADA)+MTX vs those treated with initial placebo (PBO)+MTX and who either continued unaltered therapy or rapidly added ADA following an inadequate response (IR).

Methods: OPTIMA was a 78-week (wk), phase 4, randomized, controlled trial of initial ADA+MTX vs PBO+MTX in MTX-naïve pts ≥18 years, <1 year disease duration, and active RA. Therapy adjustments were made at wk 26 on the basis of achieving a target of stable low disease activity [LDA, defined for this study as DAS28(CRP) <3.2] at wks 22 and 26 (Period 1, P1): ADA+MTX-responders (R) were re-randomized to either withdraw or continue ADA (ADA Withdrawal and Continuation arms, respectively) and PBO+MTX-R continued randomized therapy (MTX Continuation arm) for an additional 52 wks (P2); IR-pts received open-label (OL) ADA+MTX during P2 (OL ADA Carry On and Rescue ADA arms). This post hoc analysis evaluated the proportion of pts who entered P2 and were in LDA, had normal function (HAQ-DI <0.5), and/or the absence of radiographic progression (ΔmTSS ≤0.5) at wk 78 by initial treatment group (ie, the ADA+MTX group includes ADA Withdrawal, Continuation, and OL Carry On arms; the PBO+MTX group includes MTX Continuation and Rescue ADA arms). To account for the full population of P1 ADA+MTX-R, those who withdrew ADA during P2 were replaced by an equivalent proportion of R from the ADA Continuation arm.

Results: Among pts who entered P2 (ADA+MTX, N=466; PBO+MTX, N=460), significantly more were in LDA, had normal function, and/or the absence of radiographic progression following 26 wks of treatment with ADA+MTX vs PBO+MTX (**Table**). Differences in clinical and functional outcomes between initial treatment groups disappeared following an additional 26 or 52 wks of treatment, during which time PBO+MTX-IR (n=348) were switched to OL ADA+MTX. Although the addition of OL ADA to PBO+MTX-IR slowed radiographic progression during P2, more pts who received ADA+MTX from baseline had no radiographic progression at wk 78 than pts who received initial PBO+MTX.

Table. Week 26, 52, and 78 Clinical, Functional, and Radiographic Outcomes in Patients Who Received Continued ADA + MTX Versus Those Who Continued PBO + MTX or Added Open-label ADA Following an Inadequate Response

Outcome	ADA + MTX, n/N (%)[a]			PBO + MTX, n/N (%)[b]		
	Wk 26	Wk 52	Wk 78	Wk 26	Wk 52	Wk 78
DAS28(CRP) <3.2[c]	246/466 (53)	304/465 (65)	303/465 (65)	139/460 (30)***	284/460 (62)	300/460 (65)
HAQ-DI <0.5[c]	211/466 (45)	220/466 (47)	224/466 (48)	150/460 (33)***	203/460 (44)	208/460 (45)
ΔmTSS ≤0.5[d]	402/462 (87)	379/445 (86)	382/443 (86)	330/459 (72)***	318/440 (72)***	318/440 (72)***
DAS28(CRP) <3.2[c] + ΔmTSS ≤0.5[d]	216/462 (47)	260/443 (59)	266/443 (60)	112/459 (24)***	196/440 (45)	211/440 (48)***
DAS28(CRP) <3.2[c] + HAQ-DI <0.5[c] + ΔmTSS ≤0.5[d]	146/462 (32)	168/443 (38)	174/443 (39)	82/459 (18)***	120/440 (27)***	135/440 (31)**

[a]Includes patients from the ADA Continuation (n = 105) and OL ADA Carry On (n = 259) arms, as well as the proportional equivalent number of responders from the ADA Withdrawal arm (n = 102).
[b]Includes patients from the MTX Continuation (n = 112) and Rescue ADA (n = 348) arms.
[c]Last observation carried forward.
[d]Multiple imputations.
*** and ** for P <0.001 and <0.01, respectively, for differences between initial treatments from chi-square.
ADA, adalimumab; MTX, methotrexate; PBO, placebo; Wk, week; DAS28(CRP), 28-joint disease activity score with C-reactive protein; HAQ-DI, disability index of the health assessment questionnaire; ΔmTSS, change in modified Total Sharp score.

Conclusion: Early RA pts treated with PBO+MTX were able to achieve comparable long-term clinical and functional outcomes on a group level to those who began treatment with the combination of ADA+MTX, but only if therapy was optimized by the addition of ADA in PBO+MTX-IR. Still, continued ADA+MTX therapy conferred a radiographic benefit over 78 wks, although the difference did not appear to translate to an additional functional benefit.

A Multicenter, Randomized, Controlled, Open-Label Pilot Study of the Feasibility of Discontinuation of Adalimumab in Rheumatoid Arthritis Patients in Stable Clinical Remission. Katerina Chatzidionysiou[1], Carl Turesson[2], Annika Teleman[3], Ann Knight[4], Elisabet Lindqvist[5], Per Larsson[6], Lars Cöster[7], Barbro Rydberg[8], Ronald F. van Vollenhoven[9] and Mikael Heimbürger[10]. [1]Karolinska Institute, Stockholm, Sweden, [2]Lund University, Malmö, Sweden, [3]Department of Rheumatology, Spenshult Hospital, Oskarstrom, Sweden, [4]Institution for Medical Sciences, Uppsala University, Uppsala, Sweden, [5]Section for Rheumatology Lund University, Lund, Sweden, [6]Karolinska University Hospital, Stockholm, Sweden, [7]University Hospital, Linköping, Sweden, [8]Kärnsjukhuset, Skövde, Sweden, [9]The Karolinska Institute, Stockholm, Sweden, [10]Abbott Scandinavia, Stockholm, Sweden

Background/Purpose: Treatment with TNF blockers, once started as therapy for RA, is usually continued indefinitely. Information about the possibility to discontinue anti-TNF therapy in RA patients who have obtained remission is limited. If remission could be sustained after cessation of anti-TNF therapy, this would have vast clinical as well as economic implications. The objective of the ADMIRE trial was to assess the possibility of discontinuing adalimumab treatment while maintaining remission in RA patients in stable remission (DAS 28<2.6 for ≥3 months) on combination therapy with adalimumab + methotrexate (MTX).

Methods: A randomized, controlled, open label pilot study of RA patients in stable remission treated with adalimumab + MTX. Patients were randomized in a 1:1 ratio to continue with adalimumab + MTX (arm AM) or to discontinue the biologic agent and continue with MTX monotherapy (arm M) for 52 weeks. Flare was defined as DAS28>2.6 or an increase in DAS28 (DeltaDAS28) of more than 1.2 from baseline at any time. Patients in arm M with a flare restarted adalimumab. The primary endpoint was the proportion of patients in remission at week 28 in both arms. Nonresponder imputation (ie, "flare" imputed) was performed for patients with no available DAS28 at week 28 (this included most patients who had a flare in the M group and restarted adalimumab).

Results: Thirty-three patients were enrolled in the study and were randomized to arm AM (n=17) and arm M (n=16). One patient in arm AM was excluded (did not fulfill inclusion criteria) and one patient in arm M was excluded due to protocol violation. The median (IQR) age of patients was 61 (53–65) years, median (IQR) disease duration was 8 (5–15) years and 67% were female. Median (IQR) DAS28 was 1.86 (1.53–2.39) and MTX dose was 20 mg/w (12.5–20) at baseline. At the end of 28 weeks, 15/16 patients (94%) and 5/15 patients (33%) in arms AM and M, respectively, were in remission (P=0.001). In the M group, 3/15 patients were in remission on MTX only. The proportion of patients with a flare during the first 28 weeks in the AM and M arms was 50% (8/16) and 80% (12/15), respectively (P=0.08). The number of patients in the AM and M arms with at least one DeltaDAS28>1.2 during the first 28 weeks was 1/16 (6%) and 8/15 (53%), respectively (P=0.005). Other results from secondary analyses are shown in Table 1.

Table 1. Primary and secondary efficacy endpoints.

Outcome	Arm AM (adalimumab + MTX) n=16	Arm M (MTX) n=15	Difference between groups*
No. (%) of patients in remission at week 28	15/16 (94%)	5/15 (33%)	0.001
No. (%) of patients with at least 1 flare during first 28 weeks	8/16 (50%)	12/15 (80%)	0.08
No. (%) of patients with at least 1 DAS28>2.6 during first 28 weeks	8/16 (50%)	11/15 (73%)	0.2
No. (%) of patients with at least 1 DeltaDAS28>1.2 during first 28 weeks	1/16 (6%)	8/15 (53%)	0.005
No. (%) of patients with at least 1 DeltaDAS28>0.6 during first 28 weeks	8/16 (50%)	13/15 (87%)	0.04
No. (%) of patients with at least 1 DAS28>2.6 AND DeltaDAS28>1.2 during first 28 weeks	1/16 (6%)	7/15 (47%)	0.01
No. (%) of patients with at least 1 DAS28>2.6 AND DeltaDAS28>0.6 during first 28 weeks	5/16 (31%)	11/15 (73%)	0.02
Relapse-free survival (mean weeks)	22 (95%CI, 18–26)	16 (95%CI, 10–21)	0.05

*Fisher exact test for categorical variables; log-rank (Mantel-Cox) test for survival analysis.

Conclusion: In this pilot study, remission was rarely maintained in patients with long standing RA who discontinued adalimumab. Compared to patients who continued combination therapy, the proportion in sustained remission was significantly lower for the primary and most secondary endpoints. Adalimumab discontinuation may be feasible in only a minority of patients with established RA in stable clinical remission on adalimumab + MTX.

Effect of Certolizumab Pegol On Signs and Symptoms of Ankylosing Spondyltitis and Non-Radiographic Axial Spondyloarthritis: 24 Week Results of a Double Blind Randomized Placebo-Controlled Phase 3 Axial Spondyloarthritis Study. Robert B. M. Landewé[1], Martin Rudwaleit[2], Désirée van der Heijde[3], Maxime Dougados[4], Walter P. Maksymowych[5], Jurgen Braun[6], Atul A. Deodhar[7], Christian Stach[8], Bengt Hoepken[8], Geoffroy Coteur[9], Danuta Kielar[9], Andreas Fichtner[8], Terri Arledge[10] and Joachim Sieper[11]. [1]Academic Medical Center/University of Amsterdam & Atrium Medical Center, Amsterdam, Netherlands, [2]Endokrinologikum Berlin, Berlin, Germany, [3]Leiden University Medical Center, Leiden, Netherlands, [4]Paris-Descartes University, APHP, Cochin Hospital, Paris, France, [5]University of Alberta, Edmonton, AB, [6]Rheumazentrum Ruhrgebiet, Herne, Germany, [7]Oregon Health & Science University, Portland, OR, [8]UCB Pharma, Monheim am Rheim, Germany, [9]UCB Pharma, Brussels, Belgium, [10]UCB Pharma, Rtp, NC, [11]Charité Universitätesmedizin Berlin, Berlin, Germany

Background/Purpose: Axial spondyloarthritis (axSpA) includes both ankylosing spondylitis (AS) and non-radiographic axSpA (nr-axSpA), as defined by the ASAS criteria.[1] RAPID-axSpA (NCT01087762) is the first report of certolizumab pegol (CZP), a PEGylated Fc-free anti-TNF, in axSpA,

and the first randomized controlled trial of an anti-TNF to include the entire axSpA population.

Methods: The ongoing 158 week (wk) RAPID-axSpA trial is double-blind and placebo (PBO) controlled to Wk24, dose-blind to Wk48 and then open label to Wk158. Recruited patients (pts) had adult-onset active axSpA as defined by the ASAS criteria,[1] BASDAI ≥4, spinal pain ≥4 on a 10 point scale, CRP > upper limit of normal or sacroillitis on MRI. Pts must have failed ≥1 NSAID. Up to 40% of pts could have experienced secondary failure to 1 previous anti-TNF. The pt population reflected the broad axSpA population, including AS pts meeting the modified New York criteria and nr-axSpA pts who met the ASAS MRI or clinical criteria. Pts were randomized 1:1:1 to PBO, or 400mg CZP at Wk 0, 2 and 4 (loading dose, LD) followed by either 200mg CZP every 2 wks (Q2W) or 400mg CZP every 4 wks (Q4W). Pts receiving PBO who failed to achieve an ASAS20 response at both Wks 14 and 16 were rescued and randomized at Wk16 to receive CZP 200mg Q2W or CZP 400mg Q4W following LD. The primary endpoint was ASAS20 response at Wk12. Non-responder imputation was used for ASAS responses; last observation carried forward was used for BASFI, BASMI and BASDAI.

Results: 325 pts were randomized. Baseline (BL) characteristics were similar between treatment groups (PBO/CZP 200 mg Q2W/CZP 400 mg Q4W) with the exception of higher CRP concentrations, and greater proportion of anti-TNF experienced pts in the PBO group (25.4/17.4/21.2 mg/L; 24.3%/13.5%/10.3%, respectively). AS pts had longer disease and symptom duration at BL compared to nr-axSpA pts. Clinical improvements in ASAS20 responses at Wk12 were statistically significant in CZP 200 mg Q2W and CZP 400 mg Q4W arms vs PBO (Table) and were observed as early as Wk1 (40.5% and 34.6% vs 14.2%, p<0.001). ASAS40 response and ASAS partial remission rates were also higher in the CZP arms vs PBO. At Wks12 and 24, combined CZP arms showed statistically significant improvements vs PBO in BASDAI, BASFI, and BASMI. Similar improvements were reported with CZP vs PBO in both AS and nr-axSpA pts (Table). Adverse events (AEs) occurred in 70.4% vs 62.6%, serious AEs in 4.7% vs 4.7%, and serious infections in 1.1% vs 0 of CZP (combined dose) pts vs PBO pts, respectively. No deaths, TB or malignancies were reported.

Table. Clinical outcomes at Wk12 and Wk24 for axSpA pts in RAPID-axSpA

	AxSpA			AS			nr-axSpA		
Outcome	PBO n = 107	CZP 200mg Q2W n = 111	CZP 400mg Q4W n = 107	PBO n = 57	CZP 200mg Q2W n = 65	CZP 400mg Q4W n = 56	PBO n = 50	CZP 200mg Q2W n = 46	CZP 400mg Q4W n = 51
Week 12									
ASAS20	38.3%	57.7%*	63.6%*	36.8%	56.9%*	64.3%*	40.0%	58.7%	62.7%*

ASAS 5/6	4.7%	36.9%*	47.7%*	5.3%	33.8%*	46.4%*	4.1%	41.3%*	49.0%*
BASDAI CFB	−1.05	−3.08*	−3.01*	−1.13	−3.00*	−2.98*	−1.01	−3.27*	−3.16*
BASFI CFB	−0.40	−2.36*	−2.20*	−0.74	−2.36*	−2.29*	0.00	−2.40*	−2.07*
BASMI CFB	−0.07	−0.54*	−0.49*	−0.27	−0.62*	−0.56	0.14	−0.48*	−0.41*

*p < 0.05 vs PBO. CFB = change from baseline

Conclusion: CZP effectively and rapidly reduced the signs and symptoms of axSpA, including spinal mobility, with no new safety signals observed. Improvements were similar across CZP dosing regimens, and observed in both AS and nr-axSpA pts.

Spinal MRI Has Little Incremental Diagnostic Value Compared with MRI of the Sacroiliac Joints Alone in Early Spondyloarthritis.

Ulrich Weber[1], Veronika Zubler[1], Zheng Zhao[2], Robert GW Lambert[3], Stanley Chan[3], Susanne Juhl Pedersen[4], Mikkel Ostergaard[5] and Walter P. Maksymowych[3]. [1]Balgrist University Hospital, Zurich, Switzerland, [2]Department of Rheumatology, University of Alberta and PLA General Hospital, Beijing, PR China, Beijing, China, [3]University of Alberta, Edmonton, AB, [4]Glostrup Hospital, Copenhagen, Denmark, [5]Copenhagen University Hospital at Glostrup, Glostrup, Denmark

Background/Purpose: The definition of a positive MRI as major criterion in the Assessment of SpondyloArthritis classification criteria for axial spondyloarthritis (SpA) is based on MRI of the sacroiliac joints (SIJ) alone. It is not known whether additional MRI of the spine may enhance diagnostic certainty over and above SIJ MRI alone. We aimed to assess the incremental diagnostic value of spinal MRI evaluated both separately from and combined with SIJ MRI in early SpA compared to SIJ MRI alone.

Methods: The study sample comprised 2 independent cohorts A/B of 130 consecutive patients with back pain ≤50 years newly referred to 2 university clinics, and 20 healthy controls (HC), in whom both SIJ and spinal MRI were available. Patients were classified according to clinical examination and pelvic radiography as having non-radiographic SpA (nr-axSpA; n=50), ankylosing spondylitis (AS; n=33), or mechanical back pain (MBP; n=47). SIJ and spinal MRI were assessed by 3 blinded readers according to standardized modules. Readers recorded presence/absence of SpA and their level of confidence in this conclusion by global evaluation of the MRI scans on a 0–10 scale (0 = definitely not SpA; 10 = definite SpA). SIJ alone and spinal MRI alone were read independently 6 months apart, with another interval of 1–3 months to the combined assessment of both SIJ and spinal MRI (combined read). We analysed differences between SIJ alone versus spinal MRI alone, and SIJ alone versus combined read of SIJ and spinal MRI. This was done descriptively by the number/percentage of subjects recorded concordantly by any 2 readers for each group and for the 2 cohorts.

Results: For cohorts A and B, respectively, and for assessment of SIJ and spinal scans independently there were 0% and 16.1% of nr-axSpA patients who showed spinal lesions in the absence of SIJ lesions, while 15.8% and 19.4% of nr-axSpA patients considered having a negative SIJ MRI showed a positive spinal MRI according to global assessment. Low confidence (5–7) in a diagnosis of SpA by global evaluation of SIJ MRI increased to high confidence (8–10) by global evaluation of spinal MRI in only 0% and 3.2% of nr-axSpA patients in the 2 cohorts. For cohorts A and B, 5.3% and 3.2% of nr-axSpA patients considered negative for SpA by SIJ MRI scan alone were re-classified as being positive for SpA by global evaluation of combined SIJ and spinal scans. 57.1% and 30.3% of the MBP patients (cohort A/B) showed lesions only on spinal MRI. Up to 15.0% and 18.2% of all controls were considered as having SpA by spinal MRI scan alone, based on spinal BME in 60.9% and on fat infiltration in 26.1% of these subjects.

Number (percentage) of subjects as recorded concordantly by any 2 readers for comparisons of SIJ alone versus spinal MRI alone, and SIJ alone versus combined SIJ and spinal read

Cohort	Cohort A (n=62)				Cohort B (n=88)		
Group	nr-axSpA	AS	MBP	HC	nr-axSpA	AS	MBP
Number of subjects	19	9	14	20	31	24	33
Lesions SIJ-/Spine+	0 (0)	0 (0)	8 (57.1)	7 (35.0)	5 (16.1)	0 (0)	10 (30.3)
Global SIJ-/Spine+	3 (15.8)	0 (0)	1 (7.1)	3 (15.0)	6 (19.4)	0 (0)	6 (18.2)
Global SIJ-/Combination read+	1 (5.3)	0 (0)	0 (0)	0 (0)	1 (3.2)	0 (0)	0 (0)
Global Spine-/Combination read+	7 (36.8)	2 (22.2)	0 (0)	1 (5.0)	5 (16.1)	6 (25.0)	4 (12.1)

Conclusion: Spinal MRI adds little incremental value compared to SIJ MRI alone in terms of lesion detection and classification of early SpA patients.

Changes in Active Inflammatory Lesions Assessed by Magnetic Reso-nance Imaging: Results of the Infliximab As First Line Therapy in Patients with Early Active Axial Spondyloarthritis Trial. Joachim Sieper[1], Jan Lenaerts[2], Jürgen Wollenhaupt[3], Vadim Mazurov[4], L. Myasou-tova[5], Sung-Hwan Park[6], Yeong W. Song[7], Ruji Yao[8], Denesh Chitkara[8] and Nathan Vastesaeger[9]. [1]Charité, University Medicine Berlin, Berlin, Ger-many, [2]Reuma-instituut, Hasselt, Belgium, [3]Schön-Klinik, Hamburg, Ger-many, [4]St. Petersburg Medical Academy, St. Petersburg, Russia, [5]Kazan State Medical University, Kazan, Russia, [6]Catholic University of Korea, Seoul, South Korea, [7]Seoul National University, Seoul, South Korea, [8]Merck Sharp and Dohme, Kenilworth, NJ, [9]Merck Sharp and Dohme, Brussels, Belgium

Background/Purpose: Few studies have evaluated changes in active inflammation of spine and sacroiliac (SI) joints by MRI during long-term treatment for axial SpA, and no data are available comparing TNF-blockers with NSAIDs.

Objectives: To determine whether combination infliximab (IFX)+NSAID therapy is superior to NSAID monotherapy for improvement in inflammatory lesions in patients with early, active axial SpA who were naïve to NSAIDs or treated with a submaximal dose of NSAIDs and to measure changes in lesions during follow-up with either NPX or no treatment in patients who achieved ASAS partial remission.

Methods: Part I of the INFAST study was a double-blind, randomized controlled trial of IFX in biologic-naïve patients 18–48 years of age with early (<3 years symptom duration), active axial SpA with signs of active sacroiliitis on MRI. Patients were randomized (2:1) to receive 28 weeks of treatment with either IV IFX 5 mg/kg (weeks 0, 2, 6, 12, 18, and 24)+NPX 1000 mg/d or IV PBO+NPX 1000 mg/d. In Part II of INFAST, patients who had achieved ASAS partial remission at week 28 continued in Part II with no IFX treatment and were randomized (1:1 ratio) to continue on NPX or to stop NPX until week 52. MRIs of spine and SI joints at baseline, week 28, and week 52 were used to assess active, inflammatory lesions. Group differences were analyzed descriptively or using Fisher exact tests.

Results: ASAS partial remission at week 28, the primary outcome, was achieved by more patients treated with IFX+NPX (61.9%) than PBO+NPX (35.3%), $P=0.0021$. At week 52, similar percentages of patients in the NPX and no-treatment groups maintained partial remission (47.5 vs 40%). 88% of patients had readable MRIs showing active SI lesions at baseline; 59% had spine lesions. A change from presence at baseline to complete absence of lesions at week 28 occurred more often with IFX+NPX than PBO+NPX for the SI joint (21.9% vs 3.9%, $P=0.0043$) and spine plus SI joints (16.2% vs 0%, $P=0.0016$), but not for spine alone (29.5% vs 15.7%, $P=0.0764$). In Part II, no treatment group differences were observed on these measures. Scores from Part I and II are shown in Table 1 and Table 2, respectively.

Table 1. MRI Scores in Part I

Outcome	IFX+NPX (N=105)			PBO+NPX (N=51)		
	Baseline	Week 28	Change, Median (% Change)	Baseline	Week 28	Change, Median (% Change)
Berlin MRI spine score						
Mean	2.9	0.5		4.2	1.5	
Median	0.8	0.0	–0.5 (–66.7)	1.0	0.5	0.0
SI joint score						
Mean	5.6	1.3		6.6	3.0	
Median	4.0	0.5	–2.0 (–50.0)	6.5	2.5	–3.0 (–46.2)

Table 2. MRI Scores in Part II (Patients in ASAS Partial Remission at Week 28)

Outcome	NPX (N=40)			No Treatment (N=40)		
	Week 28	Week 52	Change, Median (% Change)	Week 28	Week 52	Change, Median (% Change)
Berlin MRI spine score						
Mean	0.3	1.2		1.0	3.2	
Median	0.0	0.0	0.0	0.0	1.0	0.0
SI joint score						
Mean	1.9	4.0		1.6	3.3	
Median	1.3	3.5	1.1 (90.0)	0.5	2.5	1.0 (200.0)

The safety profile was consistent with that of other anti-TNF biologics.

Conclusion: Patients with early, active axial SpA who were treated with IFX+NPX had greater MRI improvement and a greater percentage achieved MRI remission than patients treated with NPX alone. During follow-up, no differences were observed in MRI measures for patients who received NPX vs no treatment.

780

The Relationship of Inflammation, Fatty Degeneration and the Effect of Long-Term TNF-Blocker Treatment On the Development of New Bone Formation in Patients with Ankylosing Spondylitis. Xenofon Baraliakos[1], Frank Heldmann[2], Joachim Listing[3], Johanna Callhoff[3], Juergen Braun[1] and EASIC[4]. [1]Rheumazentrum Ruhrgebiet, Herne, Germany, [2]Rheumazentrum Ruhrgebiet, Herne, Ghana, [3]German Rheumatism Research Center, Berlin, Germany, [4]Herne, Germany

Background/Purpose: Clinical trial results suggest that new bone for-mation is neither inhibited nor augmented by anti-TNF agents in ankylosing spondylitis (AS). Recently, a potential role of different inflammatory lesions such as inflammation (INF) and fatty degeneration (FD) to predict new bone formation in patients with active AS was suggested. This is the first study to analyze the relationship between INF and FD as assessed by magnetic resonance imaging (MRI) and syndesmophyte formation as assessed by conventional radiography in vertebral edges (VE) of AS patients under long-term anti-TNF treatment.

Methods: Images were scored blinded for the time point of investigation of MRIs and x-rays of patients who participated in the EASIC Registry. Most patients were treated with infliximab. Presence or absence of INF, FD and syndesmophytes was documented on the level of VEs in the anterior part of the spine at each time point. Data were compared using Fisher′s exact test after adjustment for within-patient variation. Relative risk (RR) calculation based on a general linear model and Poisson variation.

Results: Complete sets of MRIs of 73 AS patients were evaluated at BL and 2y (1,526 VEs, 89 with and 1,437 without syndesmophytes or ankylosis at BL) and were related to complete sets of conventional radiographs of the same patients at BL, 2y and 5y. The amount of VEs with INF decreased significantly from 22.5% at BL to 1.5% after 2y, while in contrast, the amount of VEs with FD increased from 23.9% (n=364) at BL to 32.4% at 2y. In parallel, the VEs with syndesmophytes increased from 5.3% to 7.7% between BL and 2y. Overall, 35 and 60 new syndesmophytes developed after 2y and 5y, respectively, from VEs without baseline radiographic damage. The most frequent MRI pathology for syndesmophyte development at BL was the parallel occurrence of both MRI lesions, INF and FD: 22.9% and 16.7% at 2y and 5y, respectively. On the other hand, most of the new syndesmophytes (57.1% after 2y and 58.3% after 5y) seen on radiographs showed neither FD nor INF at BL. Syndesmophyte occurrence at baseline was the only significant predictor for development of these new syndesmophytes. The RR for syndesmophyte development was significant for the occurrence of the FD/INF combination at both follow-up time points, with a RR of 5.0 (p=0.002) after 2y and RR of 3.3 (p=0.009) after 5y, but only if FD lesions remained unchanged under anti-TNF treatment at 2y. On the other hand, no new syndesmophyte developed after 2y or 5y when INF was resolved. Importantly, we saw no new syndesmophyte developing after resolution of inflammation and evolution of new FD at the same VE.

Conclusion: Both spinal inflammation and fatty degeneration were associated with syndesmophyte development but fatty degeneration showed the highest risk for new syndesmophytes. However, >50% of the new bone formation observed in under anti-TNF treatment over 5 years was not preceded by either one of those. Overall, rather few syndesmophytes developed over 5 years in AS patients treated with anti-TNF. The sequence of INF – FD – new bone formation under anti-TNF was not seen at all. It seems that anti-TNF treatment has a more beneficial effect in the process of bone formation in patients with early (INF) but not late (FD) stages of the disease.

781

Ankylosing Spondylitis Is Associated with an Increased Risk of Osteoporotic Fractures: A Population-Based Cohort Study. Juan Muñoz-Ortego[1], Peter Vestergaard[2], Josep Blanch[3], Paul Wordsworth[4], Andrew Judge[5], M. Kassim Javaid[6], Nigel K. Arden[6], Cyrus Cooper[7], Adolfo Díez-Pérez[8] and Daniel Prieto-Alhambra[9]. [1]Hospital Sagrat Cor, Barcelona (Spain), Barcelona, Spain, [2]Aarhus University Hospital THG, Aarhus (Denmark), Aarhus, Denmark, [3]Hospital del Mar, Parc de Salut Mar, Barcelona, Spain, [4]Nuffield Orthopaedic Centre, Oxford, United Kingdom, [5]Oxford University, Oxford, United Kingdom, [6]Oxford NIHR Musculoskeletal Biomedical Research Unit, University of Oxford, Oxford, UK, Oxford, United Kingdom, [7]University of Oxford; Southampton General Hospital, Southampton, United Kingdom, [8]Hospital del Mar-IMIM, Universitat Autònoma de Barcelona, Barcelona; and RETICEF, ISCIII Madrid; Spain, Barcelona, Spain, [9]URFOA-IMIM, Parc de Salut Mar; Idiap Jordi Gol; University of Oxford; University of Southampton, Barcelona, Spain

Background/Purpose: Patients with Ankylosing Spondylitis (AS) have reduced bone mass, and altered biomechanics at the spine, but their fracture risk remains unclear. We have used a large population-based public health database to study the association between AS and incident fractures.

Methods: We screened the SIDIAP Database (www.sidiap.org) to identify those aged 15 years or older with a diagnosis of Ankylosing Spondylitis (ICD-10 M45), and ascertained incident osteoporotic (OP) fractures (any but skull, fingers and toes) in this population in the period 2006–2011. Five controls with no AS or other inflammatory arthritis were matched on gender, age and General Practitioner (GP). SIDIAP contains the anonymised medical records and pharmacy invoice data of a representative >4.9 million people (80% of the total population). Cox regression stratified on matched sets was used to estimate adjusted (body mass index, smoking, alcohol and oral corticosteroids) hazard ratios (HR) according to AS status. We tested for a priori defined interactions with age, gender, inflammatory bowel disease (IBD) and regular NSAID use.

Results: We identified 6,474 AS patients (0.14% of the population) and 32,346 controls and observed them for a median (inter-quartile range) of 5.98 (2.67–5.99) years. OP and clinical spine fracture rates were 9.64/1,000 person-years (8.52–10.90) and 2.12(1.63–2.76) among AS compared to 8.05 (95%CI 7.57–8.56) and 1.05(0.88–1.24) in controls respectively [Figure]. Adjusted HRs for OP and clinical spine fractures were 1.18 (95% CI 1.02–1.36; p=0.02) and 1.90 (1.37–2.63; p<0.001) respectively for AS patients. Further adjustment for oral corticosteroid use attenuated the association with OP fractures (HR 1.15 (0.99–1.32; p=0.06) but not with clinical spine fractures (HR 1.80 (1.30–2.51); p<0.001). No interactions were present with IBD. By contrast, there were relevant interactions with NSAID use (p=0.001) and gender (p=0.07) on OP fracture: adjusted HRs 1.20 (1.02–1.42; p=0.002) and 0.75 (0.55–1.02; p=0.07) for NSAID non-users VS users respectively [Figure]; and 1.01 (0.80–1.26; p=0.95) for females and 1.28 (1.08–1.53; p=0.006) for males. Similar interactions were found for NSAID use and age on clinical spine fractures (p=0.02 and p=0.03 respectively) [Figure].
Figure.

Conclusion: Patients with AS are at 18% higher risk of osteoporotic fracture related to use of oral corticosteroids, and at almost double risk of clinical spine fractures, independently of oral corticosteroids. The excess risk associated with AS is biggest in younger males who do not take oral NSAIDs regularly.

782

Anti-TNF Therapy Slows Radiographic Progression of Ankylosing Spondylitis. Nigil Haroon[1], Robert D. Inman[2], Thomas J. Learch[3], Michael H. Weisman[4], Michael M. Ward[5], John D. Reveille[6] and Lianne S. Gensler[7]. [1]University Health Network, Toronto Western Research Institute, University of Toronto, Toronto, ON, [2]Toronto Western Research Institute, University Health Network and University of Toronto, Toronto, ON, [3]Cedars-Sinai, Los Angeles, CA, [4]Cedars-Sinai Medical Center, Los Angeles, CA, [5]NIAMS/NIH, Bethesda, MD, [6]Univ of Texas Health Science Center at Houston, Houston, TX, [7]UCSF, San Francisco, CA

Background/Purpose: The influence of anti-TNF therapy on radiographic progression in ankylosing spondylitis (AS) is not well established. We studied this effect on radiographic progression in AS patients.

Methods: Three-hundred-and-seventy-six patients were included with at least 2 sets of radiograph at least 1.5 years apart (range 1.5 to 9 years) from a multicenter longitudinal cohort of 1600 AS patients. Patients with total spinal ankylosis at baseline were excluded. Patients were assessed at least annually on a protocol format. Time-averaged BASDAI, ESR and CRP, NSAID and anti-TNF indices were calculated. Full recommended dose of NSAID/anti-TNF taken for the entire period between x-rays were assigned a score of 100. Total anti-TNF exposure was calculated from the anti-TNF index and the years of exposure. Patients with mSASSS increase at a rate of $\geq$ 1 unit/year were considered progressors. T-test, Chi-square and logistic regression were performed. For multivariate analysis, variables were selected from those that were significant in the univariate analysis. Variables were separated in different models based on the correlation matrix.

Results: The mean age of patients was 40.8 $\pm$ 13.8 years (75% males and 92% HLA-B27 positive) and the mean disease duration was 16.5 $\pm$ 12.9 years. Among patients enrolled, 60% had never smoked and 17% stopped smoking in the period between radiographs. No baseline radiographic abnormality was seen in 44% patients and 35% showed progression $\geq$ 1 mSASSS unit/year.

In the univariate analysis, males progressed faster (1.2 vs 0.8 mSASSS unit/year) with an odds ratio (OR) of 1.9 (95% CI: 1.09–3.39; p=0.02). Smokers had an odds of progression of 1.6 (95% CI: 1.02–2.54; p=0.04). Other significant variables included age of onset, baseline and time-averaged CRP and ESR and cumulative dose of anti-TNF received (Table 1A). The NSAID index was not significant in the univariate analysis. In multivariate analysis (Table 1B), the following variables remained significant: Gender (β=3.7;p=0.003), baseline ESR (β=1.03;p=0.001), baseline mSASSS (β=1.05;p=2 $\times$ 10^{-5}) and cumulative anti-TNF exposure (β=0.99;p=0.006). To estimate the effect with any exposure to biologics, cumulative anti-TNF exposure was substituted with the dichotomous variable: history of anti-TNF exposure. Anti-TNF use was protective against progression with an OR of 0.4 (p=0.006). The other variables remained significant as in the previous model.

Table 1A. Univariate and Multivariate Regression Analysis for radiographic progression

A. Univariate Regression

Covariate	p value	Odds Ratio	Confidence Interval
Male Gender	0.02	1.93	1.10–3.39
Age of Onset	0.004	1.03	1.01–1.06
Disease Duration	2 $\times$ 10-5	1.04	1.02–1.06
Smoking History	0.04	1.61	1.02–2.54
Baseline CRP	0.004	1.03	1.01–1.05
Time-Averaged CRP	0.002	1.05	1.02–1.08
Baseline ESR	0.0001	1.03	1.01–1.04
Time-Averaged ESR	0.006	1.02	1.01–1.04
Baseline mSASSS	1 $\times$ 10-11	1.07	1.05–1.09
Total Biologic Exposure	0.04	0.99	0.99–1.00

Table 1B. Univariate Regression

Model 1

Variables included: Gender, Disease Duration, Baseline ESR, Baseline mSASSS & Total Anti-TNF Exposure

Male Gender	0.003	3.70	1.57–8.70
Baseline ESR	0.001	1.03	1.01–1.04
Baseline mSASSS	2×10^{-5}	1.05	1.03–1.08
Total Anti-TNF Exposure	0.006	0.998	0.997–0.999

Model 2

Variables included: Gender, Age of Onset, Baseline ESR, Baseline mSASSS & Total Anti-TNF Exposure

Male Gender	0.01	2.7	1.3–5.9
Baseline ESR	0.0004	1.03	1.01–1.04
Baseline mSASSS	1×10^{-8}	1.06	1.040–1.09
Total Anti-TNF Exposure	0.04	0.99	0.99–1.000

Model 3

Variables included: Gender, Disease Duration, Baseline ESR, Baseline mSASSS & Anti-TNF (Y/N)

Male Gender	0.01	2.6	1.2–5.4
Baseline ESR	5×10^{-5}	1.03	1.01–1.04
Baseline mSASSS	3×10^{-9}	1.07	1.04–1.09
Anti-TNF Use (Yes/No)	0.006	0.44	0.24–0.79

Age of onset and Disease duration were strongly correlated in the matrix (R=0.98) and so they were included in separate models. Only one inflammatory parameter (Baseline ESR) was used for the same reason. Model 3 was used to calculate the Odds of progression in patients who took anti-TNF at some time compared to those with no exposure.

Conclusion: Inflammation is associated with radiographic progression. Anti-TNF therapy slows the rate of radiographic progression in AS.

ACR Concurrent Abstract Session
Systemic Sclerosis, Fibrosing Syndromes and Raynaud's – Pathogenesis, Animal Models and Genetics
Sunday, November 11, 2012, 2:30 PM–4:00 PM

783

The Wnt Inhibitors DKK1 and SFRP1 Are Downregulated by Promoter Hypermethylation in Systemic Sclerosis. Clara Dees[1], Inga Schlottmann[1], Robin Funke[1], Alfiya Distler[1], Katrin Palumbo-Zerr[2], Pawel Zerr[2], Oliver Distler[3], Georg A. Schett[2] and Joerg HW Distler[2]. [1]Department of Internal Medicine 3 and Institute for Clinical Immunology, University of Erlangen-Nuremberg, Erlangen, Germany, [2]Department of Internal Medicine III and Institute for Clinical Immunology, University of Erlangen-Nuremberg, Erlangen, Germany, [3]University Hospital Zurich, Zurich, Switzerland

Background/Purpose: Tissue fibrosis caused by pathological activation of fibroblasts is a major hallmark of systemic sclerosis (SSc). Epigenetic gene silencing of anti-fibrotic genes such as FLI1 by DNA methylation has been implicated in the pathogenesis of SSc. Also increased activation of the Wnt pathway with decreased expression of endogenous inhibitors has recently been shown to play a prominent role in tissue fibrosis in SSc. However, the molecular mechanisms leading to the decreased expression of Wnt inhibitors is incompletely understood. In the present study, we evaluated whether the expression of endogenous Wnt inhibitors might be silenced through DNA methylation.

Methods: The methylation status of endogenous Wnt inhibitors in leukocytes and fibroblasts was evaluated by methylation-specific PCR. Gene expression in fibroblasts and human skin was analyzed by real-time PCR and immunohistochemistry. The expression of endogenous Wnt inhibitors was also evaluated in the mouse model of bleomycin-induced dermal fibrosis. 5-aza-2-deoxycytidine (5-aza) was used to inhibit DNA methyltransferases (Dnmts) in cultured fibroblasts and mice.

Results: Significant hypermethylation of the promoters of DKK1 and SFRP1 was observed in leukocytes isolated from blood samples of SSc patients. Increased methylation in the promoter region of DKK1 and SFRP1 was also found in cultured fibroblasts from SSc patients. This hypermethylation resulted in decreased gene transcription by 56 ± 5 % for DKK1 and by 89 ± 3 % for SFRP1 (p < 0.05 for both) compared to fibroblasts from healthy

subjects. Of note, treatment with 5-aza re-activated the transcription of SFRP1 in SSc fibroblasts from 11 ± 3 % to 52 ± 16 % of control levels and the expression of DKK1 was completely reversed to control levels (p < 0.05 each). Consistent with the reduced mRNA levels, the protein levels of both DKK1 and SFRP1 were severely decreased in skin of SSc patients as analyzed by immunohistochemistry. In addition, decreased expression of DKK1 and SFRP1 was also found in experimental fibrosis. In the model of bleomycin-induced dermal fibrosis, the mRNA levels of DKK1 decreased by 73 ± 5 % (p = 0.036) upon bleomycin challenge and those of SFRP1 by 35 ± 3 % (p = 0.004). Both genes were re-activated by treatment of bleomycin-challenged mice with 5-aza. Compared to untreated mice injected with bleomycin, the mRNA levels increased upon treatment with 5-aza by 504 ± 42 % (p = 0.024) for DKK1 and by 131 ± 23 % (p = 0.015) for SFRP1. Similar results were obtained for protein levels. Consistently, 5-aza significantly reduced bleomycin-induced dermal fibrosis with decreased dermal thickening and reductions in hydroxyproline content and myofibro-blast counts.

Conclusion: We demonstrate that the endogenous Wnt inhibitors DKK1 and SFRP1 are downregulated by promoter hypermethylation in SSc. Inhibition of Dnmts by 5-aza re-activated gene expression in SSc fibroblasts and in experimental fibrosis. As different inhibitors of Dnmts are already approved for other diseases and are well tolerated, our findings might have direct translational implications and provide a novel approach to inhibit Wnt signaling in SSc.

784

Neutralization of Plasminogen Activator Inhibitor-1 Resolves Skin Fibrosis and Vascular Injury in a Murine Model of Human Scleroderma. Raphael Lemaire[1], Tim Burwell[1], Tracy Delaney[1], Cindy Chen[1], Julie Bakken[1], Lily Cheng[1], Philip Brohawn[1], Isabelle de Mendez[2], Dominic Corkill[2], Anthony Coyle[3], Ronald Herbst[1] and Jane Connor[1]. [1]MedImmune LLC, Gaithersburg, MD, [2]Medimmune, LLC, Cambridge, England, [3]Pfizer, Inc., Cambridge (formerly at MedImmune LLC, Gaithersburg, MD, USA)

Background/Purpose: Scleroderma is a systemic autoimmune disease in which thrombosis and fibrosis contribute to skin pathology. Plasminogen activator inhibitor-1 (PAI-1) is the major inhibitor of pro-fibrinolytic plasminogen activators uPA and tPA and its expression has been shown to be increased in the skin of scleroderma patients. The purpose of this study was to evaluate the contribution of PAI-1 inhibition of PAs to pathological changes in the skin in an animal model that recapitulates both the fibrosis and occlusive vasculopathy of human scleroderma.

Methods: B10D2 splenocytes were injected into BALB/c Rag-2$-/-$ mice resulting in a model of graft-vs-host disease-induced skin fibrosis (GVHD). A monoclonal antibody that selectively prevents the binding of PAI-1 to its target PAs was administered ip two times per week beginning either at time of engraftment or at week 3 post-engraftment. Effect of PAI-1 neutralization was assessed on clinical skin score, gene expression and histological changes in the skin. In addition, the effect of blocking PAI-1 on MMP-1 activation was evaluated in vitro in human dermal microvascular endothelial cells (HMVECs).

Results: In this model fibrosis peaks at week 6 post-graft, following the inflammation peak at week 4. PAI-1 expression is increased in the skin beginning at week
2. Prophylactic neutralization of PAI-1 significantly reduced the clinical skin score in a dose-dependent manner as early as week 2 post-graft. Clinical benefits were associated with normalization of fibrinolysis genes (plasmin, PAI-1- uPA, uPAR, KLK6) and this correlated with resolution of vascular injury markers (VCAM-1, MMP-12), T cell infiltration and TNF-α levels in skin, as assessed over the inflammatory phase of the disease (week 1–4). Administration of the antibody in a therapeutic regimen also resulted in significant reduction of the clinical skin score. Clinical benefits were associated with normalization of fibrinolysis along with resolution of skin fibrosis over the chronic phase of the disease (week 4–6) as shown by reduction of dermal thickness and extracellular collagen which correlated with reduction of expression of pro-fibrotic cytokines (TGF-β, IL-13) and matrix turnover regulators (TIMP-1). The matrix turnover component of PAI-1 inhibition was

further supported where neutralization of PAI-1 in cultured dermal HMVECs decreased MMP-1 activation in a concentration-dependent manner.

Conclusion: These data suggest that PAI-1 plays a key role in both the skin vasculopathy and fibrosis observed in this murine model of human scleroderma and that inhibition of the binding of PAI-1 to PAs resolves fibrosis via two distinct plasmin-based mechanisms: (1) directly via reducing MMP activation and (2) indirectly via reducing infiltration of profibrotic cytokine-secreting inflammatory cells following thrombolysis-based resolution of vascular injury and activation.

785

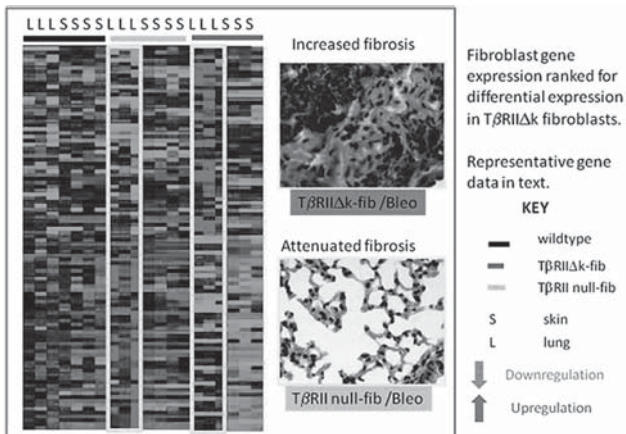
Resident Lung Fibroblast Gene Expression Signatures Predict Susceptibility or Resistance to Experimental Lung Fibrosis. Emma Derrett-Smith[1], Rachel Hoyles[1], Korsa Khan[1], David J. Abraham[1] and Christopher P. Denton[2]. [1]UCL Medical School, London, United Kingdom, [2]UCL, London, United Kingdom

Background/Purpose: In scleroderma (SSc), lung fibrosis is linked to epithelial damage and dysregulated repair mechanisms. Resident lung fibroblasts may affect multiple cell types including epithelium, endothelium, smooth muscle cells and fibrocytes. We have used two complementary transgenic mouse strains with altered TGFβ signalling to better understand the regulatory role of resident lung fibroblasts in defining susceptibility to fibrosis.

Methods: The TβRIIΔk-fib mouse model of SSc, in which TGFβ signalling is upregulated in fibroblasts, is susceptible to fibrotic lung injury whereas the TβRII-null-fib strain, in which TβRII is conditionally knocked out in fibroblasts, is resistant to bleomycin-induced lung fibrosis. We have used an illumina® microarray platform to profile lung or skin fibroblasts from these two strains and identified a cohort of genes that determine susceptibility or resistance to experimental lung fibrosis, comparing to a control group using whole lung from TβRIIΔk-fib animals and wildtype littermates (n=3) on the same microarray platform. Technical validation of data and additional quantitation of gene expression was performed using quantitative RT-PCR assays with replicate samples.

Results: The TβRIIΔk-fib lung fibroblast gene expression signature includes key genes that are implicated as pathogenic drivers of fibrosis and inflammation and potential biomarkers in SSc. Conversely, many of these genes are downregulated in TβRII-null-fib mice (figure 1), including BMP4 (fold reduction in TβRII-null-fib 31.8, p<0.02; fold upregulation in TβRIIΔk-fib compared with WT 2.01, p<0.6); elastin (TβRII-null-fib 17.8, p<0.14; TbRIIΔk-fib 1.86, p<0.09); CCL2 (TβRII-null-fib 56.8, p<0.09; TβRIIΔk-fib 1.72, p<0.03)and MMP13 (TβRII-null-fib 13.2, p<0.08; TβRIIΔk-fib 3.6, p<0.4). CTGF (CCN2) was strongly upregulated in TβRIIΔk-fib lung fibroblasts, but showed less downregulation than other genes in the TβRII-null-fib, probably reflecting multiple pathways of activation. No signature of overexpression was present in the whole lung analysis suggesting that fibroblast-specific differences in gene expression determine altered fibrotic response.

Fibroblast gene expression ranked for differential expression in TβRIIΔk fibroblasts.

Representative gene data in text.


Conclusion: These data define a cohort of genes differentially expressed in fibroblasts that associate strongly with susceptibility or resistance to experimental lung fibrosis. These transcripts include many that are important

in tissue repair and that have previously been shown to be over expressed in SSc skin samples. They suggest that resident fibroblast gene expression signature may govern fibrosis in lung and skin.

Crosstalk Between Integrins and TGFβ in the Pathogenesis and Treatment of Multiple Presentations of Scleroderma Elizabeth E. Gerber[1], Fredrick M. Wigley[2], Elaine C. Davis[3], David L. Huso[1] and Harry C. Dietz[1]. [1]Johns Hopkins University School of Medicine, Baltimore, MD, [2]Johns Hopkins University, Baltimore, MD, [3]McGill University, Montreal, QC

Background/Purpose: Scleroderma, defined as pathologic fibrosis of the skin, has many clinical presentations. In the most commonly recognized form, systemic sclerosis (SSc), previously healthy individuals acquire fibrosis of the skin and viscera associated with autoantibodies. Although a genetic contribution to SSc has been established, familial recurrence is rare and causal genes have not been found. The study of SSc is hindered by a lack of animal models that faithfully recapitulate this complex disease. In contrast, a rare disorder, stiff skin syndrome (SSS), shows childhood onset of diffuse skin fibrosis with autosomal dominant inheritance and no visceral fibrosis or autoimmunity. Both disorders have been linked to TGFβ. SSS is caused by heterozygous missense mutations in the gene encoding fibrillin-1, a major constituent of extracellular microfibrils. SSS mutations localize to the only domain that harbors an Arg-Gly-Asp motif that mediates cell-matrix interaction by integrin-binding.

Methods: Two SSS mouse models were generated by homologous recombination and either bred to $Itgb3+/-$ mice or treated with antibodies by IP injection. Primary human dermal fibroblast cultures were derived from forearm biopsies and stimulated with 2 ng/mL TGFβ1. Analyses included skin stiffness scoring, histology, flow cytometry, Western and Northern blotting, and qPCR. Data are shown as standard boxplots (R statistical software) and analyzed with 2-tailed t tests.

Results: Knock-in mutations in $Fbn1$ in mice that either reproduce a naturally-occurring SSS mutation ($Fbn1^{W1572C/+}$) or impose an obligate loss of integrin binding ($Fbn1^{D1545E/+}$), are sufficient to initiate and maintain dermal fibrosis. This associates with upregulation of surface expression of β1 and αvβ3 integrins by dermal cells. Treatment with β1 integrin activating (β1aAb) for 12 weeks reduces active αvβ3 in the dermis and prevents stiffness and skin fibrosis (Fig.1). Notably, genetic ablation of integrin β3 also prevents the phenotype and TGFβ antagonism, commenced at a later age, completely reverses it. In vitro, SSc patient cells also show aberrant integrin expression and function that contributes to a fundamental change in the signaling properties of ligand-activated TGFβ receptors, favoring activation of extracellular-regulated kinase (ERK). Integrin- or ERK-modulating treatments normalized the pro-fibrotic repertoire in SSc cells, increasing levels of matrix-inhibiting microRNA-29, and reducing both ERK activation and collagen expression (Fig.2).

Conclusion: This work demonstrates the potential to reverse established dermal fibrosis in a model of human disease and shows that despite the phenotypic differences between SSS and SSc, study of SSS animal models has offered a pathogenic sequence for scleroderma that suggests therapies for SSc, including β1 integrin activation and blockade of β3 integrin, TGFβ or ERK signaling.

Aberrant Adipogenesis in the Pathogenesis of Scleroderma. Roberta Goncalves Marangoni, Jun Wei, Monique E. Hinchcliff, Feng Fang, Warren Tourtellotte and John Varga. Northwestern University Medical School, Chicago, IL

Background/Purpose: Skin fibrosis in systemic sclerosis (SSc) is associated with loss of subcutaneous adipose tissue (SCAT) and reduction in adiponectin. The mechanism underlying SCAT atrophy and its significance in pathogenesis are not known. In light of emerging insights into adipogenesis and the plasticity of adipogenic progenitor cells, we investigated the mechanistic basis of adipose atrophy and its relation to fibrosis in the skin.

Methods: The kinetics of SCAT loss was investigated in mouse models of dermal fibrosis. Transgenic mice were used for adipocyte lineage tracing. Modulation of adipogenic differentiation was evaluated in mouse and human stem cells and skin fibroblasts by real-time qPCR, immunoblotting, cytochemistry, and DNA microarrays.

Results: Skin biopsies from a cohort of well characterized patients with diffuse cutaneous SSc showed variable but consistent SCAT atrophy. Moreover, striking loss of SCAT was observed in mouse models of scleroderma induced by bleomycin. Careful time-course studies demonstrated that loss of SCAT preceded the onset of dermal fibrosis. Furthermore, loss of adipogenic markers preceded the increase in fibrogenic markers in the lesional skin. These observations suggest that adipogenic progenitor cell differentiation was redirected towards fibrogenic fates. Indeed, TGF-beta was able to preferentially promote fibrogenic differentiation of mouse 3T3L1 preadipocytes in vitro. Remarkably, the tyrosine kinase abl prevented adipogenesis, which was rescued by the putative antifibrotic drug imatinib. Moreover, in normal skin fibroblasts imatinib caused dramatic induction of adipogenic genes. The potential significance of preadipocyte-fibroblast transitions in fibrogenesis is directly addressed by fate-mapping studies using adipocyte-labeled transgenic reporter mice.

Conclusion: Our studies indicate that SCAT atrophy is consistently associated with human and mouse scleroderma, and appears to precede the onset of dermal fibrosis. Cellular adipocyte/fibroblast plasticity, readily induced in vitro and manipulated by imatinib, may directly contribute to fibrogenesis. We conclude that loss of SCAT might be a primary event in the pathogenesis of SSc, and adipogenic progenitor cell differentiation may be a potential target of therapeutic manipulation.

Tenofovir, a Potent Anti-Viral Agent, Is an Ecto-5'Nucleotidase (CD73) Inhibitor That Prevents Dermal Fibrosis in a Murine Model of Scleroderma. Jessica L. Feig[1], Doreen Tivon[1], Miguel Perez-Aso[1], Timothy Cardozo[1] and Bruce N. Cronstein[2]. [1]New York University School of Medicine, New York, NY, [2]NYU School of Medicine, Division of Rheumatology, New York, NY

Background/Purpose: Acyclic nucleoside phosphonates are a key class of antivirals commonly used in the treatment of both DNA and retroviral infections. Adefovir and tenofovir are AMP analogues that resemble substrates of CD73. We have previously reported that adenosine, generated by the CD73-mediated dephosphorylation of AMP, acting at A_{2A} receptors, plays a critical role in development of both hepatic and dermal fibrosis in murine models of cirrhosis and scleroderma, respectively. A recent clinical trial demonstrated that tenofovir, but not other antiviral agents, reverses hepatic fibrosis/cirrhosis in patients with hepatitis B. We therefore proposed the hypothesis that tenofovir's antifibrotic effects are mediated by inhibition of adenosine production by CD73-mediated dephosphorylation of AMP.

Methods: In silico modeling and docking studies were performed using an ICM-Browser downloaded from www.molsoft.com. Active site docking with an energy score of less than -32 kcal/mol was considered favorable. CD73 enzyme activity was quantitated by malachite green using 75–100 uM AMP substrate with CD73 transfected 293T cells or recombinant human enzyme. Bleomycin (0.25 U, SubQ)-treated mice were treated with vehicle or Tenofovir (75mg/kg, IP) [n=5 per group]. Skin breaking strength was measured using a tensiometer. Histologic samples of H&E or picrosirus red-stained slides were imaged, and pixel quantification was performed with SigmaScan software. Scar index was determined as the ratio of red/green pixels representing compact/filamentous fibers; higher numbers indicate more fibrosis. Dermal hydroxyproline content was quantified by colorimetric assay.

Results: In silico modeling data suggested that both adefovir and tenofovir bound to the enzymatic pocket of CD73. Tenofovir, but not adefovir, inhibited CD73 activity of 293T cells overexpressing CD73 (38+7.4%, at 10 uM) and of recombinant enzyme (72+1.0%, at 10uM). Tenofovir (75mg/kg) diminished bleomycin-induced dermal fibrosis in bleomycin-treated mice (73.7+3.1% reduction of hydroxyproline content

[p<0.05]; 33.5+3.8% reduction of dermal thickness [p<0.06] and reduction of breaking tension by 66.8+1.4% [p<0.05]). Picrosirius red staining showed dramatic altering of collagen quality (scar index of 1.2+0.1 vs 22.2+0.7 [p<0.001], normal skin is 2.5).

Conclusion: These results provide strong support to the hypothesis that Tenofovir reduces fibrosis via inhibition of adenosine production from AMP by CD73. Moreover, these results suggest that tenofovir may have therapeutic potential in treating fibrosis in patients suffering from non-viral fibrosing diseases such as scleroderma.

Foot Disorders Associated with Over-Pronated and Over-Supinated Foot Types: The Johnston County Osteoarthritis Project. Yvonne M. Golightly[1], Marian T. Hannan[2], Alyssa B. Dufour[3], Howard J. Hillstrom[4] and Joanne M. Jordan[5]. [1]University of North Carolina, Chapel Hill, NC, [2]Hebrew SeniorLife & Harvard Med Sch, Boston, MA, [3]Hebrew Senior-Life & Boston Univ, Boston, MA, [4]Hospital Special Surgery (HSS), New York, NY, [5]University of North Carolina Thurston Arthritis Research Center, Chapel Hill, NC

Background/Purpose: Based on clinical observations, musculoskeletal foot disorders, such as hallux valgus or plantar fasciitis, appear to occur more frequently in a pronated foot type. Other disorders, like hammer toes or Tailor's bunions, may occur more often in a supinated (high arch) foot type. The purpose of this cross-sectional analysis was to determine whether specific foot disorders were associated with over-pronated and over-supinated foot types in a large, biracial community-based cohort of men and women 50 years of age or older.

Methods: Of 1,695 Johnston County Osteoarthritis Project participants clinically evaluated for foot disorders in 2006–2010, complete foot pressure data were available for 1,466 (1,425 with bilateral and 41 with unilateral foot data; mean age 68.5 years, mean body mass index [BMI] 31.2 kg/m^2, 67.2% women, 29.5% African American). Two trained examiners used the validated Foot Assessment Clinical Tool to determine the presence or absence of foot disorders. Foot pressure scans were recorded for both feet as participants walked at a normal pace over a Tekscan Matscan system (Tekscan Inc., Boston, MA). The center of pressure excursion index (CPEI) was calculated for each foot. CPEI cutoff values were set a priori to create a 3-category foot type variable: over-pronated (≤ 7.3), over-supinated (≥ 21.0), and neutral (> 7.3 to < 21.0; referent). With the foot as the unit of analysis, separate multivariate logistic regression models using generalized estimating equations were performed to examine the association between foot type and each foot disorder, adjusting for age, BMI, gender, and race. Effect modification between foot type and age, BMI, gender, or race were examined (p<0.10 for interaction was considered statistically significant).

Results: Of 2,891 feet available for analysis, 66.5% had a neutral foot type, 13.9% were over-pronated, and 19.7% were over-supinated. Hallux valgus was the most common foot disorder (57.1%), followed by overlapping toes (27.1%), hammer toes (25.9%), Morton's neuroma (6.0%), Tailors' bunions (5.4%), plantar fasciitis (3.4%), and claw toes (2.1%). Table shows results of adjusted models. Compared to a neutral foot type, an over-pronated foot type was associated with hallux valgus (adjusted odds ratio [aOR]=1.36, 95% confidence interval [CI]=1.13–1.65) and overlapping toes (aOR=1.36, 95% CI=1.12–1.64), while an over-supinated foot type was inversely associated with hallux valgus (aOR=0.85, 95% CI=0.74–0.97). These associations did not differ by age, BMI, gender, or race.

Table.

Foot Disorder	Foot Type	Foot disorder/ Foot Type (%)	Unadjusted OR (95% CI)	Adjusted* OR (95% CI)
Hallux Valgus	Over-Pronated	277/401 (69.1)	1.41 (1.17–1.70)	1.36 (1.13–1.65)
	Neutral	1095/1922 (57.0)	1.00	1.00
	Over-Supinated	279/568 (49.1)	0.85 (0.74–0.96)	0.85 (0.74–0.97)
Overlapping Toes	Over-Pronated	136/401 (33.9)	1.38 (1.15–1.67)	1.36 (1.12–1.64)
	Neutral	500/1922 (26.0)	1.00	1.00
	Over-Supinated	148/568 (26.1)	0.97 (0.80–1.18)	0.97 (0.80–1.18)
Hammer Toes	Over-Pronated	107/401 (26.7)	0.96 (0.75–1.22)	0.89 (0.69–1.15)
	Neutral	489/1922 (25.4)	1.00	1.00
	Over-Supinated	152/568 (26.8)	0.98 (0.80–1.20)	1.00 (0.81–1.23)
Morton's Neuroma	Over-Pronated	19/401 (4.7)	0.76 (0.48–1.20)	0.79 (0.49–1.25)
	Neutral	115/1922 (6.0)	1.00	1.00
	Over-Supinated	40/568 (7.0)	1.14 (0.84–1.53)	1.11 (0.82–1.50)
Tailor's Bunions	Over-Pronated	36/401 (9.0)	1.14 (0.86–1.51)	1.23 (0.93–1.62)
	Neutral	93/1922 (4.8)	1.00	1.00
	Over-Supinated	26/568 (4.6)	0.85 (0.59–1.22)	0.85 (0.60–1.22)
Plantar Fasciitis	Over-Pronated	14/401 (3.5)	0.92 (0.50–1.70)	0.98 (0.53–1.82)
	Neutral	64/1922 (3.3)	1.00	1.00
	Over-Supinated	20/568 (3.5)	1.14 (0.78–1.67)	1.13 (0.76–1.67)
Claw Toes	Over-Pronated	7/401 (1.8)	0.75 (0.37–1.52)	0.69 (0.34–1.42)
	Neutral	42/1922 (2.2)	1.00	1.00
	Over-Supinated	11/568 (1.9)	0.93 (0.51–1.69)	0.89 (0.48–1.64)

*Adjusted for age, BMI, gender, race.

Conclusion: Hallux valgus and overlapping toes were the only foot disorders strongly related to foot type in this sample. Future studies should determine the longitudinal association between foot types and foot disorders as well as examine shoe and orthotic interventions for specific foot types as preventive approaches for foot disorders.

Biomechanical Function Agrees with Clinical Implications of Foot Disorders in a Population-Based Study. Thomas J. Hagedorn[1], Alyssa B. Dufour[2], Jody L. Riskowski[3], Howard J. Hillstrom[4], Virginia A. Casey[1] and Marian T. Hannan[5]. [1]Hebrew Senior Life, Boston, MA, [2]Hebrew SeniorLife & Boston Univ, Boston, MA, [3]Hebrew SeniorLife & Harvard Med School, Boston, MA, [4]Hospital Special Surgery (HSS), New York, NY, [5]Hebrew SeniorLife & Harvard Med Sch, Boston, MA

Background/Purpose: Foot disorders are thought to be associated with foot structure and function. However, no population-based studies have objectively evaluated this question. Insights into the relations of foot structure and function with specific foot disorders may further our understanding of their impact. The purpose of this study was to evaluate the relation of foot disorders to foot structure and function in a population-based study.

Methods: The Framingham Foot Study is a cross-sectional population-based study of ambulatory adults (aged 36–100) examined from 2002–08. A podiatric-trained examiner performed a validated foot exam to record presence of specific foot disorders (hallux valgus, hammer toes, claw toes, hallux rigidus, plantar fasciitis, Morton's neuroma, tailor's bunion, and overlapping toes). A Tekscan Matscan pressure mat was used to collect loading data from each foot while walking, and during bipedal standing. From these data, center of pressure excursion index (CPEI), a measure of foot function during walking, and modified arch index (MAI), a measure of foot structure while standing, were calculated for each foot. Participants with valid foot pressure and examination data were included in this analysis. Feet in the top and bottom 20% of CPEI values were classified as supinators and pronators respectively; the middle 60% was the referent. High-arch feet were defined as the bottom 20% of MAI values, while low-arch feet were defined as the top 20%; referent was the middle 60%. Logistic regression, using generalized estimation equations to account for correlations between feet, was used to estimate odds ratios and 95% confidence intervals between foot function, structure and each foot disorder.

Results: There were 3145 participants contributing 5517 feet (Table 1). Hallux valgus and hammer toes were the most common foot disorders. Prevalence of hallux valgus and overlapping toes was higher among prona-

tors, while prevalence of hallux valgus and hallux rigidus was lower among supinators (Table 2). Low arches were associated with a higher prevalence of Morton's neuroma and hammer toes.

Table 1. Population characteristics and prevalence of foot disorders in the study sample. Prevalence by foot (N=5517)

Characteristic	Mean ± Std Dev
Age (years)	66.2 ± 10.5
BMI (kg/m^2)	28.3 ± 5.5
Weight (lbs)	174.1 ± 39.3
Height (in)	65.5 ± 3.9
Foot Disorder	**Prevalence N (%)**
Hallux Valgus	1472 (26.3)
Hammer Toes	894 (16.2)
Morton's Neuroma	439 (8.0)
Overlapping Toes	294 (5.3)
Tailor's Bunion	197 (3.6)
Plantar Fasciitis	177 (3.2)
Hallux Rigidus	173 (3.1)
Claw Toes	74 (1.3)

Table 2. Odds ratios and 95% confidence intervals for GEE analysis of foot structure, function, and disorders.

	Foot Function (defined by CPEI)		Foot Structure (defined by MAI)	
	Pronator	Supinator	Low Arch	High Arch
Hallux Valgus	1.15 (1.01, 1.30)*	0.78 (0.69, 0.89)†	0.95 (0.83, 1.10)	0.95 (0.83, 1.09)
Hammer Toes	0.91 (0.78, 1.05)	0.93 (0.79, 1.09)	1.33 (1.14, 1.57)†	0.99 (0.83, 1.19)
Morton's Neuroma	0.83 (0.66, 1.06)	0.97 (0.77, 1.23)	1.29 (1.01, 1.65)*	1.15 (0.90, 1.47)

Tailor's Bunion	1.07 (0.79, 1.46)	0.80 (0.60, 1.07)	1.19 (0.85, 1.69)	1.17 (0.88, 1.55)
Plantar Fasciitis	0.98 (0.68, 1.41)	1.22 (0.89, 1.68)	1.16 (0.79, 1.69)	1.10 (0.75, 1.61)
Hallux Rigidus	1.17 (0.92, 1.48)	0.58 (0.41, 0.83)†	1.24 (0.93, 1.65)	0.86 (0.59, 1.25)
Claw Toes	1.06 (0.67, 1.69)	0.85 (0.49, 1.47)	0.84 (0.49, 1,44)	0.79 (0.42, 1.50)

* 0.01 < p < 0.05
† p < 0.01

Conclusion: Foot structure and function were related to prevalence of specific foot disorders in this population. The results are in agreement with biomechanical theory of and clinical implications from specific foot disorders. However, these cross-sectional data cannot confirm a causal relation. These results underscore the utility of clinical input in understanding the relations between foot structure, function, and disorders and may provide insights for interventions to improve function.

Leg Muscle Mass Is Not Affected by Foot Pain, Structure or Function: The Framingham Foot Study. Alyssa B. Dufour[1], Marian T. Hannan[2], Patricia P. Katz[3], Jody L. Riskowski[4], Thomas J. Hagedorn[5], Virginia A. Casey[5] and Robert R. McLean[6]. [1]Hebrew SeniorLife & Boston Univ, Boston, MA, [2]Hebrew SeniorLife & Harvard Med Sch, Boston, MA, [3]Univercity of California San Francisco, San Francisco, CA, [4]Hebrew SeniorLife & Harvard Med School, Boston, MA, [5]Hebrew Senior Life, Boston, MA, [6]Hebrew Senior Life/Harvard Medical School, Boston, MA

Background/Purpose: While foot pain has been linked to poor outcomes, little is known about how the foot might affect physical functioning or, specifically, leg muscle mass. As no studies have examined the association between leg muscle mass and foot pain, structure or function, the purpose was to evaluate the relation of leg muscle mass to these characteristics, in a population-based study of older men and women. We hypothesized that foot pain and poor foot function/structure (e.g. supination or pronation) would be linked to low leg muscle mass.

Methods: Framingham Foot Study participants with complete data on leg muscle mass as well as foot pain, structure and function (2002–08) were included in this study. Whole body DXA (Lunar DPX-L) was used to measure leg muscle mass (kg). Foot pain (y/n) was present if pain, aching or stiffness was reported on most days of the month. Data from a Tekscan Matscan pressure mat were used to calculate foot structure, as the modified arch index (MAI) during bipedal standing, and foot function, as the center of pressure excursion index (CPEI) while walking using the two-step method. Feet in the top or bottom 20% of CPEI values were classified as supinators or pronators, respectively, and feet in the middle 60% were the referent group. The bottom and top 20% of MAI values were considered high and low arched

feet, respectively, with the referent the middle 60%. The foot with CPEI or MAI value farthest from the respective median value was chosen as the foot of interest for each participant. Crude and adjusted (age, body mass index (BMI, kg/m^2), sex) multinomial (for foot structure and function outcomes) logistic regression was used to determine the association of a 1 standard deviation (SD) increase in leg muscle mass, both crude and normalized to height, with foot pain, structure and function. Sex-specific models were also examined.

Results: Of the 1798 participants (age: 67 $\pm$ 10 years; BMI: 28 $\pm$ 4.9 kg/m^2; 57% women), the average leg muscle mass was 17.51 $\pm$ 2.23 kg in men and 11.60 $\pm$ 1.51 kg in women. 21% reported foot pain. A 1 SD increase in leg muscle mass was associated with 18% lower odds of foot pain, 25% lower odds of pronation and 19% higher odds of supination, compared to the referent. A 1 SD increase in muscle mass was associated with 14% higher odds of low arch and 15% lower odds of high arch. Adjustment for age and BMI did not change the results, but associations were attenuated after adding sex to the model. Results were similar for muscle mass normalized to height and sex-specific models.

Table. Odds ratios and 95% confidence intervals for the associated between one standard deviation increase in leg muscle mass and foot pain, foot structure (MAI), and foot function (CPEI)

	n (%)	Crude Model OR (95% CI)	p-value	Adjusted Model (age, BMI, sex) OR (95% CI)	p-value
Foot pain	385 (21)	0.83 (0.74, 0.94)	0.0023	0.93 (0.74, 1.18)	0.5727
Foot Structure (MAI)					
low arch	474 (26)	1.13 (1.01, 1.27)	0.0296	0.90 (0.71, 1.13)	0.3671
high arch	548 (30)	0.85 (0.76, 0.95)	0.0048	0.82 (0.65, 1.03)	0.0949
Foot Function (CPEI)					
pronator	559 (31)	0.74 (0.66, 0.83)	<.0001	0.96 (0.76, 1.21)	0.7233
supinator	535 (30)	1.17 (1.05, 1.31)	0.0055	0.84 (0.67, 1.05)	0.1197

Conclusion: Our results suggest that although leg muscle mass was associated with foot pain, foot structure and foot function in our population of middle-aged and older adults, these relations are confounded by sex. Leg muscle mass is likely not a determinant of foot pain, structure or function. These results highlight the need for future work to examine the role of foot pain, structure and function in understanding other aspects of impairment and physical function.

Associations of Foot Structure and Function to Low Back and Lower Extremity Pain. Jody L. Riskowski[1], Alyssa B. Dufour[2], Thomas J. Hagedorn[3], Howard J. Hillstrom[4], Virginia A. Casey[3] and Marian T. Hannan[1]. [1]Hebrew SeniorLife & Harvard Medical School, Boston, MA, [2]Hebrew SeniorLife & Boston Univ, Boston, MA, [3]Hebrew SeniorLife, Boston, MA, [4]Hospital Special Surgery (HSS), New York, NY

Background/Purpose: Common risk factors of low back/lower extremity (LB/LE) joint pain are age, gender and body mass index (BMI), with women, older adults and overweight/obese individuals at increased risk. However, as foot motion during gait influences the movement pattern through the kinetic chain, foot structure and function may also be associated with lower extremity joint pain. Thus, the aim was to evaluate the relations of LB/LE pain to foot structure and function in a population-based study.

Methods: Framingham Foot Study members with complete data on pain in the LB/LE joints as well as foot structure and function were included.

LB/LE joint pain was determined by the response to the NHANES-type question, "On most days do you have pain, aching or stiffness in your [low back, hips, knees, ankles, or feet]?" Bilateral and unilateral pain were weighted the same; responses were dichotomized to yes or no.

A pressure mat (Matscan, Tekscan Inc.) yielded foot structure and function data during bipedal standing, and while walking, using the two-step method. From these data, modified arch index (MAI), a measure of foot structure, and center of pressure excursion index (CPEI), a measure of foot function, were calculated.

Foot structure classification used MAI, with participants who had a foot in the top or bottom 20% of these values considered low arch or high arch, respectively, with the middle 60% the referent. Foot function classification used CPEI, with those who had a foot in the top or bottom 20% of these

values denoted as supinators or pronators, respectively, with the middle 60% the referent.

Crude and adjusted (age, gender, BMI) logistic regression analysis (SAS, v. 9.3) determined associations of LB/LE pain to foot structure and function. Alpha was set to $p \leq 0.05$.

Results: There were 1856 participants (age: 63.8 $\pm$ 8.9 years; BMI: 28.6 $\pm$ 5.6 kg/m^2; 56% women). Of the sites assessed, low back pain was the most common at 34.1%, followed by knee pain at 29.4%; ankle pain was the least prevalent at 11.2% (Table 1).

Those with high arch foot structure had 26% lower odds of low back pain, whereas those with low arch structure had higher odds of knee (57%) and ankle (47%) pain. Supinated foot function during gait was associated with a 31% reduced odds of hip pain. After adjustment, odds ratios were attenuated and confidence intervals widened.

Table 1. Crude and adjusted odds ratios (with 95% confidence intervals) of associations of lower extremity joint pain to foot structure, assessed using modified arch index (MAI), and to foot function, assessed using center of pressure excursion index (CPEI).

Region of Interest	N, % with Pain	MAI – Crude Model Low Arch	MAI – Crude Model High Arch	MAI – Crude Model Low Arch	MAI – Crude Model High Arch
Low Back	632, 34.1%	1.08 (0.85, 1.35)	**0.74 (0.57, 0.95)**	0.94 (0.74, 1.21)	0.80 (0.61, 1.03)
Hips	325, 17.5%	1.25 (0.94, 1.66)	0.98 (0.71, 1.34)	1.04 (0.83, 1.53)	1.12 (0.83, 1.53)
Knees	546, 29.4%	**1.57 (1.24, 1.99)**	0.86 (0.66, 1.13)	1.17 (0.91, 1.52)	1.05 (0.80, 1.39)
Ankles	207, 11.2%	**1.47 (1.05, 2.06)**	1.00 (0.68, 1.47)	1.14 (0.79, 1.64)	1.16 (0.78, 1.71)
Feet	487, 26.2%	1.22 (0.95, 1.56)	0.84 (0.64, 1.11)	1.04 (0.80, 1.35)	0.92 (0.70, 1.22)

Region of Interest	N, % with Pain	CPEI – Crude Model Pronators	CPEI – Crude Model Supinators	CPEI – Adjusted Model* Pronators	CPEI – Adjusted Model* Supinators
Low Back	632, 34.1%	1.20 (0.96, 1.51)	0.91 (0.72, 1.16)	1.19 (0.94, 1.49)	0.98 (0.77, 1.25)
Hips	325, 17.5%	0.82 (0.62, 1.08)	**0.69 (0.51, 0.93)**	0.76 (0.57, 1.02)	0.78 (0.57, 1.05)
Knees	546, 29.4%	0.92 (0.72, 1.16)	0.90 (0.70, 1.14)	0.94 (0.73, 1.20)	0.97 (0.75, 1.26)
Ankles	207, 11.2%	0.86 (0.61, 1.22)	0.92 (0.65, 1.30)	0.86 (0.61, 1.23)	0.99 (0.69, 1.42)
Feet	487, 26.2%	1.10 (0.87, 1.41)	0.89 (0.69, 1.15)	1.08 (0.84, 1.39)	0.97 (0.74, 1.26)

* Model adjusted by age, gender, body mass index

Conclusion: A low arch structure, but not high arch structure or foot function, is associated with greater odds of lower extremity joint pain. The results suggest that differences in the kinetic chain may exist between those with high, low, and normal arch structure, and future studies should evaluate if differences in movement patterns are related to foot structure. Further, as this study is cross-sectional, longitudinal studies are needed to determine the cause-effect relations between foot structure and function to LB/LE pain.

Associations of Foot Forces and Pressures to Regional Foot Pain: The Framingham Foot Study. Jody L. Riskowski[1], Thomas J. Hagedorn[2], Alyssa B. Dufour[3], Virginia A. Casey[4] and Marian T. Hannan[1]. [1]Hebrew SeniorLife & Harvard Med School, Boston, MA, [2]Hebrew SeniorLife, Boston, MA, [3]Hebrew SeniorLife & Boston Univ, Boston, MA, [4]Hebrew Senior Life, Boston, MA

Background/Purpose: Foot pain is a risk factor for disability; however, not all foot pain is the same. Foot pain etiology can vary by region (e.g., toe pain may arise from overlapping toes, forefoot pain from hallux valgus), suggesting its effects on foot biomechanics may differ as well. Therefore, the aim of this study was to evaluate differences in foot biomechanics during gait by region of foot pain.

Methods: Framingham Foot Study participants with complete data on regional foot pain, foot biomechanics, and foot disorders were included in this study.

A trained examiner conducted a validated foot exam to determine presence of the following structural foot disorders: hallux valgus, hallux rigidus, claw toes, overlapping toes and hammer toes.

Biomechanical data were collected using a pressure mat (Tekscan Matscan) as participants walked barefoot at a self-selected pace. Data were processed (Novel Automask) to extract maximum force and peak pressure at the toes, forefoot, midfoot, and rearfoot.

Participants selected location(s) of foot pain from a graphic, with location options including toe, nail, ball of foot, forefoot, arch, heel and hindfoot. The eight locations of pain were collapsed into four regions: toes (toe and nail pain); forefoot (forefoot and ball pain); midfoot (arch pain); and rearfoot (heel and hindfoot pain).

Each foot was classified into one of seven groups: 1) toe pain only; 2) forefoot pain only; 3) midfoot pain only; 4) rearfoot pain only; 5) pain in two regions; 6) pain in three or more regions; and 7) no regional pain (referent).

A per-foot analysis using General Estimating Equations (SAS, v. 9.3) determined associations between regional foot pain and biomechanical measures, adjusting for age, gender, weight and presence of structural foot disorders. Alpha was set to p≤0.05.

Results: There were 3158 participants (6280 feet) included (age: 66 ± 10.5 years; BMI: 28 ± 5.5 kg/m^2; 56% women), with 2634 (42%) feet having one or more structural foot disorder.

After adjustment, individuals with midfoot pain had higher midfoot force with greater toe pressure (Figure 1), while those with forefoot pain had greater rearfoot force and less toe force, compared to the referent. Individuals with pain in toes, rearfoot, and multiple regions typically displayed lower rearfoot pressure and force relative to the referent.

Regional peak pressure relative to referent

Regional maximum force relative to referent

Toe Pain · Forefoot Pain · Midfoot Pain · Rearfoot Pain · Pain in 2 regions · Pain in 3 regions
Conclusion: Region of foot pain is associated with biomechanical differences at the pain locale and other foot regions. These results suggest that region of foot pain may be associated with biomechanical differences during gait at other lower extremity joints (e.g., knee and ankle). As changes in gait affect mobility and fall risk, future work should evaluate how region of foot pain affects lower extremity function, falls and disability.

How Many Steps/Day Are Associated with a Community Level Gait Speed Among Older Adults with or At High Risk of Knee OA? Daniel K. White[1], Roger Fielding[2], Tuhina Neogi[3], Michael P. LaValley[4], K. Douglas Gross[5], Michael C. Nevitt[6], C.E. Lewis[7], James Torner[8] and Catrine Tudor-Locke[9]. [1]Boston University, Boston, MA, [2]Tufts Medical Center, [3]Boston Univ School of Medicine, Boston, MA, [4]Boston University School of Public Health, Boston, MA, [5]MGH Institute of Health Professions, Boston, MA, [6]University of California-San Francisco, San Francisco, CA, [7]University of Alabama, Birmingham City, AL, [8]University of Iowa, Iowa City, Iowa City, IA, [9]Pennington Biomedical Research Center, Baton Rouge

Background/Purpose: While recommended levels of physical activity associated with reducing the risk of poor health outcomes are well known, it is unclear what minimal level of walking is associated with functional benchmarks specific to older adults. The purpose of this study was to examine the minimal number of steps/day associated with walking at a community level gait speed in older adults with or at high risk of knee osteoarthritis (OA).

Methods: The Multicenter Osteoarthritis Study (MOST) is an NIH funded longitudinal study of older men and women who have or are at high risk for knee OA. Participants at the 60-month visit wore a StepWatch Activity Monitor to record walking behavior over 7 days. Usual gait speed (m/s) during a 20 meter walk was determined at the same clinic visit. Walking behavior (steps/day) that best discriminated a gait speed of ≥1.2 m/s (speed needed to cross the street) was determined using a Receiver Operator Curve (ROC). Sensitivity, specificity, and positive predictive value (PPV) was calculated to quantify how well the identified steps/day predicted walking at least 1.2 m/s.

Results: Among 1,757 participants considered (67 ± 8 yrs, BMI 31 ± 6 kg/m^2, female 59%), mean walking behavior was 7,094 ± 2,917 steps/day [range 640–21,593] and mean gait speed was 1.22 m/s ± 0.21 [range 0.4 – 2.1]. Walking at least 6,500 steps/day discriminated meeting a gait speed of ≥1.2 m/s (sensitivity = 70%, specificity = 64%, PPV = 71%).

Conclusion: Most older adults with or at high risk of knee OA who walk at least 6,500 steps/day have gait speeds associated with walking in the community. While further confirmation is needed, at present clinicians may consider setting a goal of 6,500 steps/day as a minimal level of walking for older adults with or at high risk of knee OA.

Racial Differences in Pain Coping Efficacy in Patients with Hip and Knee Osteoarthritis. Kelli D. Allen[1], Hayden B. Bosworth[1], Cynthia Coffman[1], Jennifer H. Lindquist[1], Nina R. Sperber[1], Morris Weinberger[2] and Eugene Z. Oddone[1]. [1]Duke and Durham VA Medical Center, Durham, NC, [2]University of North Carolina at Chapel Hill & Durham VA Medical Center, Durham, NC

Background/Purpose: Studies have shown that African Americans with osteoarthritis (OA) have greater pain than Caucasians. However, little is known about whether there are racial differences in patients' perceived ability to cope with OA-related pain (coping efficacy). This study examined relationships among race, pain coping efficacy, and pain severity in patients with hip and knee OA.

Methods: We analyzed baseline data from 515 participants in a randomized controlled trial of a telephone-based OA self-management program (mean age = 60 years; 93% male; 46% non-white − 43% African American, 3% other racial/ethnic minorities). Pain coping efficacy was assessed with two questions: "Based on all the things you did to cope, or deal, with your arthritis pain during the last week, 1.) how much **control** do you feel you had over it and 2.) how much were you able to **decrease** it?" Responses used a 7-point Likert scale (0=no control/can't decrease it at all to 6 = complete control/can decrease it completely). Pain severity was assessed with the Arthritis Impact Measurement Scales-2 (AIMS2) pain subscale, which includes 5 items; total scores range from of 0 (least) to 10 (worst) pain. We first fit simple linear regression models to examine the associations of pain severity (AIMS2) and race with the two pain coping efficacy questions. We then used multiple linear regression modeling to examine associations of pain coping efficacy with race and pain severity, as well as whether the relationship between pain coping efficacy and pain severity differed by race (interaction term).

Results: More severe pain was associated with lower pain coping efficacy (regression coefficient = −0.22, p <0.0001 for ability to **decrease** pain, regression coefficient = −0.28, p<0.0001 for perceived **control** over pain). There was no racial difference in perceived ability to **decrease** pain (regression coefficient = −0.13, p=0.37). However, mean perceived **control** over pain was 0.36 points lower for non-whites compared to whites (2.99 vs. 3.35, p = 0.01). In the multiple linear regression model, perceived **control** over pain was 0.76 points lower for non-whites compared to whites (p = 0.09), and more severe pain was associated with lower perceived **control** (regression coefficient = −0.21, p<0.001). In addition, there was some evidence that the relationship between perceived pain control and pain severity differed by race (interaction term p=0.05); specifically, the slope was steeper for non-whites, so that the racial difference in perceived pain control was greater at higher levels of pain (with non-whites perceiving less pain control at higher pain levels).

Conclusion: Non-white patients with OA perceived less control over their pain than whites, and this difference appears to be particularly accentuated at greater pain levels. These results highlight the importance of building our understanding of effective mechanisms to reduce racial differences in both pain severity and pain coping efficacy among individuals with OA.

Disclosure: K. D. Allen, None; **H. B. Bosworth**, None; **C. Coffman**, None; **J. H. Lindquist**, None; **N. R. Sperber**, None; **M. Weinberger**, None; **E. Z. Oddone**, None.

African American Adults Less Willing to Undergo Joint Replacement Surgery: The Multicenter Osteoarthritis Study. Julie J. Keysor[1], Huan J. Chang[2], Tianzhong Yang[3], Cora E. Lewis[4], James Torner[5], Michael C. Nevitt[6] and David T. Felson[3]. [1]Boston Univ Sargent College, Boston, MA, [2]The Journal of the American Medical Association, Chicago, IL, [3]Boston Univ School of Medicine, Boston, MA, [4]University of Alabama, Birmingham City, Birmingham, AL, [5]University of Iowa, Iowa City, Iowa City, IA, [6]University of California-San Francisco, San Francisco, CA

Background/Purpose: "Willingness" to undergo joint replacement surgery (JRS) is predictive of subsequent JRS among community-dwelling older adults and could, at least in part, explain the noted ethnic disparity in JRS utilization. Differences between African Americans and whites in JRS "willingness" have not been explored nor have other factors that affect willingness.

Methods: The Multicenter Osteoarthritis Study (MOST) is a prospective community-based study of 3026 adults 50–79 years old with or at risk of developing symptomatic knee or hip osteoarthritis (OA). Participants were from Birmingham, Alabama and Iowa City, Iowa. "Willingness to undergo JRS" was ascertained among participants at the 60-month visit as follows: "based on your understanding of the risks and benefits of hip and knee joint replacement surgery and if your symptoms were severe enough, would you be willing to have joint replacement surgery for your hips or knees?" Responses were coded "willing" or "not willing". The following risk factors for willingness were assessed at the same time: age, gender, education, and race (African American and white); living situation (alone vs. with someone), comorbidity, OA radiographic severity, pain severity, function, depressive symptoms, pain catastrophizing, and study site. We excluded participants who already had a knee or hip replacement (N=438). We used logistic regression to examine the association of ethnicity with JRS willingness after adjusting for covariates.

Results: 1808 subjects who participated in the 60 month exam were included. The mean age of the sample was 67.7 (SD 7.8); 60% were female, 14% were African American, 27% did not have education beyond high school;18.4% lived alone; 11% had high depressive symptoms; 25% reported high pain catastrophizing. In crude and adjusted models, African Americans were significantly less likely to report being "willing" to undergo JRS (Table 1). Willingness declined with age and those from Alabama were less willing than subjects from Iowa. Men and persons with depressive symptoms tended to be less willing (p=0.06). Knee OA severity, pain severity, function, pain catastrophizing, andr living situation were not associated with willingness.

Table 1. Risk Factors Associated with "Willingness" to Have a Total Joint Replacement (Odds Ratios below one signify decreased willingness to undergo THR or TKR; Bold highlight indicates p=0.05 significance)

Variable (range)	Unadjusted Odds Ratio	Unadjusted 95% Confidence Interval	Adjusted Odds Ratio	Adjusted 95% Confidence Interval
Race (African American vs. White)	**0.27**	**0.20, 0.35**	**0.32**	**0.23,0.45**
Age 50–59 years			1	referent
Age 60–69 years			**0.81**	**0.59, 1.11**
Age 70–79 years			**0.50**	**0.36, 0.69**
Age 80+ years			**0.37**	**0.22, 0.60**
Alabama site (referent Iowa)			**0.68**	**0.53, 0.89**
Male (referent female)			1.3*	1.00, 1.64*
Lives alone (referent lives with someone)			1.0	0.75, 1.34
OA Severity			0.93	0.85, 1.04
Education (referent: some high school)			1.14	0.63, 2.06
Comorbidity			1.04	0.95, 1.14
Pain Severity (1–10)			0.98	0.92, 1.05
WOMAC function (lowest tertile: best)			1.0	referent
WOMAC function (middle tertile)			1.16	0.85, 1.58
WOMAC function (highest tertile: worst)			1.10	0.74, 1.62
Depressive symptoms (referent no symptoms)			0.71*	0.50, 1.02*
Pain catastrophizing			0.81	0.62, 1.07

* Approached significance at p=.06

Conclusion: "Willingness" may explain some of the disparities in TKR utilization between African Americans and whites. Older and depressed persons and persons from certain locale's may also be less willing to have TKRs and THRs. Longitudinal studies are needed to establish causality.

Clinical and Biomechanical Characteristics of Total Hip Arthroplasty Responders and Nonresponders. Genna Waldman[1] and Kharma C. Foucher[2]. [1]Rush Medical College, Chicago, IL, [2]Rush University Medical Center, Chicago, IL

Background/Purpose: In a recent study, 14% of total hip arthroplasty (THA) patients were classified as nonresponders, using osteoarthritis (OA) treatment response criteria[1]. Identifying characteristics of responders and nonresponders could lead to better ways to identify and manage likely nonresponders. The purpose of this study was to test the hypothesis that responders have different preoperative and postoperative clinical and gait characteristics than nonresponders. A secondary goal was to evaluate the utility of the Harris hip score (HHS) for calculating response.

Methods: We identified 132 THA patients with pre- and one year postoperative gait and HHS data from our IRB-approved data repository. We calculated responder criteria in three ways based on the literature[1]: (i) Return to Normal (RTN): follow-up HHS ≥ 2 standard deviations above baseline; (ii) a modified version of OMERACT-OARSI responder criteria: relative change $\geq 20\%$; and (iii) Minimally Important Different (MID): follow-up HHS score ≥ 0.5 standard deviation above baseline. Gait variables of interest were self-selected normal walking speed, sagittal plane dynamic range of motion (ROM) and the 3D peak external moments. We used t-tests to compare pre- and postoperative gait variables for responders and nonresponders.

Results: 20%, 13% and 7% of patients were classified as nonresponders based on RTN, modified OMERACT-OARSI, and MID criteria, respectively. Using the modified OMERACT-OARSI criteria, baseline physical characteristics were similar for both groups (table). Preoperatively, nonresponders had 35% higher HHS (p<0.001) and 25% higher ROM (p=0.021) compared to responders. After surgery, nonresponders had significantly lower HHS compared to responders (p<0.001), as well as lower adduction and external rotation moments (p=0.038). Findings were similar when comparisons were done using the other responder criteria.

Table. Characteristics of THA subjects classified as responders and nonresponders

		Responders (87%)	Nonresponders (13%)	p value
Baseline Physical Characteristics	Age (yrs)	60 ± 10	61 ± 10	0.868
	BMI (kg/m2)	29 ± 5	28 ± 4	0.475
	Sex	58 F/57 M	8 F/9 M	0.795
Clinical Characteristics	*Preoperative HHS	**55 ± 13**	**74 ± 14**	**<0.001**
	*Postoperative HHS	**93 ± 8**	**80 ± 17**	**<0.001**
	*Absolute Change	**39 ± 12**	**6 ± 8**	**<0.001**
	*Relative Change (%)	**80 ± 44**	**9 ± 11**	**<0.001**
Preoperative Gait Biomechanics	'Normal' walking speed (m/s)	1.01 ± 0.24	1.02 ± 0.20	0.930
	*Dynamic sagittal plane range of motion (degrees)	**16 ± 6**	**20 ± 6**	**0.021**
	Peak Flexion Moment (%Body Weight × Height)	4.19 ± 1.49	4.97 ± 1.98	0.140
	Peak Extension Moment (%Body Weight × Height)	1.79 ±0.86	1.80 ± 0.67	0.954
	Peak Adduction Moment (%Body Weight × Height)	3.45 ± 1.02	3.23 ± 1.30	0.423
	Peak Abduction Moment (%Body Weight × Height)	1.60 ± 0.86	1.73 ± 0.75	0.548
	Peak External Rotation Moment (%Body Weight × Height)	0.33 ± 0.21	0.34 ± 0.26	0.818
	Peak Internal Rotation Moment (%Body Weight × Height)	0.37 ± 0.22	0.37 ± 0.15	0.994
Postoperative Gait Biomechanics	'Normal' walking speed (m/s)	1.19 ±0.19	1.13 ± 0.19	0.249
	Dynamic sagittal plane hip range of motion (degrees)	25 ± 6	25 ± 6	0.915
	Peak Flexion Moment (%Body Weight × Height)	5.91 ± 2.03	5.82 ± 2.17	0.852
	Peak Extension Moment (%Body Weight × Height)	2.70 ± 1.10	2.82 ± 0.83	0.664
	*Peak Adduction Moment (%Body Weight × Height)	**3.54 ± 0.94**	**3.03 ± 0.91**	**0.038**
	Peak Abduction Moment (%Body Weight × Height)	1.88 ± 0.84	1.87 ± 0.97	0.921
	*Peak External Rotation Moment (%Body Weight × Height)	**0.43 ± 0.23**	**0.31 ± 0.21**	**0.038**
	Peak Internal Rotation Moment (%Body Weight × Height)	0.51 ±0.21	0.44 ±0.18	0.201

*bold text indicates t-test or chi-square test p<0.05

Conclusion: Although a different score was used, a similar proportion of THA patients were classified as nonresponders here as in a previous study[1]. This suggests that the HHS can be used to calculate response criteria if WOMAC scores are unavailable. HHS and ROM were initially higher in patients who would become nonresponders, but after surgery the nonresponders were left with lower mean HHS and lower adduction and external rotation moments. These gait moments reflect net activity of hip abductors. More work is needed to determine whether addressing the abductor impairment suggested by the biomechanical data would improve response. These results demonstrate that some patients who would appear to be more highly functioning before surgery may have both poorer responses and poorer final outcomes.

A Rich Description of Clinical Exam Features in Patients with Knee Osteoarthritis and Their Correlation with Functional Outcomes.

Maura D. Iversen[1], Kelli Sylvester[2], Abigail Grader[2], Michelle A. Frits[3], Marie Boneparth[4], Megan Whitmore[4], Jane Lucas[5], Fatima Shahzad[6], Jeffrey B. Driban[6] and Chenchen Wang[6]. [1]Northeastern University, Department of Physical Therapy, and Brigham & Women's Hospital, Harvard Medical School, Boston, MA, [2]Department of Physical Therapy, Northeastern University, Boston, MA, [3]Brigham and Women's Hospital, Boston, MA, [4]Tufts Medical Center, Boston, [5]Back Bay Physical Therapy, Boston, [6]Tufts Medical Center, Boston, MA

Background/Purpose: Assessments of symptomatic knee osteoarthritis (KOA) rely on physical measures for clinical decision-making. However, there is limited literature on the association between examination procedures and reported KOA symptoms and activity limitations. This study aims to: (1) provide a rich clinical description of patients with KOA and (2) correlate examination findings with self-reported measures to determine the most efficient exam procedures to classify disease severity.

Methods: This is a secondary analysis of baseline data from 47 patients with symptomatic and radiographic KOA recruited for a randomized clinical trial comparing tai chi and physical therapy. Patients completed self-reported outcome surveys (e.g., WOMAC Osteoarthritis Index [VAS scale]), performance tests (Timed Walk, repeated Sit-to-Stand, 6-min Walk Test, Berg balance), and a standardized physical examination by a physical therapist. The exam included: an interview, muscle flexibility (Ober and Ely), muscle strength testing, ligamentous stability and meniscus integrity tests (e.g., Lachman, McMurray), pain provocation (patella compression), range-of-motion and functional assessments (Waldron squat test). Descriptive statistics and correlations were used to characterize the sample and determine associations between exam procedures, performance tests and outcome measures.

Results: Patients were 58 years of age (SD=9.8), 68% were female, 54% were Caucasian. Most (78%) had a high school education/some college and 30% were employed. 83% had unilateral knee involvement and 25% used an ambulatory device. Patients reported limited function (mean WOMAC function =879.5 [SD= 376]) and pain (mean WOMAC pain = 254.5 [SD=99]) and were at low fall risk (mean Berg= 53.8[SD=2.7]). Few patients tested positive for ligament instability and 2/3 tested positive for patellofemoral involvement. There was a low to moderate correlation between self-reported pain and subject performance on tests of functional strength, aerobic fitness and walking speed. Iliotibial band tightness (based on a positive Ober test) was significantly correlated with increased pain, stiffness and self-reported functional limitations **(TABLE 1)**.

Table 1. Correlations with Self-reported KOA Symptoms and Clinical Test Performance and Physical Examination Procedures

Clinical and Performance Tests	M ± SD N (%)	WOMAC pain	WOMAC stiffness	WOMAC function
6-minute Walk Test (meters)	403.6 ± 83.5	**r=−0.37**	r=−0.20	**r=−0.42**
		p=0.01	p=0.18	**p=0.004**
Timed Walk (20m; sec)	18 ± 3.5	**r=0.32**	r=0.20	**r=0.44**
		p=0.03	p=0.18	**p=0.002**
Timed Chair Stand Test (sec)	31.2.3±11.3	r=0.20	r=0.29	**r=0.37**
		p=0.20	p=0.06	**p=0.01**
Positive Ely	43 (92)	r=−0.05	r=0.24	r=0.03
		p=0.70	p=0.10	p=0.80
Positive Ober	17 (36)	**r=−0.35**	**r= −0.37**	**r=−0.44**
		p=0.02	**p=0.008**	**p=0.002**
Positive Lachman	4 (9)	r=−0.09	r=−0.14	r=−0.07
		p=0.50	p=0.3	p=0.60
Positive McMurray	20 (43)	r=0.07	r=−0.07	r=−0.02
		p=0.60	p=0.6	p=0.90
Positive Waldron Test (pain and crepitus with squat)	8 (17)	r=−0.09	r=−0.15	r=−0.10
		p=0.50	p=0.3	p=0.40
Grind Test (pain with patella compression)	31 (66)	r=0.10	r=−0.17	r=−0.02
		p=0.50	p=0.25	p=0.90

Note: M = mean, SD = standard deviation WOMAC= Western Ontario and McMaster Index

Conclusion: Patients with symptomatic KOA had varied clinical presentations. Those with iliotibial band tightness reported more knee pain, stiffness, and functional limitations. Pain provocation tests were not associated with greater dysfunction or symptoms although most patients tested positive with these tests. Self-reported pain correlated significantly with physical performance test outcomes. The Ober test appears to be a useful clinical maneuver that is associated with KOA related functional difficulties and symptoms. Clinical performance tests of gait speed and aerobic capacity may help identify patients with more severe disease and are less costly than radiographic tests.

Does Unpredictable Intermittent Knee Pain Limit Functional Ability and Walking Frequency in Knee OA?

Daniel K. White[1], Gillian A. Hawker[2], David T. Felson[1], K. Douglas Gross[3], Jingbo Niu[4], Michael C. Nevitt[5], C.E. Lewis[6], James Torner[7] and Tuhina Neogi[4]. [1]Boston University, Boston, MA, [2]Women's College Research Institute, University of Toronto, Toronto, ON, [3]MGH Institute of Health Professions, Boston, MA, [4]Boston Univ School of Medicine, Boston, MA, [5]University of California-San Francisco, San Francisco, CA, [6]University of Alabama, Birmingham City, AL, [7]University of Iowa, Iowa City, Iowa City, IA

Background/Purpose: People with knee osteoarthritis (OA) reported that unpredictable pain restricts their ability to engage in physical activities in a qualitative study. Since walking is the most common physical activity employed by older adults, it would be important to understand if unpredictable pain impacts walking frequency, which would have important health implications. It is also not clear if unpredictable pain contributes to other functional limitations or restrictions in health-related quality of life (HRQOL). We therefore evaluated the association of unpredictable pain with walking frequency, more general function, and physical health related quality of life in people with or at high risk of knee OA.

Methods: The Multicenter Osteoarthritis Study (MOST) is a NIH funded longitudinal study of people who have or are at high risk for knee OA. Participants at the 84-month visit who indicated they had intermittent knee pain were asked to rate the frequency of unpredictable pain, i.e., starts without warning, and the frequency of predictable pain, i.e., starts with a trigger. Both were rated on a Likert scale (Never to Very Often). Participants were categorized as having no pain, predominantly unpredictable pain, predominantly predictable pain, or both types according to the worst knee. At the same visit, gait speed over 20 meters, the WOMAC physical function (PF) subscale, and the SF-12 physical function (as a measure of HRQOL) subscale were collected. Steps/day was also collected using a pedometer (Stepwatch) over the next 7 days. We calculated study outcomes according to the presence of unpredictable and/or predictable pain, adjusting for age, sex, BMI, comorbidities, frequency of pain, and depressive symptoms using linear regression.

Results: Of data from the 84-month study visit to date, 664 people had intermittent knee pain (Age 68.5 ± 7.6 yrs, BMI 31.3 ± 6.6 kg/m[2], female 70%). Predominantly unpredictable pain was reported in 12%; these subjects had significantly more self-reported functional limitation (WOMAC-PF). However, other outcomes were not statistically significantly different compared with those with no pain. Subjects with predictable pain and both pain types also had worse WOMAC-PF compared with those with no pain, however all other outcomes had values similar to those with no pain. See Table.

Table. Mean and standard error values stratified by pain categories. Mean values are adjusted for age, sex, BMI, comorbidities, frequency of knee pain and depressive symptoms. * indicates p<0.01 compared with 'None' Pain type

Pain type	N (%)	Outcome	Mean	Standard Error
None (i.e., never or seldom predictable	40 (6)	Steps/day	6765.4	484.2
and/or unpredictable pain)		Gait speed (m/s)	1.17	0.02
		WOMAC PF	13.9	1.5
		SF-12	42.3	1.5
Predominantly Unpredictable Pain	80 (12)	Steps/day	7339.2	383.6
		Gait speed (m/s)	1.15	0.02
		WOMAC PF*	15.7	1.1
		SF-12	42.2	1.1
Predominantly Predictable Pain	375 (56)	Steps/day	7353.1	185.0
		Gait speed (m/s)	1.17	0.01
		WOMAC PF*	18.4	0.6
		SF-12	40.8	0.6
Both Unpredictable and predictable pain	169 (25)	Steps/day	7036.1	278.1
		Gait speed (m/s)	1.15	0.02
		WOMAC PF*	21.1	0.8
		SF-12	40.5	0.8

Conclusion: While unpredictable knee pain was associated with more self-reported functional limitation, it was not associated with walking ability and frequency, or HRQOL. Similar findings were noted for those with predictable pain. Pain, regardless of its predictability, may not necessarily adversely affect engagement in walking, but does appear to affect self-perceived function.

BMI, Occupational Activity, and Leisure-Time Physical Activity: an Exploration of Risk Factors and Modifiers for Knee Osteoarthritis. Kathryn Remmes Martin[1], Diana Kuh[2], Tamara B. Harris[1], Jack M. Guralnik[3], David Coggon[4] and Andrew K. Wills[5]. [1]NIA/NIH, Bethesda, MD, [2]Medical Research Council, London, United Kingdom, [3]University of Maryland, Baltimore, [4]University of Southampton, Southampton, United Kingdom, [5]University of Bristol, Bristol, United Kingdom

Background/Purpose: Risk of knee osteoarthritis (OA) is increased by obesity, and also by physical activities which mechanically stress the joint. The few studies which have examined the interaction between body mass index (BMI) and activity have yielded inconsistent findings. We examined whether the association of BMI across adult life on midlife knee OA was modified by occupational activity and/or leisure-time physical activity (PA).

Methods: Data came from a nationally representative British birth cohort in which 2597 participants underwent clinical examination and assessment of knee OA at 53y. Main exposures at 36, 43 and 53 years: BMI (kg/m²), self-reported leisure-time PA (inactive, less-active, and most-active) and occupational activity – kneeling/squatting; lifting; climbing; or sitting, with likelihood of exposure (unlikely, somewhat-likely and most-likely) assigned using a job-exposure matrix. Odds ratios (OR) for knee OA were estimated at each time-point using logistic regression. Interactions between BMI and occupational or leisure-time PA were tested using a likelihood ratio test (LRT); where p was<0.05, we identified elevated risk by examining BMI in each activity-level, and activity in each BMI-stratum based on standard deviations (-1SD, 0SD, and 1SD). Analyses were stratified by sex, and adjusted models included socioeconomic position and health status variables.

Results: For men, evidence of an interaction between BMI and lifting (LRT p=0.01) occurred only at 43y. BMI increased knee OA risk for men who were most-likely to lift at work (OR per z-score of BMI: 3.55, 95%CI: 1.72–7.33). Interestingly, among those men most-likely to lift at work, those with lower BMI (≤0SD) were at lower risk of knee OA than those somewhat-likely to lift (-1SD - OR: 0.14, 95%CI: 0.03–0.60; 0SD - OR: 0.30, 95%CI: 0.11–0.84). For women, evidence of an interaction between BMI and leisure-time PA (LRT: p=0.005) occurred only at 43y. BMI increased knee OA risk at higher levels of PA (OR per z-score of BMI: 1.59, 95%CI: 1.26–2.00 in inactive; 1.70, 95%CI: 1.14–2.55 in less-active; and 4.44; 95%CI: 2.26–8.36 in most-active). Interestingly, among those women who were most-active, those with lower BMI (≤0SD) were at lower risk of knee

OA than those less-active (-1SD - OR: 0.14, 95%CI: 0.04–0.48; 0SD - OR: 0.36, 95%CI: 0.18–0.73).

Conclusion: Our results suggest that high BMI may be more detrimental to joint health among individuals exposed to greater levels of activity. A better understanding of these relationships may be required to optimize the potential benefits of PA and identify high risk groups within particular occupations.

Symptom Improvement in Fibromyalgia Patients Is Related to Reduced Network Connectivity As Measured by EEG Coherence. Jeffrey B. Hargrove[1], Robert M. Bennett[2], Daniel J. Clauw[3], George Mashour[3] and Lauren Briggs[4]. [1]Kettering University, Flint, MI, [2]Oregon Health & Science Univ, Portland, OR, [3]University of Michigan, Ann Arbor, MI, [4]Grand Valley State University, Allendale, MI

Background/Purpose: To assess changes in brain functional network connectivity (FC) in fibromyalgia (FM) patients treated with Reduced Impedance Noninvasive Cortical Electrostimulation (RINCE). Previous studies using fMRI have reported increased FC in FM, and pain reduction has been shown to correlate with reduced FC following intervention (Arthritis Rheum. Epub 2012). Herein, we explored the notion that FC, as evaluated by electroencephalography (EEG) coherence, would be reduced by treatment with RINCE and associated with clinical improvements.

Methods: Changes in EEG coherence in subjects receiving RINCE (N=37) were compared to subjects receiving sham (N=35). Coherence is a correlation of relative amplitude and phase between pairs of EEG signals that provides information about FC across brain regions. Under IRB-approval, eyes-closed resting EEG was collected for each subject at baseline and within one week of RINCE therapy completion. EEG was collected at 19 International 10–20 electrode sites using a linked-ear reference, sampled at 16-bits, 512 samples per second. EEG files were edited to remove non-EEG artifact. To reduce coherence biasing due to cortical volume conduction over short spatial distances, only non-neighboring electrode pairings (N=118) were analyzed. Coherence was calculated using NeuroGuide 2.0 software and low frequency (1–4Hz) signal components were analyzed and compared between groups. FM symptomatology was assessed with the Fibromyalgia Impact Questionnaire (FIQ) and the SF-36.

Results: Baseline coherence was consistent between groups in 112 of 118 electrode pairs (95%, P<0.05). Following RINCE treatment, a number of significant positive correlations in both inter- and intra-hemispherical electrode pairings were found between change from baseline coherence and improvements in total FIQ and SF-36 domains (see Figure 1). Subjects experiencing reduced coherence in the electrode pairs correlating to FIQ improvement had significantly greater improvements in FIQ total score and pain VAS scale when compared to those with stable or increased coherence (see Table 1).

Table 1. Changes in FIQ total score and pain VAS scale as a function of coherence response

	Intragroup Comparisons			
	RINCE Group		SHAM Group	
	Reduced Coherence	Increased Coherence	Reduced Coherence	Increased Coherence
Baseline FIQ	58.9	64.1	57.2	59.1
End-of-Study FIQ	35.4	53.0	49.1	57.2
P-Value	<0.001	0.023	<0.01	0.80
Baseline Pain VAS	6.9	6.6	6.7	5.5
End-of-Study Pain VAS	3.9	4.9	5.6	5.8
P-Value	<0.01	0.02	0.02	0.87

	Intergroup Comparisons					
	RINCE Group			SHAM Group		
	Reduced Coherence	Increased Coherence	P-Value	Reduced Coherence	Increased Coherence	P-Value
MCFB FIQ	−45%	−19%	<0.001	−14%	−1%	0.07
MCFB Pain VAS	−41%	−20%	0.03	−19%	+7%	0.01

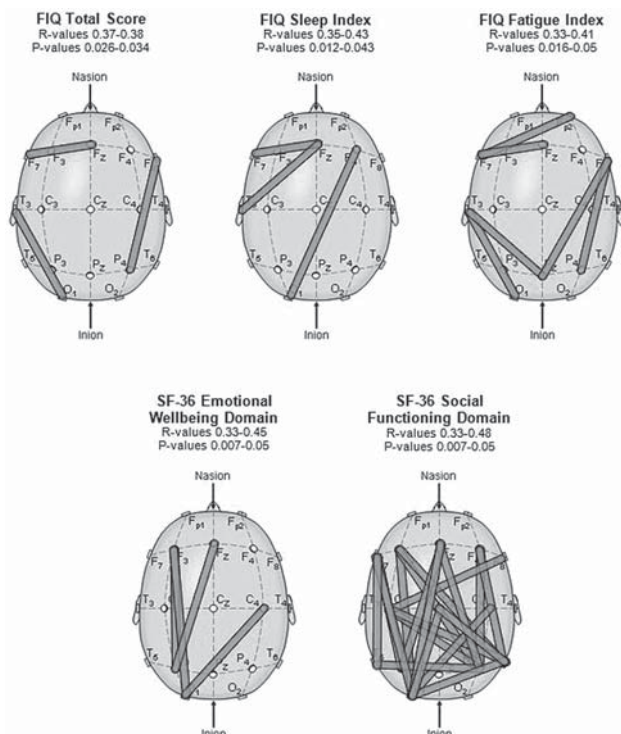
MCFB = mean change from baseline

FIQ Total Score
R-values 0.37-0.38
P-values 0.026-0.034

FIQ Sleep Index
R-values 0.35-0.43
P-values 0.012-0.043

FIQ Fatigue Index
R-values 0.33-0.41
P-values 0.016-0.05

SF-36 Emotional
Wellbeing Domain
R-values 0.33-0.45
P-values 0.007-0.05

SF-36 Social
Functioning Domain
R-values 0.33-0.48
P-values 0.007-0.05


Conclusion: In this study, improvements in FIQ total score and pain VAS scale were greatest in FM subjects showing reductions in brain functional network connectivity based on changes in EEG coherence. This result strengthens previous claims that reduced connectivity may be an objective biomarker of improvement in FM clinical trials. Importantly, it expands the methodology to the use of EEG, which is less costly than fMRI and more generally practical for use in point of care settings.

Milnacipran Reduces Brain Activity During Pain in Fibromyalgia. Anson E. Kairys, Richard E. Harris, Eric Ichesco, Johnson P. Hampson, Steven Harte, Daniel J. Clauw and Tobias Schmidt-Wilcke. University of Michigan, Ann Arbor, MI

Background/Purpose: Fibromyalgia (FM) is a chronic pain condition characterized by widespread musculoskeletal pain and a number of concomitant symptoms such as fatigue, sleep disturbance, cognitive dysfunction, anxiety, and depression. Milnacipran is a dual serotonin-norepinephrine reuptake inhibitor which has been shown to reduce pain and improve function in FM, however its clinical mechanism of action is largely unknown. Based on its neurotransmitter action in preclinical models, we hypothesized that milnacipran may decrease pain related brain activity in patients with FM.

Methods: 15 FM patients completed a randomized double-blind two-period cross-over study of milnacipran versus placebo. Each 7-week period (drug or placebo) was followed by a 14 day taper and washout.Prior to and following each period, fMRI scans were acquired for each patient. During the fMRI scanning session, pressure was applied to the patient's thumbnail bed. Two pressure intensities were delivered to all subjects in a pseudo-random sequence. One pressure intensity was individually calibrated for each subject to elicit a perceived pain rating of approximately 50/100 (moderate pain).The other pressure intensity was held constant for all subjects at 1.5 kg/cm^2. All fMRI data were pre-processed using SPM5. Regressors of interest (two pressure intensities) were convolved with the hemodynamic response function and applied to voxel-wise statistics. Images were then analyzed using a flexible factorial design within SPM5 to investigate changes in brain activations pre and post drug/placebo treatment. Regions of interest (ROIs) showing

significant changes in blood-oxygen-level-dependent (BOLD) activation during either placebo or drug were extracted and analyzed using SPSS 19.

Results: During milnacipran treatment, FM patients displayed a significant reduction in pain-evoked BOLD activity within the right posterior and left mid-insula (post- minus pre- milnacipran percent BOLD change -0.727 ± 1.09 and -0.485 ± 0.837 respectively) and left inferior parietal lobule (IPL) (mean difference $\pm$ SD: -1.08 ± 1.27; all p<0.05 corrected). None of these changes were seen during treatment with placebo, and in fact an increase in insula BOLD activity during placebo was detected (0.707 ± 0.766 and 0.630 ± 0.581 respectively). The increase in right insula BOLD during placebo appeared to be due to incomplete washout of milnacipran during the cross-over as evidenced by decreased BOLD activity pre-placebo for those taking drug first (n=8; -0.651 ± 0.489; p<0.05).No significant correlations between changes in BOLD activation for any region and improvements in clinical pain were detected (all p>0.10).

Conclusion: Milnacipran reduces pain-evoked BOLD activity within the insula and IPL. Additionally; we find a sustained decrease in insular BOLD activation which persists following the removal of the drug. Although we did not detect a relationship with pain improvement in this small sample, larger samples may be needed to associate brain activity with the clinical mechanism of action of milnacipran.These findings have implications for randomized controlled trials of milnacipran in chronic pain populations.

803

Frontal Brain Connectivity to the Default Mode Network Is Associated with Subjective Fatigue Irrespective of Pain and Depression. Johnson P. Hampson[1], Daniel J. Clauw[1], Jieun Kim[2], Vitaly Napadow[3] and Richard E. Harris[1]. [1]University of Michigan, Ann Arbor, MI, [2]Athinoula A. Martinos Center for Biomedical Imaging, Charlestown, MA, [3]Martinos Center for Biomedical Imaging, Charlestown, MA

Background/Purpose: Chronic pain patients report increased levels of fatigue; however, very little is known about the underlying mechanisms of this symptom. Previous work by our group found that chronic pain patients diagnosed with fibromyalgia (FM) have elevated levels of intrinsic connectivity between the insula and the Default Mode Network (DMN) [1], a network thought to be engaged in self-referential thinking.Moreover reductions in DMN to insula connectivity were associated with concomitant reductions in clinical pain [2]. In this exploratory analysis, we investigate the relationship between longitudinal changes in fatigue levels and variation in DMN connectivity, while controlling for pain and depression.

Methods: 17 FM patients underwent resting state fMRI at baseline and at 4 weeks following non-pharmacological intervention. Within-subject resting fMRI data analysis was performed using FSL dual-regression Independent Component Analysis as reported previously [1, 2]. Group level multiple linear regression was done with FSL using change in resting DMN connectivity from baseline to post therapy versus change in fatigue scores, correcting for age and pain or depression. Clinical fatigue, pain, and depressive symptoms were assessed with Multidimensional Fatigue Inventory, the Short Form of the McGill pain questionnaire, and the Center for Epidemiologic Studies Depression questionnaires respectively.

Results: Following therapy there was a trend for reduced fatigue levels (difference mean $= -1.37$; SD $= -0.09 \pm 2.84$; p=0.06). No significant correlation was seen between change in fatigue and pain scores (p=0.92), but a trend towards positive correlation between change in fatigue and depression (p=0.07). FM patients demonstrated significant (p<0.05 corrected) positive correlations between changes in resting DMN connectivity to multiple brain regions and changes in self reported fatigue, even after adjusting for pain and depression.These regions included the bilateral superior frontal gyrus (pain corrected r=0.79 and depression corrected r=0.80), insula (pain corrected r=0.50 and depression corrected r=0.62), and thalamus (pain corrected r=0.63 and depression corrected r=0.72).

Conclusion: This study suggests that connectivity of multiple brain regions to the DMN is associated with subjective reports of fatigue. While the insula and thalamus are known to be involved in pain processing and modulation, the superior frontal gyrus is more typically involved in cognitive function. We speculate that enhanced connectivity of this structure to the

DMN could signify altered cognitive function specifically during periods of elevated fatigue.

A Comparison of the Nociceptive Flexion Reflex, Pressure Algometry and Summated Widespread Pain in the Diagnosis of Fibromyalgia. Robert M. Bennett[1], Kim D. Jones[2] and Janice Hoffman[3]. [1]Oregon Health & Science Univ, Portland, OR, [2]Oregon Health Sciences University, Portland, OR, [3]Oregon Health & Science University, Portland, OR

Background/Purpose: To reevaluate the usefulness of the nociceptive flexion reflex (NFR) in distinguishing between FM patients and healthy controls, compared to computerized algometry and a summated measure of pain in 24 anatomical sites. NFR is a reflex contraction of the biceps femoris muscle elicited by progressive electrical stimulation of the sural nerve. It is measured as the least current (mA) required to stimulate the biceps contraction. Previous studies have reported that FM patients required less current to elicit biceps contraction than healthy controls (HC) *(Arthritis Rheum. 2003 48(5):1420–9, Pain. 2004 Jan;107(1):7–15.)*

Methods: The NFR threshold (NFRz) was evaluated by using a single ascending series of stimulations of 4 mA increments, and the biceps femoris contraction (EMG) was timed in relation to the onset of the stimulus to define the RIII reflex. The evaluation of the NFRz used a computerized NFR Interval z score, defined as NFR Interval Mean-baseline divided by the baseline SD, as previously described *(Pain. 2009 Sep;145(1–2):211–8).* B. Computerized algometry was performed at 4 paired sites (volar forearm, mid trapezius, mid gluteal area and mid-point of anterior thigh) with the average of 3 readings at each site, using an AlgoMed Pressure Algometer (Medoc, Durham, NC.) All subjects estimated their current pain level (VAS 0 –10) at 24 locations representative of widespread pain (Arthritis Res Ther. 2009;11(4); the VASs at the 24 sites were summated into a single figure (0 –; 240).

Results: The study was approved by the OHSU IRB. All subjects were female and FM diagnosis was based on the 1990 ACR criteria. The ages of the FM and HC subjects were similar, but the FM had a higher BMI. In contradistinction to 2 previously reported studies, comparing FM to HC, the NFRz was slightly higher (NS 0.18) in the FM subjects (table 1). As was expected the FM subjects had higher pain ratings on activation of the reflex, but endured more electrical stimulations (NS). Both the mean algometer scores at 4 paired sites and the summated pain at 24 locations provided a very significant discrimination between FM and HC.

	FM N=30	HC N=30	P value
Age	53.2	46.1	0.16
BMI	32.58	28.44	0.039
Current activating biceps reflex NFRz (mA)	24.94	19.10	0.180
Pain VAS at NFRz	68.06	39.66	0.004
Max Current Reached during testing (mA)	33.00	24.48	0.170
Max VAS Rating Given	87.50	66.44	0.002
Number of electrical stimulations	20.57	18.60	0.361
Mean algometer scores at 4 paired sited (kPa)	113.8	465.5	≤0.0001
Summated pain in 24 areas	111	12	≤0.0001

Conclusion: In this study, we were unable to confirm that the nociceptive flexion reflex is decreased in FM patients compared to HC. This difference maybe due to the employment, in the current study, of a computerized evaluation of the NFRz which used a strict definition of the NFRz. On the other hand, 2 less technically demanding methodologies, namely pressure pain at 4 paired sites and a summation of pain VAS at 24 widespread locations, provided a highly significant discrimination between FM and HC. These latter 2 methods need to be studied in a broad variety of rheumatic disorders to evaluate their utility in diagnosing FM in the clinical setting.

Milnacipran Increases Cortical to Brainstem Connectivity During Pain in Fibromyalgia. Eric Ichesco, Tobias Schmidt-Wilcke, Anson E. Kairys, Johnson P. Hampson, Steven E. Harte, Daniel J. Clauw and Richard E. Harris. University of Michigan, Ann Arbor, MI

Background/Purpose: Fibromyalgia (FM) is a chronic widespread pain disorder characterized by muscle tenderness, fatigue, poor sleep, and mood disturbance.Milnacipran is a dual serotonin-norepinephrine reuptake inhibitor FDA-approved for the treatment of this condition; however its clinical mechanism of action remains unknown.We used functional connectivity magnetic resonance imaging (fcMRI) to examine the effect of milnacipran on brain connectivity during evoked pressure pain.

Methods: 13 patients with FM completed a randomized double-blind two-period cross-over study of milnacipran versus placebo. Each 7-week period (drug or placebo) was followed by a 14 day taper and washout.Prior to and following each period, all subjects underwent fcMRI during which pressure was applied to their thumbnail. Two pressure intensities were delivered in a pseudo-random sequence: an individually calibrated pressure evoking moderate pain (50 on a 100 point Numerical Rating Scale [NRS]) and an equal pressure across all subjects. All fcMRI data were preprocessed and analyzed using Statistical Parametric Mapping 5 and the CONN toolbox-.Seed based functional connectivity analyses included three anterior cingulate cortex (ACC) and bilateral periaqueductal gray (PAG) regions.Paired t-test image comparisons were deemed significant at p<0.05 cluster level corrected. Pearson's r values for connectivity were extracted and correlated with clinical pain from the Brief Pain Inventory (BPI) and "average evoked pain" acquired immediately after the fcMRI run (NRS) for placebo and drug treatments using SPSS 19.

Results: Milnacipran treatment was associated with *increased* connectivity between multiple cortical regions and brain stem areas involved with descending analgesia: the perigenual ACC (seed region) showed greater connectivity to the pons and PAG (both p<0.05 corrected), and the PAG (seed region) showed greater connectivity with the bilateral mid insula cortex and the supplementary motor area/mid cingulate cortex (midCC; all p<0.05 corrected).Milnacipran also significantly *decreased* inter-cortical connectivity between the ACC seed regions and the inferior parietal lobule and midCC (p<0.05 corrected).These effects were not detected during the placebo period (all p>0.05).Interestingly increases in ACC to PAG connectivity following milnacipran were associated with the decreases in clinical pain (BPI interference: r = −0.672, p = 0.012) while decreases in connectivity between the ACC and midCC were associated with reduced levels of average evoked pain (r = 0.648, p = 0.017).

Conclusion: Here we provide the first evidence that milnacipran alters brain connectivity during evoked pain in patients with FM.The increased connectivity between the ACC and the PAG suggests that the analgesic action of milnacipran involves, at least in part, enhanced cortical modulation of brainstem sites implicated in descending antinociception. Conversely, the brain regions that show decreased connectivity during milnacipran therapy are regions where functional connectivity is increased in chronic pain states, and is associated with clinical pain report.

Posterior Insula Combined Glutamate and GlutamineIs Associated with Pain in Fibromyalgia: A Replication Study. Eric Ichesco, Daniel J. Clauw, Steven E. Harte, Anson E. Kairys, Johnson P. Hampson, Tobias Schmidt-Wilcke and Richard E. Harris. University of Michigan, Ann Arbor, MI

Background/Purpose: Central pain augmentation resulting from enhanced excitatory and/or decreased inhibitory neurotransmission is a proposed mechanism underlying the pathophysiology of functional pain syndromes such as fibromyalgia (FM). Previously, we demonstrated that glutamate (Glu), an excitatory neurotransmitter, and combined Glu and glutamine (Glx) levels are higher within the posterior insula of patients with FM [Harris et al. AnR 2009]. Moreover we also found that reduction in the levels of posterior insula Glx and Glu, following a non-pharmacologic intervention, were also associated with decreased pain [Harris et al. AnR 2008].Here we sought to replicate these findings in a separate sample of FM

patients within the placebo arm of a randomized crossover trial of milnacipran versus placebo.

Methods: Thirteen female individuals (mean age 41.8 yrs, SD = 11.0) satisfying 1990 American College of Rheumatology criteria for FM completed a randomized double-blind two-period cross-over study of milnacipran versus placebo. For the purposes of this analysis, only the placebo periods were studied.Each 7-week period (drug or placebo) was followed by a 14 day taper and washout.Prior to and following each period, proton magnetic resonance spectroscopy (^{1}H-MRS) of the right posterior insula was acquired for each patient at rest.Individual patient spectra were fit with the Linear Combination Model program and the levels of Glx were estimated relative to levels of creatine (Cr) (i.e. Glx/Cr ratio).Immediately prior to each ^{1}H-MRS scan, evoked pressure-pain was delivered to the left thumbnail bed during a functional magnetic resonance imaging (fMRI) run (fMRI data not presented here). Subjects reported their "average pain", during this fMRI run, using a numerical rating scale (0–100; 0=no pain and 100=worst pain imaginable) following each session.This pressure pain rating was correlated with Glx levels.

Results: Cross sectional analysis, prior to placebo administration, demonstrated that Glx/Cr levels were positively related to subjective pain report during evoked pressure pain (r = 0.811, p < 0.001): higher Glx/Cr was associated with greater pain.Moreover the change in Glx/Cr from pre- to post-placebo was also positively correlated with the change in evoked pain report (r = 0.697, p = 0.008): reductions in Glx/Cr were associated with reductions in pain.Glx changes were not related to clinical pain (p < 0.05).

Conclusion: Similar to our previous findings, concentrations of Glx within the right posterior insula were found to be positively correlated with pain report in both cross-sectional and longitudinal analyses. These results add to the growing body of literature indicating that ^{1}H-MRS derived levels of Glx may serve as a marker or surrogate end point for clinical trials of FM.Replication of these findings in other pain states is recommended.

Predictors of Rheumatoid Arthritis: Quantitative and Semiquantitative Sonographic Measurements of Peripheral Joints. Flavia S. Machado, Rita N.V. Furtado, Rogerio D. Takahashi, Ana Leticia P. de Buosi and Jamil Natour. Universidade Federal de São Paulo, São Paulo, Brazil

Background/Purpose: Sonographic quantitative and semiquantitative measurements in peripheral joints of normal subjects are yet to be defined, as are sonographic predictors of rheumatoid arthritis (RA). Our objetive was to estimate quantitative and semiquantitative ultrasound measurements predictors of RA in small, medium and large joints.

Methods: A cross-sectional study was carried out involving 78 healthy volunteers (HV) and 60 patients with RA (ACR), matched for age group and gender. A "blind" radiologist used a My Lab 60 XVision machine (Esaote, Biomedica - Genova, Italy) with a linear array (6–18MHz) to evaluate 6.348 joint recesses. Quantitative measurements of synovial recess (QSR) (mm) and semiquantitative measurements of synovial hyperplasia (SSH), Power Doppler (SPD) and bone erosion (SBE) (scores 0–3) were performed. To determine the chance to detect RA, ROC curve analysis for QSR measurements were performed (specificity 98.7%) and, for the semiquantitative measures, an univariate logistic regression (expressed in odds ratio - OR) was carried out. P value <0.05 was set as significant.

Results: The mean age (± SD) was 46.48 (9.14) and 43.89 (9.09), respectively for the HV and RA groups. The sample was homogeneous for gender, age group and skin color. RA group: mean disease duration was 7.89 years (± 6.76) and DAS-28 4.20 (± 1.71). Statistical difference was observed between groups for QSR (p<0.013) for most of the recesses. Mean (±SD) (mm) of QSR, respectively for HV and RA groups (HV/RA), were: radiocarpal: 2.07 (0.56)/3.24 (1.24); distal radioulnar: 1.45 (0.37)/2.28 (1.11); ulnocarpal: 1.37 (0.59)/2.74 (1.76); dorsal 2ndMCP: 1.06 (0.53)/1.51 (0.96);

palmar 2ndMCP: 0.88 (0.60)/1.40 (1.01); dorsal 3rdMCP: 0.81 (0.62)/1.24 (0.99); dorsal 2ndPIP: 0.46 (0.25)/0.76 (0.64); dorsal 3rdPIP: 0.44 (0.32)/0.83 (0.56); palmar 3rdPIP: 0.83 (0.27)/1.11 (0.55); coronoid fossa: 0.97 (1.06)/2.18 (2.27); olecranean fossa: 1.51 (1.17)/2.79 (2.65); posterior GH recess: 2.43 (0.45)/3.03 (1.29); knee: 2.21 (1.65)/3.95 (2.96); talocrural: 2.38 (1.13)/3.34 (1.99); talonavicular: 2.67 (1.10)/3.56 (1.50); subtalar: 2.15 (1.13)/3.07 (1.71); dorsal 5thMTP: 0.72 (0.70)/1.47 (1.11). Cutoff values of QSR specific of RA (AUC>0,700) were: radiocarpal 3.78mm; ulnocarpal 3.07mm; distal radioulnar 2.21mm; dorsal 3rd PIP 1.19mm; knee 6.7mm and dorsal 5th MTP 2.33mm. For semiquantitative measurements, progression from score 0 to 3, at the recesses with greater chance to detect RA were: SSH: ulnocarpal (OR=100, p<0.001); radiocarpal (OR=70, p<0.001); distal radioulnar (OR=43, p<0.001) and knee (OR=28, p<0.001); SPD: radiocarpal (OR=66, p<0.001); SBE: radiocarpal (OR=324, p=p<0.001); lateral 5thMTP (OR=100, p=p<0.001); 2nd MCP (dorsal and radial)(OR= 92, p<0.001) and ulnocarpal (OR=48, p<0.001). Inter-observer reliability for quantitative and semi-quantitative measures ranged from 0.563 to 0.872 and 0.341 to 0.823, respectively.

Conclusion: Quantitative measures specific of RA were found in almost all recesses. Semiquantitative measurements analysis showed that the worst scores found at radiocarpal, ulnocarpal and lateral 5thMTP recesses increases the chance to detect RA.

808

Power Doppler Is Predictive of Treatment Failure in Early Rheumatoid Arthritis Patients: A One Year Follow-up Study. Karine R. Luz, Rita N.V. Furtado, Marcelo M. Pinheiro, Giovanna S. Petterle and Jamil Natour. Universidade Federal de São Paulo, São Paulo, Brazil

Background/Purpose: It is known that ultrasound (US) is a useful test to monitor rheumatoid arthritis (RA) patients. However, to date, no study has shown the US parameters to be able to predict treatment failure in RA patients.Thus the aim of the present study was to evaluate the findings of a new ultrasound score (US10) of the hand and wrist joints (US10) to predict treatment failure in early RA patients.

Methods: A 12-months cohort study was carried out in patients with early RA, with less-than-1 year symptom with no previous use of disease-modifying antirheumatic drugs (DMARD). The patients underwent clinical, laboratory assessment and blinded US examination (US10) at baseline, 3, 6, 9 and 12 months. The US10 included the following joints:wrist, second and third metacarpophalangeal (MCP) and proximal interphalangeal (PIP) joints. This score was composed by the following parameters, a first one was according to inflammation: a qualitative (0–1) and semi-quantitative(0–3) scoring to synovial proliferation(SPQ10,SPSQ10) and to power Doppler (PD) (PDQ10,PDSQ10), and qualitative (0–1) gray scale and PD scores for tenosynovitis/paratendinosis (GSTN10, PDTN). A second US finding was categorised according to joint damage: a qualitative (0–1) and semi-quantitative(0–3) scoring to bone erosions (ERQ10, ERSQ10) and to cartilage damage (CAQ10, CASQ10).All patients were treated by a single rheumatologist following similar treatment protocol performed according to clinical activity criteria of the joint 28-Disease Activity Score (DAS 28) and the Physician's Global Assessment (AGM). Three treatment failures were observed over these 12 months: first DMARD failure (Failure 1), a second DMARD failure (Failure 2) and a first immunobiological failure (Failure 3).

Results: 48 patients completed the study, and 41 (85.41%) hadFailure 1, 25 (52%) had a Failure 2 and five (10.5%) patients had a Failure 3. The respective PDQ10 baseline was a predictor for Failure 1 and Failure 2 with the following cutoff values: 2.5 (S = 87.8%, E = 71.42% PPV = 94.7% and NPV = 50%) and 4.5 (S = 84%, E = 47.82%, PPV = 63.6% and NPV=73.3%). The PDSQ10 baseline was also a predictor for Failures 1 and 2 with the respective cutoff values: 5.0 (S = 90.2%, E = 71.4%, PPV = 94.9% and NPV = 55.6 %) and 9.5 (S = 84%, E = 47.82%, PPV = 63.6% and NPV 73.3%). Furthermore, there was an increase in 1.47 and 1.19 OR per unit increase in score PDQ10 to predict Failures 1 and 2 (p<0,005). The PDSQ10 at baseline also showed an OR of 1.18 and 1.7 (95%, p <0.005) to predict failure for the first and second DMARD, respectively.

Conclusion: US10, with the PDQ10 and PDSQ10 parameters was found to be useful to predict the first and second DMARD failure in early RA patients.

Ultrasonography Predicts Achievement of Deeper Remission After DAS28-Based Clinical Remission of Rheumatoid Arthritis. Ryusuke Yoshimi, Maasa Hama, Daiga Kishimoto, Reikou Watanabe, Takeaki Uehara, Yukiko Asami, Atsushi Ihata, Atsuhisa Ueda, Mitsuhiro Takeno and Yoshiaki Ishigatsubo. Yokohama City University Graduate School of Medicine, Yokohama, Japan

Background/Purpose: Although clinical remission is an agreeable goal of treatment in rheumatoid arthritis (RA), the definition is still controversial. Indeed, progressive structural damage is often found even after achieving DAS28-based remission, suggesting the criteria are not satisfactory for true remission. There is accumulating evidence that ultrasonography (US) is helpful for judgment of the disease remission. Here we investigated whether US is useful for predicting Boolean remission in RA patients who had been satisfied with DAS28-based remission criteria.

Methods: Twenty-seven RA patients who had been in DAS28-based clinical remission (DAS28-ESR < 2.6 or DAS28-CRP < 2.3) for more than 2 months were recruited and monitored for 2 years. Patients who had clinical flare-up were excluded, and the remaining patients were divided based on Boolean remission criteria at 2 years. Bilateral wrists and all of MCPs and PIPs were examined by Gray scale (GS) and power Doppler (PD) US at the entry. GS and PD signals were scored in each joint from 0 to 3, respectively. Total GS score and total PD score were calculated by summing up the score of individual joints. Hand X-ray was evaluated by van der Heijde-modified total Sharp score (mTSS) at the entry and end of study.

Results: Five patients dropped out of the study due to clinical flare-up, while DAS28 remission had been maintained for 2 years in 22 patients, including 16 patients (73%) who met Boolean remission criteria at the end of study. Both total GS score and total PD score at baseline were significantly lower in Boolean remission group than non-remission group (*Table*). There was no significant difference in other baseline parameters, including duration of disease, duration of remission, mTSS, and disease activity composite parameters between two groups (*Table*). However, the increase of patient's global visual analogue scale (gVAS) and mTSS were significantly smaller during 2 year study period in Boolean remission group than non-remission group (-4.69 ± 10.3 vs 13.2 ± 20.3, $p = 0.023$, and 0.31 ± 2.36 vs 3.67 ± 3.35, $p = 0.047$, respectively). In US findings at the entry, total GS score, but not total PD score, was associated with clinical stage, mTSS at baseline, and swollen joint count, tender joint count and gVAS at 2 years. Furthermore, Boolean remission was achieved in all of the 11 patients having total GS score 7 or less at the entry, whereas 6 (55%) of the other 11 patients failed to reach Boolean remission. On the other hand, progression of mTSS was rather associated with high total PD score, but not with total GS score, at the entry.

Table. Correlation between Boolean-based remission at 2 years and baseline variables

Baseline variable	Boolean-based Remission (*n* = 16)	Boolean-based non-remission (*n* = 6)	*p*
Age (year)	57.3 ± 11.3	55.3 ± 11.9	0.74
Sex	M: 4 cases, F: 12 cases	M: 0 cases, F: 6 cases	0.29
Duration of RA (month)	87.9 ± 50.7	70.3 ± 22.8	0.96
Duration of remission (month)	21.5 ± 19.0	17.8 ± 13.8	0.93
Clinical stage	2.06 ± 0.97	2.50 ± 0.76	0.28
modified total Sharp score	12.4 ± 11.9	33.8 ± 33.4	0.14
Total GS score	7.75 ± 6.02	16.0 ± 11.3	0.012*
Total PD score	1.06 ± 1.14	6.33 ± 6.99	0.020*
DAS28-CRP	1.59 ± 0.52	1.66 ± 0.34	0.76
DAS28-ESR	1.97 ± 0.59	2.23 ± 0.50	0.38
Boolean-based remission	6 cases (38%)	1 case (17%)	0.62
Swollen joint count	0.38 ± 0.60	1.33 ± 1.11	0.060
Tender joint count	0.25 ± 0.43	0.33 ± 0.47	1.00
Global VAS (mm)	10.6 ± 9.45	10.2 ± 4.74	0.93
ESR (mm/h)	11.6 ± 6.65	16.3 ± 17.7	0.39
CRP (mg/dl)	0.13 ± 0.16	0.04 ± 0.01	0.17
MMP-3 (ng/ml)	98.5 ± 105	51.8 ± 12.1	0.32
RF (U/ml)	85.6 ± 90.7	54.1 ± 52.5	0.49

*$p < 0.05$

Conclusion: This study shows that none or low grade of GS and PD findings in US are associated with the achievement of Boolean remission in near future and that GS findings are implicated in exacerbation of clinical parameters composing Boolean remission criteria. Thus, US is essential for assessment and prediction of "true remission" of RA.

Assessment of Omeract Global Power Doppler Ultrasonography 44-Joint Scoring System and Reduced Joint Scoring Systems in Rheumatoid Arthritis Patients Treated with Abatacept Plus Background Methotrexate. MA D'Agostino[1], R. Wakefield[2], H. Berner Hammer[3], O. Vittecoq[4], M. Galeazzi[5], P. Balint[6], E. Filippucci[7], I. Moller[8], A. Iagnocco[9], E. Naredo[10], Mikkel Ostergaard[11], C. Gaillez[12], K. Van Holder[13], M. Le Bars[12] and OMERACT-US Task Force[14]. [1]AP-HP Ambroise Pare Hospital, Boulogne-Billancourt, France, [2]University of Leeds, Leeds, United Kingdom, [3]Diakonhjemmet Hospital, Oslo, Norway, [4]University Hospital, Rouen, France, [5]University of Siena, Siena, Italy, [6]National Institute, Budapest, Hungary, [7]University Politecnica delle Marche, Ancona, Italy, [8]Instituto Poal, Barcelona, Spain, [9]Sapienza Università di Roma, Roma, Italy, [10]Hospital Severo Ochoa, Madrid, Spain, [11]Copenhagen University Hospital at Glostrup, Glostrup, Denmark, [12]Bristol-Myers Squibb, Rueil Malmaison, France, [13]Bristol-Myers Squibb, Braine-L'Alleud, Belgium, [14]Paris

Background/Purpose: The first international trial using the standardized global OMERACT Power Doppler Ultrasonography (PDUS) synovitis scoring system[1] showed early and significant signs of improvement in synovitis in abatacept-treated pts with RA, demonstrating the sensitivity of this score.[2] This trial evaluated paired MCPs 2–5 for its primary endpoint. However, there is no consensus on the minimum joint count needed to evaluate response with the OMERACT PDUS synovitis score. Additional analyses evaluated the effect of abatacept on the OMERACT global PDUS synovitis score, using a paired 22-joint count and a reduced set of joints defined here as Global Synovitis Score (GLOSS). We compare the responsiveness of GLOSS with two published reduced joint counts.[3,4]

Methods: This 6-month, single-arm, open-label study enrolled RA pts with inadequate response to MTX, and DAS28 (CRP) >3.2 or ≥6 tender and swollen joints and CRP >ULN. Global PDUS paired 22-joint score was assessed at baseline (BL); Days 7, 15, 29, 43, and 57; and then monthly by a PDUS examiner blinded from clinical assessments. A reduced subset of joints (GLOSS) that best represented the global PDUS score for paired 22 joints of all pts over three time points was identified at BL, Days 85 and 169, based on principal component analysis. The number of joints was selected based on Eigen values using a statistical method described by Jolliffe.[5] The three best subsets of paired joints, one for each time point, were identified using two methods, based on values of efficiency measure (EM) of the reduced subset: EM ≥0.6 at all three time points and the subset with the highest minimum EM over the three time points. The sensitivity to change was assessed for GLOSS and the existing 12-joint[3] and 7-joint[4] sets using standardized response mean (SRM) in a *post hoc* analysis.

Results: BL demographics and mean change from BL in global PDUS score (MCPs 2–5) over 6 months have been reported.[2] Mean change (95% CIs) from BL in global paired PDUS 22-joint score was −1.7 (−3.4, −0.1; n=87) at Day 7 and improved up to Day 169 [−15.7 (−19.0, −12.5; n=95)]. The GLOSS that best represented the global paired PDUS 22-joint score of all pts over the three time points was identified as 9 paired joints: shoulder, elbow, wrist, MCP1, MCP4, PIP2, knee, MTP3, and MTP5. When comparing the GLOSS with the published reduced joint sets (bilaterally taken), mean changes from BL improved up to Day 169 for all, with a similar SRM (Table).

Joint count	n	Mean change in joint count (95% CI)	SRM
GLOSS	84	−6.4 (−7.9, −4.9)	−0.949
12-joint set	85	−5.3 (−6.5, −4.2)	−0.994
7-joint set	85	−6.6 (−8.0, −5.3)	−1.053

n=number of pts with BL and post-BL measurements

Conclusion: Abatacept + MTX resulted in early (Day 7, by global PDUS 22-joint score) and continuous reductions in synovitis to Day 169 (with global

PDUS 22-joint score and 9-joint GLOSS). The GLOSS 9-joint subset and the 12- and 7-joint sets all demonstrated a similar sensitivity to change.

The Relationship Between Power Doppler Ultrasonography Outcomes and Clinical Efficacy in Abatacept-Treated Patients with Rheumatoid Arthritis and in Inadequate Response to Methotrexate.

MA D'Agostino[1], R. Wakefield[2], H. Berner Hammer[3], O. Vittecoq[4], M. Galeazzi[5], P. Balint[6], E. Filippucci[7], I. Moller[8], A. Iagnocco[9], E. Naredo[10], Mikkel Ostergaard[11], C. Gaillez[12], K. Van Holder[13], M. Le Bars[12] and OMERACT Ultrasound Task Force[14]. [1]AP-HP Ambroise Pare Hospital, Boulogne-Billancourt, France, [2]University of Leeds, Leeds, United Kingdom, [3]Diakonhjemmet Hospital, Oslo, Norway, [4]University Hospital, Rouen, France, [5]University of Siena, Siena, Italy, [6]National Institute, Budapest, Hungary, [7]University Politecnica delle Marche, Ancona, Italy, [8]Instituto Poal, Barcelona, Spain, [9]Sapienza Università di Roma, Roma, Italy, [10]Hospital Severo Ochoa, Madrid, Spain, [11]Copenhagen University Hospital at Glostrup, Glostrup, Denmark, [12]Bristol-Myers Squibb, Rueil Malmaison, France, [13]Bristol-Myers Squibb, Braine-L'Alleud, Belgium, [14]Paris

Background/Purpose: An exploratory study using the standardized global OMERACT Power Doppler Ultrasonography (PDUS) scoring system[1] in patients (pts) with established RA and inadequate response to MTX treated with abatacept (ABA) + background MTX demonstrated early signs of improvement in synovitis of paired MCPs 2–5 at Day 7 with further improvement up to Day 169 (Mth 6).[2] This analysis investigates the relationship between DAS28 disease status at Day 169 and PDUS improvement at Day 85 (Mth 3) using three joint counts (paired MCPs 2–5, paired 22-joints, and a reduced set of paired 9-joints [Global Synovitis Score; 'GLOSS']); and if changes in PDUS at Day 85 in any of the joint counts can differentiate between early (<3 mths) and late (>3 mths) responders.

Methods: This was a *post hoc* analysis of pts who completed 6 mths of treatment with ABA + MTX in the open-label, exploratory Phase IIIb study.[2] Global PDUS scores for paired MCPs 2–5 (range: 0–24 units), 22 joints (range: 0–132 units), and a reduced subset of 9 joints (GLOSS: shoulder, elbow, wrist, MCP1, MCP4, PIP2, knee, MTP3, and MTP5; range: 0–54 units) were assessed at baseline (BL) and Mths 3 and 6 by a blinded PDUS examiner. Changes in global and component (synovial hypertrophy, power Doppler [PD], and joint effusion) PDUS paired MCPs 2–5 scores at Mth 3 were analyzed according to remission status (DAS28 <2.6) at Mth 6. In pts reaching LDAS (DAS28 ≤3.2) at Mth 6, changes in global PDUS paired MCPs 2–5, 22 joints, and GLOSS from BL to Mth 3 were summarized according to whether pts achieved clinically meaningful improvement (CMI) in DAS28 (≥1.2) or not at Mth 3 (early vs late responders).

Results: Similar mean change from BL to Mth 3 in global PDUS and synovial hypertrophy was observed irrespective of remission status at Mth 6. A numerically greater improvement in PD signal was seen in pts who reached remission at Mth 6 vs those who did not (Table 1). In pts achieving LDAS at Mth 6, the global PDUS paired 22-joint score and GLOSS, but not MCPs 2–5, could discriminate numerically between early vs late responders (Table 2).

Table 1. Mean change (95% CIs) from BL to Mth 3 in global PDUS paired MCPs (2–5) scores and components, according to remission status at Mth 6

N=104	Global PDUS (MCPs 2–5) score	Synovial hypertrophy	Power Doppler	Joint effusion
Remission (n=37)				
Mean change (95% CI)	−4.2 (−5.9, −2.6)	−3.8 (−5.3, −2.3)	**−4.9 (−6.2, −3.7)**	−1.9 (−3.2, −0.7)
No remission (n=43)				
Mean change (95% CI)	−4.0 (−5.2, −2.8)	−3.9 (−5.0, −2.7)	**−2.6 (−3.8, −1.4)**	−1.4 (−2.4, −0.5)

Table 2. Mean change (95% CIs) in global PDUS scores from BL to Mth 3 in pts who achieved LDAS at Mth 6, according to early or late response

Patients in LDAS at Mth 6	Global PDUS (MCPs 2–5) score	Global PDUS 22-joint score	GLOSS
Early responders (at least CMI at Mth 3) (n=37)	−4.2 (−5.8, −2.5)	−12.6 (−17.2, −8.0)	−6.1* (−8.0, −4.1)
Late responders (no CMI at Mth 3) (n=10)	−4.3 (−6.2, −2.4)	−10.6 (−16.7, −4.5)	−4.3 (−6.2, −2.4)

*n=36
n is the number of pts with BL and post-BL measurements

Conclusion: This first international study using the standardized global OMERACT PDUS score showed that abatacept-treated pts demonstrated improvements in PDUS paired MCP 2–5 scores regardless of remission status at Mth 6. However, pts in remission at Mth 6 had numerically greater improvements in PD MCPs 2–5 at Mth 3 than those who were not. In pts reaching LDAS at Mth 6, improvements in all PDUS scores were seen regardless of responder status. Early responders could be identified by numerically greater improvement of either global PDUS paired 22-joint score or GLOSS.

Intravenous Golimumab Inhibits Radiographic Progression and Maintains Clinical Efficacy and Safety in Patients with Active Rheumatoid Arthritis Despite Methotrexate Therapy: 1-Year Results of a Phase 3 Trial.

Michael Weinblatt[1], Clifton O. Bingham III[2], Alan Mendelsohn[3], Lenore Noonan[3], Shihong Sheng[3], Lilianne Kim[3], Kim Hung[3], Jiandong Lu[3]. Daniel Baker[3] and Rene Westhovens[4], [1]Rheumatology & Immunology, Brigham & Women's Hospital, Boston, MA, [2]Johns Hopkins University, Baltimore, MD, [3]Janssen Research & Development, LLC, Spring House, PA, [4]University Hospital KU Leuven, Leuven, Belgium

Background/Purpose: To evaluate long-term clinical/radiographic efficacy of IV golimumab(GLM) 2mg/kg+MTX in pts with active RA despite MTX through wk 52.

Methods: Pts (n=592) with active RA (≥6/66 swollen joints, ≥6/68 tender joints, CRP≥1.0mg/dL, RF and/or anti-CCP positive at screening) despite ≥3months of MTX(15–25mg/wk) participated in this multicenter, randomized, double-blind, placebo(PBO)-controlled study. Pts were randomized to IV GLM 2mg/kg or PBO at wks0&4 and q8wks; all pts continued stable MTX. Pts randomized to PBO with <10% improvement in SJC+TJC at wk16 could early escape to IV GLM 2mg/kg (wks16&20, q8wks). All PBO pts received IV GLM 2mg/kg starting at wk24. Primary study endpoint was wk14 ACR20 response; major secondary clinical efficacy endpoints are reported through wk24. Radiographs of hands and feet were taken at baseline, wk24(wk16 for early escape) and wk52 and were scored by 2 independent readers and adjudicator (as needed) using modified vdHS score.

Results: Baseline demographic and disease characteristics were comparable between grps. 93% of pts (553/592) continued through wk52. 39 pts d/c, mostly due to AEs(18 pts).GLM+MTX-tx pts demonstrated significantly (sig) less radiographic progression (total vdHS+subscores) vs PBO+MTX at wk24. Pts randomized to PBO+MTX who began GLM at wk16/24 demonstrated marked

slowing of radiographic progression, to the same rate as pts randomized to GLM, from wk24 to wk52. At wk14, sig (p<0.001) larger proportions of GLM+MTX vs PBO+MTX pts achieved ACR20,DAS28-CRP good/moderate, ACR50 and ACR70 responses and greater median improvement in HAQ score (0.50vs0.13). Through wk52, ACR20, ACR50, ACR70, and DAS28 good/moderate response rates in pts randomized to GLM+MTX were 66%, 39%, 18%, and 81%, resp. Among pts who achieved ACR20, ACR50, ACR70 and DAS28 good/moderate responses by wk24, 82%, 72%, 61%, and 88%, resp, maintained response through wk52. Through wk52, all GLM-tx pts were followed for an average of 44wks. AEs and serious AEs occurred in 65% and 9%, resp, of GLM-tx pts (vs 43% and 4% at wk24). 1 case of TB and no serious opportunistic infections were reported through wk52. 1 pt receiving GLM+MTX (0.16%) died. Through wk52, the proportions of infusions and pts with infusion reactions were 0.7% and 3.6%, resp, (vs 1.1% and 3.5% at wk24).

Table. Summary of efficacy among randomized pts. Data shown are number (%) of pts or mean±SD/median (interquartile range).

*Primary endpoint, **, ***p-value vs. placebo + MTX < 0.01, 0.001, respectively.
*Pts with missing total vdHS score at wk24 were excluded.

Conclusion: GLM+MTX sig inhibited radiographic progression (for total vdHS and subscores) at wk24&52. Among PBO-tx pts who began GLM at wk16/wk24, marked slowing of radiographic progression, to the rate in pts randomized to GLM, was observed from week 24 to wk52. IV GLM+MTX sig improved and maintained RA signs/symptoms in pts with active RA despite ongoing MTX and continued to demonstrate an acceptable safety profile through wk52.

Rilonacept for Gout Flare Prophylaxis in Patients with Chronic Kidney Disease: Analysis of 3 Clinical Trials. Robert Terkeltaub[1], Robert R. Evans[2], Steven P. Weinstein[2], Richard Wu[3] and H. Ralph Schumacher[4]. [1]VA Medical Ctr, San Diego, CA, [2]Regeneron Pharmaceuticals Inc, Tarrytown, NY, [3]Regeneron Pharmaceuticals, Inc., Tarrytown, NY, [4]University of Pennsylvania and VA Medical Center, Philadelphia, PA

Background/Purpose: Gout flare (GF) prophylaxis in patients (pts) with chronic kidney disease (CKD; estimated glomerular filtration rate [eGFR] <60 ml/min/1.73m^2) remains challenging, since prophylaxis with NSAIDs or colchicine may not be advisable in these patients. Three phase 3 trials demonstrated that weekly subcutaneous administration of rilonacept, an IL-1 antagonist, reduced GFs in pts initiating urate-lowering therapy (ULT). This post hoc analysis of the 3 trials evaluated rilonacept in pts stratified by presence and absence of CKD.

Methods: PRESURGE-1 and PRESURGE-2 were similar randomized confirmatory efficacy trials with a 16-week treatment period (80 pts per group: placebo [Pbo], rilonacept 80mg/week [R80], rilonacept 160mg/week [R160]); RESURGE was a large 16-week randomized safety trial that also assessed GFs. Pts with eGFR <30ml/min/1.73m^2 were excluded from these studies. In this analysis, only pts with initial serum urate ≥7.5 mg/dL, ≥2 gout flares in the prior year, and initiating ULT were included. GFs/pt, and % of pts with ≥1 and ≥2 GFs were analyzed stratified by baseline eGFR <60 ml/min/1.73m^2 and ≥60 ml/min/1.73m^2, and included pts pooled from PRESURGE-1 and PRE-SURGE-2; RESURGE alone; and pts pooled from all 3 studies. Safety was based on adverse events (AEs) in the overall safety database stratified by eGFR.

Results: While pooled data from PRESURGE-1 and PRESURGE-2 showed that for pts with CKD, R80 (n=21) and R160 (n=19) reduced GFs/pt by 33% and 53% relative to Pbo (n=26), respectively, the effect on the proportion of pts with GFs was variable, likely due to low pt numbers. Results from the much larger RESURGE study showed that for CKD pts (Pbo, n=23; R160, n=63), GFs/pt were reduced by 65%, from 3.13 (Pbo) to 1.11 (R160), with fewer pts reporting ≥1 GF (41% vs 74%) and ≥2 GFs (24% vs 48%); for pts with eGFR ≥60 (Pbo, n=120; R160, n=339), GFs/pt were reduced by 75%, from 1.78 (Pbo) to 0.45 (R160), with fewer pts on R160 reporting ≥1 GF (25% vs 53%) and ≥2 GFs (10% vs 38%). Pooled data from the 3 studies showed a consistent effect of rilonacept to prevent GFs in pts with CKD across the endpoints (Table). In studies of rilonacept for GF prophylaxis, within each eGFR category the incidence of treatment-emergent AEs and serious AEs, respectively, were similar between treatment groups (eGFR <60: placebo, 64.2% and 8.6%; all rilonacept, 67.6% and 6.0%. eGFR ≥60: placebo, 59.0% and 3.3%; all rilonacept 65.6% and 3.0%), although SAEs were more frequent in the eGFR <60 subgroup.

	Placebo (n = 306)	Rilonacept 80 mg (n = 162)	Rilonacept 160 mg (n = 585)
All patients, n	304	162	585
Flares per patient, mean (SD)	1.65 (2.40)	0.51 (1.14)	0.50 (1.11)
Patients with ≥1 flare, %	54.9	28.4	26.7
Patients with ≥2 flares, %	38.2	11.7	11.3
Baseline eGFR < 60 ml/min/1.73m^2, n	49	21	82
Flares per patient, mean (SD)	2.24 (3.63)	0.86 (1.28)	0.96 (1.66)
Patients with ≥1 flare, %	59.2	42.9	39.8
Patients with ≥2 flares, %	36.7	28.6	23.3
Baseline eGFR ≥60 ml/min/1.73m^2, n	255	141	483
Flares per patient, mean (SD)	1.54 (2.08)	0.46 (1.11)	0.43 (0.98)
Patients with ≥1 flare, %	54.1	26.2	24.6
Patients with ≥2 flares, %	38.4	9.2	9.5

Conclusion: Rilonacept demonstrated efficacy and tolerability for GF prophylaxis in pts with CKD for whom other agents might be inadvisable.

Familial Aggregation and Heritability of Gout in Taiwan: A Nationwide Population Study. Chang-Fu Kuo[1], Matthew J. Grainge[1], Lai-Chu See[2], Kuang-Hui Yu[3], Shue-Fen Luo[3], Ana M. Valdes[4], Weiya Zhang[1] and Michael Doherty[1]. [1]University of Nottingham, Nottingham, United Kingdom, [2]Chang Gung University, Taoyuan, Taiwan, [3]Chang Gung Memorial Hospital, Taoyuan, Taiwan, [4]St. Thomas' Hospital, King's College London, London, United Kingdom

Background/Purpose: Gout has long been recognised to cluster within families. However, formal evidence for familial aggregation is scant and discordant and the magnitude of any genetic component remains unclear. Therefore we undertook the present study to estimate the familial risk of gout in individuals with affected first-degree relatives compared to individuals with no affected first-degree relatives.We also estimated the heritability and population attributable risk to assess the magnitude of genetic contribution to susceptibility to gout.

Methods: Using data from the National Health Insurance Research Database in Taiwan, we conducted a nationwide cross-sectional study of data collected from 11,770,921 men and 11,697,080 women in 2004. The case definition of gout consisted of a physician diagnosis and the use of gout-specific treatment. We identified individuals with first-degree relatives affected by gout and compared the prevalence of disease between individuals with and without affected first-degree relatives. The marginal Cox proportional hazard model with an equal follow-up time for all subjects was used to estimate RR and the 95% confidence interval (CI). This model was used to account for shared environment and case clustering within families with robust variance, and to adjust for age, place of residence, income levels and occupation.C:\Users\Users\zandis\Google Drive\Familial aggregation and heritability of gout in Taiwan submitting old.docx - _ENREF_16 The RR was estimated for different first-degree relative categories and for the number of first-degree relatives affected by gout. eritability (h^2) was estimated using the multifactorial polygenic model.

Results: The prevalence of gout was higher in individuals with affected first-degree relatives (6.92%) than those without (4.83%). The overall familial relative risk (RR) was 1.92 (95% CI, 1.90–1.93). The RRs (95% CIs) for an individual with an affected twin, sibling, offspring and parent were 2.89 (2.65–3.16), 2.26 (2.21–2.32), 2.07 (2.05–2.09) and 1.77 (1.75–1.78), respectively. The RR (95% CI) increased with the number of affected first-degree relatives, from 1.86 (1.85–1.88), 3.02 (2.95–3.09) and 4.48 (4.07–4.92) for one, two or three or more affected relatives. The heritability of gout was 0.46 (95% CI, 0.44–0.47). The population attributable risk associated with familial aggregation in Taiwan was 5.77% (95% CI, 5.65%–5.82%).

Conclusion: This first ever population-based study confirms that gout aggregates within families. The heritability of gout is high in the general population in Taiwan and genetic predisposition contributes to a significant proportion of gout development.

815

Exploratory Analysis of Radiographic Change in Patients Treated with Intensive Urate-Lowering Therapy. Nicola Dalbeth[1], Anthony Doyle[1], Fiona M. McQueen[1], John S. Sundy[2] and Herbert S. B. Baraf[3]. [1]University of Auckland, Auckland, New Zealand, [2]Duke University Medical Center, Durham, NC, [3]Arthritis & Rheumatism Associates, Wheaton, MD

Background/Purpose: In patients with gout, tophi are strongly associated with radiographic damage.Effective urate-lowering therapy (ULT) reduces tophus size.However, no studies to date have convincingly demonstrated that ULT can inhibit progression or promote healing of radiographic damage.Pegloticase therapy leads to dramatic reductions in serum urate (SU) concentrations and subcutaneous tophi in patients who respond to treatment.The aim of this exploratory analysis was to describe radiographic changes following treatment with pegloticase.

Methods: Serial plain radiographs of the hands and feet were obtained as standard of care from patients with severe chronic gout treated with pegloticase.Paired films at baseline and 12 months were available for nine patients.Five of these patients had films at baseline, 12 and 24 months.Radiographs were analysed sequentially in chronological order by two observers; a musculoskeletal radiologist and a rheumatologist with experience in radiographic scoring.Radiographs were scored for erosion and joint space narrowing according to the modified Sharp-van der Heijde method, validated for gout.Scorers were blinded to each other's scores and to the clinical characteristics of the patients (including the clinical response to pegloticase).Inter-observer ICCs were 0.89 (0.76–0.95) for total scores and 0.83 (0.53–0.94) for change scores.A detailed qualitative site-by-site analysis was also undertaken to define additional changes observed from baseline.

Results: All patients had sustained SU <1 mg/dL during pegloticase treatment.For the entire group, median (range) total radiographic scores reduced from 73 (1.5–138) at baseline to 60.5 (1.5–110) at 12 months, p=0.01.Median (range) erosion scores reduced from 48.5 (1.5–98.5) at baseline to 42.0 (1–71.5) after one year, p=0.003.In contrast, narrowing scores did not change over the one year period; baseline narrowing scores were 24.5 (0–43) and at one year 22.5 (0.5–41.5), p=0.26.Further reductions were observed in total scores and erosion scores in the five patients with films available at 24 months following treatment, but not in narrowing scores (one way ANOVA p=0.009 for total score, 0.02 for erosion and 0.95 for narrowing).Qualitative site-by-site analysis identified regression of soft tissue masses, increased sclerosis, and filling in of erosions in the follow-up films (Figure).

Figure 1. Paired radiographs of the fingers of the right hand in a patient with tophaceous gout A. at baseline, B. after one year of pegloticase therapy.

Conclusion: This exploratory analysis suggests that intensive urate-lowering therapy can lead to improvement in structural damage, particularly bone erosion, in patients with severe chronic gout.

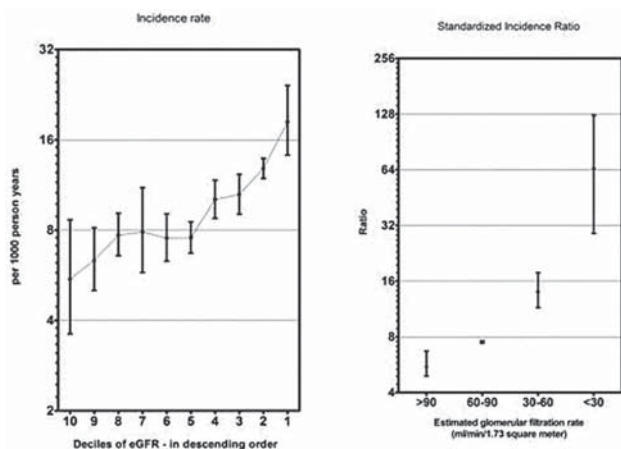
816

Glomerular Filtration Rate, Chronic Kidney Disease and Incidence of Physician Diagnosed Gout. Eswar Krishnan. Stanford University, Stanford, CA

Background/Purpose: The kidney is the major organ of urate excretion in humans. Yet, there are few studies that assess whether reduced glomerular filtration and/or kidney damage increases the incidence of gout.

Methods: Seven-year follow up data from the Multiple Risk Factor Intervention Trial, a primary prevention trial for cardiovascular disease among 12,886 men aged 35 to 57 years were analyzed. At each of seven annual visits, participants were assessed for gout by the study physician. Chronic kidney disease was defined as per the National Kidney Foundation guidelines. Standardized incidence ratios (SIR) we computed using data from the Rochester Epidemiology Project.Cox proportional hazards regression analysis was used to assess the association between gout and chronic kidney disease after accounting for the effects of potential confounders (age, race, blood pressure, alcohol and fructose consumption, body mass index, fasting triglycerides, use of aspirin, diabetes status, and diuretic use).

Results: Overall there were 722 cases of incident gout over 76,602 person-years of follow up. The incidence and SIR of goutincreased with decreasing eGFR (**Figure**). The multivariable adjusted hazard ratio for those with chronic kidney disease was 1.9 (1.6, 2.2). Each standard deviation decline in eGFR was associated with a hazard ratio of 1.4 (1.3, 1.5).Addition

of serum urate as well as urate-chronic kidney disease interaction term did not attenuate the hazard ratio.


Conclusion: Chronic kidney disease is an independent risk factor for gout. The large magnitude of the metrics of association was not explained by hyperuricemia associated with chronic kidney disease.

Feasibility of Using a Pharnacist-Based Gout Management Clinic to Improve Serum Uric Acid in Gout Patients an a Large Prepaid Health Plan. Robert D. Goldfien[1], Michele S. Ng[2], Goldie M. Yip[2], Alice Hwe[2], Alice Pressman[2] and Andy L. Avins[2]. [1]Kaiser Permanente, Richmond, CA, [2]Kaiser Permanente, Oakland, CA

Background/Purpose: Effective treatment for recurrent gout has been hampered by a number of problems including outdated treatment approaches, a failure to treat to target, and poor medication adherence by patients. To address these shortcomings, we set up referral-based gout management clinic and made it available to primary care physicians at a single Kaiser Permanente Medical Center. Patients deemed appropriate for uric acid lowering treatment were referred by their primary care physicians to the clinic.

Methods: The gout management clinic is a pharmacist-staffed, protocol-based program. The pharmacist, under the supervision of a Board Certified Rheumatologist, initiates and/or adjusts urate-lowering medications and monitored lab parameters and clinical course. The protocol employs standard gout medications (including medicatons to prevent and treat gout flares) and laboratory monitoring to achieve and maintain a serum uric acid (SUA) level of 6.0 or less. Patients are monitored until a target SUA ismaintained for at least 3 months prior to discharge from the clinic.

Results: Results for the first 100 consecutive patients enrolled in this ongoing clinic are reported here.To date, a SUA of 6.0 or less has been achieved in 67 patients, and no serious adverse reactions have been seen.The mean pre-treatment SUA was 9.3+/− 1.9 mg/dl, and the average (most recent or final) SUA with treatment is 5.9 +/−1.4 mg/dl.Thirty-five patients have already completed the program and have been discharged back to their primary care physicians. Of these, 29 were on allopurinol at a mean dose of 314 mg/day.(Range 100–750 mg).The remaining patients, were on febuxostat (3 patients and probenecid (2 patients).

Conclusion: These results show that recurrent gout can be effectively and safely managed by a protocol based population management program. This approach was efficient and required a minimal time commitment on the part of the supervising rheumatologist.

Levotofisopam Has Uricosuric Activity and Reduces Serum Urate Levels in Patients with Gout. Robert J. Noveck[1], Zongyao Wang[1], Ann Forsthoe-fel[1], Kristina Sigmon[1], Pauliana C. Hall[2], John C. Keogh[3] and John S. Sundy[1]. [1]Duke University Medical Center, Durham, NC, [2]PCH Integrated Regulatory Services, Inc., Laguna Niguel, CA, [3]Keogh Medical Writing, Philadelphia, PA

Background/Purpose: The investigational new drug levotofisopam is the S-enantiomer of racemic tofisopam, a 2,3-benzodiazepine derivative approved in over 20 countries outside the US for treatment of anxiety and autonomic instability. Two Phase 1 trials of levotofisopam in healthy volunteers demonstrated acceptable safety and unexpected reductions in serum urate (SUA). This finding raised the possibility that levotofisopam may be an effective urate-lowering therapy (ULT) in patients with gout. The objectives of this proof of concept (POC) study were to evaluate the safety and tolerability of levotofisopam and its effect on SUA in patients with hyperuricemia and gout.

Methods: This was an open-label, inpatient study of levotofisopam 50 mg TID administered for 7 days to men and women with hyperuricemia and gout.Patients were required to have had1+ gout flare in the previous 6 months,1+ chronically swollen joint due to gout, or1+ tophus; and screening SUA $\geq$8.0 mg/dL and $\leq$12 mg/dL after stopping ULT for $\geq$10 days. Key exclusions were estimated GFR <60 mL/min/1.73 m^2 and 24-hour urine uric acid excretion >1000 mg. Patients were admitted for 3 days prior to dosing and received levotofisopam 50 mg as a single dose on Day 1, 50 mg TID on Days 2–6, and 50 mg as single dose on Day 7. The primary efficacy variable was % reduction in SUA from baseline to Day 7. Secondary variables included absolute reduction in SUA, proportion of subjects with SUA <6 mg/dL on Day 7, change in fractional excretion of urate, and 24-hour urinary urate on Day 6. Adverse events (AEs) were assessed during the screening, treatment, and follow-up periods.

Results: Twenty patients were to be enrolled, but after 13 subjects were dosed, the primary objective of confirming urate-lowering potential in gout patients was achieved and the study was stopped. Baseline characteristics: mean age 47.7 years (range 39–64); 11M/2F; mean BMI 28.5 kg/m^2(range 21–33). Baseline mean SUA was 8.0 mg/dL (range 7.0–9.7). At Day 7, the mean percent reduction in SUA was 48.8% (range 31.1%–64.6%). Mean absolute reduction in SUA was 3.9 mg/dL (range 2.3–5.3), and mean treated SUA was 4.1 mg/dL (range 2.9–5.8). All 13 patients achieved a therapeutic SUA of <6.0 mg/dL. Substantial reduction in SUA was observed, to <5 mg/dL in 10/13 and <4 mg/dL in 7/13 patients. Significant increases in fractional excretion of urate and 24-hour urine urate excretion were observed. There were no serious or severe AEs or premature discontinuations due to AEs. Three patients experienced gout flare. Other AEs were musculoskeletal pain/stiffness (7), headache (6), and dizziness, diarrhea, dyspepsia, toothache, rash, and ECG lead dermatitis (2 each). No clinically meaningful changes were observed in other safety assessments.

Conclusion: Monotherapy with levotofisopam led to clinically meaningful reduction of SUA in patients with hyperuricemia and gout. Treatment was generally well tolerated with 23% of the patients experiencing gout flare. Increased fractional excretion of uric acid suggests that levotofisopam reduces SUA primarily through uricosuric activity. These results support further studies to investigate the potential role of levotofisopam for in the treatment of hyperuricemia in gout.

Trajectories of Change in Physical Function: Effects On Fractures and Mortality. Kamil E. Barbour[1], Li-Yung Lui[2], Deborah E. Barnes[3], Kristine E. Ensrud[4], Anne B. Newman[5], Kristine Yaffe[3], Steven R. Cummings[6] and Jane A. Cauley[5]. [1]Centers for Disease Control and Prevention, Atlanta, GA, [2]California Pacific Medical Center, San Francisco, CA, San Francisco, [3]University of California San Francisco, San Francisco, CA, San Francisco, CA, [4]University of Minnesota and Minneapolis VAHS, Minneapolis, MN, Minneapolis, MN, [5]University of Pittsburgh, Pittsburgh, PA, [6]San Francisco Coordinating Center, CPMC Research Institute, San Francisco, CA

Background/Purpose: Prior studies have identified poor physical function as a risk factor for fractures and mortality.However, these studies did not consider change in physical function over time.We hypothesized that women

who maintain their physical function would have a lower risk of non-traumatic fracture (hip and any non-vertebral) and death.

Methods: We followed 9704 women enrolled into the Study of Osteoporotic Fractures at four U.S. clinical centers. Physical function was measured a maximum of 8 times over 19 years. The median (range) number of measurements for walking (m/s) and chair stand speed (time/s) were 6 (1–8) and 5 (1–8), respectively. Random slope and intercept models were used to determine a walking and chair stand speed slope for each woman, and for the entire population. Three groups were formed for walking speed: "maintainers" (slope ≥ −1 SD from 0, n=773, 8%); "average decliners" (1 SD below mean ≤ slope <−1 SD from 0, n=7676, 79%); "accelerated decliners" (slope >1 SD below mean, n=1255, 13%). Cox proportional hazards models were used to estimate hazard ratios (HRs; 95% CI) of fracture and mortality and control for age, BMI, physical activity, falls, fracture after age 50, diabetes, stroke, hypertension, calcium intake, health, weight change, smoking, estrogen use, and hip BMD.

Results: The HR of hip and any non-vertebral fracture was 0.64 (0.50, 0.81) and 0.76 (0.67, 0.86) for maintainers of walking speed and 1.52 (1.31, 1.76) and 1.24 (1.13, 1.36) among accelerated decliners of walking speed when compared with the average decliner group. Similar results were shown for chair stand speed. The HR of mortality was 0.49 (0.43, 0.56) for maintainers of walking speed and 0.56 (0.50, 0.64) for maintainers of chair stand speed compared with average decliner group. The HR of mortality was null for accelerated decliners of walking speed, but surprisingly 0.75 (0.70, 0.81) for accelerated decliners for chair stand speed compared with average decliners.
Figure 1. Fracture rate per 1000 women-year

Conclusion: Women who maintained physical function up to 19 years experienced a lower risk of fractures and mortality than average decliners of physical function, suggesting that maintaining physical function may be a marker for healthy aging.

In Rheumatoid Arthritis Incident Fractures Are Associated with an Increased Risk of Cardiovascular Events. Orla Ni Mhuircheartaigh, Cynthia S. Crowson, Sherine E. Gabriel, Veronique L. Roger, L. Joseph Melton III and Shreyasee Amin. Mayo Clinic, Rochester, MN

Background/Purpose: Rheumatoid Arthritis (RA) is associated with an increased risk for both fracture (fx) and cardiovascular disease (CVD) and there is increasing evidence establishing a link between these conditions. In addition to common shared risk factors (e.g., smoking), chronic inflammation may also be key to the pathogenesis of bone loss and CVD. Our aim was to determine whether an incident fx following RA diagnosis increases the risk for subsequent CVD.

Methods: We studied a population-based inception cohort (age ≥18 yrs) who fulfilled 1987 ACR criteria for RA between 1955 and 2007 and an equal number of age- and sex-matched non-RA subjects from the same underlying population. All incident fxs, CVD events (including ischemic heart disease [IHD] and heart failure [HF]) and CVD risk factors (smoking, diabetes mellitus, hypertension, dyslipidemia) were identified through a review of complete (inpatient and outpatient) community medical records. Pathologic fxs and fxs resulting from severe trauma (e.g., motor vehicle accidents) were excluded from analyses. Subjects with prior CVD were also excluded. Adjusting for age, sex, calendar year and CVD risk factors, Cox proportional hazard models were used to examine the risk for CVD following incident fx

(modeled as a time-dependent covariate) in both RA and non-RA subjects. CVD risk factors were also modeled as time-dependent covariates.

Results: We identified 1171 RA and 1171 non-RA subjects (for each group: mean age ± SD, 57 ± 16 yrs; 822 [70%] women), of whom 137 RA and 139 non-RA subjects with prior CVD were excluded. Over a follow-up of 14,125 person-years (py) (median, 10 years) and 16,125 py (median, 12 years) for RA and non-RA subjects, respectively, 406 RA and 346 non-RA subjects had an incident fx and 284 RA and 225 non-RA subjects developed CVD. Among RA subjects, but not non-RA subjects, there was an increased risk for CVD following an incident fx (Table). Results were similar following a fx at a major osteoporotic fx site (hip, spine, wrist, shoulder) [results not shown].

	Hazard Ratio* (95% CI) for CVD following Incident Fx		
	Any CVD	IHD	HF
RA subjects	1.80 (1.35, 2.40)	1.56 (1.10, 2.20)	1.81 (1.32, 2.47)
Non-RA subjects	1.12 (0.77, 1.62)	1.09 (0.71, 1.68)	1.07 (0.70, 1.63)

* adjusted for age, sex, calendar year and CVD risk factors

Conclusion: In women and men with RA, an incident fracture is associated with an increased risk of subsequent CVD. Although the mechanism underlying this association remains to be clarified, a new fx in an RA patient should be considered a sentinel event that prompts further evaluation of their cardiovascular risk.

Association of Serum Uric Acid and Incident Fractures in Elderly Men. Nancy E. Lane[1], Neeta Parimi[2], Barton Wise[3], Peggy Cawthon[4], Eric Orwoll[5] and MrOS Investigators Group[6]. [1]UC Davis School of Medicine, Sacramento, CA, [2]CPMC Research Institute, SF, CA, [3]UC Davis, School of Medicine, Sacramento, CA, [4]CPMC Research Institute, San Francisco, CA, [5]Portland, OR, [6]Sacramento, CA

Background/Purpose: Normal mineral metabolism is critical for skeletal integrity. Uric acid (UA) is produced from purines by the enzyme xanthine oxidase, and elevated levels may cause gouty arthritis and kidney stones. High uric acid levels result in endothelial damage and play a role in disease processes including hypertension, heart failure and renal disease. Conversely, UA also appears to function as an anti-oxidant and may protect against the oxidative stress associated with aging and disease. Recently, serum uric acid was reported associated with elevated bone mineral density and lower prevalence of fractures in older men (Nabipour, JBMR 2011). To confirm this association, we performed a prospective case-cohort study to understand the relation of uric acid and fracture risk in older men enrolled in the Osteoporotic Fractures in Men (MrOS) study.

Methods: In the cohort of 5994 men 65 and older attending the baseline MrOS examination, we evaluated a subgroup 1,682 men in a case-cohort study design. This group included 387 men with incident non-vertebral fractures (with 73 hip fractures) and a sample of 1385 men randomly selected from the cohort with baseline mineral and calcium hormone measurements. Serum uric acid was measured in baseline serum samples by Unical DxC 800 auto-analyser (Beckman Coulter, Fullerton, CA, USA). All men who experienced any non-vertebral fracture from baseline until February 2007 (average follow-up 4.7 years) were included in the analysis. Incident fractures were confirmed with x-ray reports. Hip bone mineral density was obtained at the baseline. Modified proportional hazards models that account for case-cohort study design were used to estimate the relative hazards (RH) of fracture in men for serum uric acid.

Results: Subjects with incident non-vertebral fractures were older, had lower total hip BMD, and higher serum phosphorus. Cases were more likely to report a history of falls and to be frail (all p<0.01). Overall, there was no difference in risk of hip fracture by baseline uric acid after adjustment for age, clinic site, BMI, race, total hip BMD, vitamin D and PTH. However, there is 19% decrease risk of non-vertebral fractures (95% CI 0.71–0.93; p=0.003) per 1 SD increase of baseline UA after multivariate adjustment. Total hip BMD was significantly higher in the group of men with high uric acid levels and increased continuously across quartiles of uric acid after multivariate adjustment (p for trend=0.009).

Conclusion: Higher serum uric acid levels were associated with a reduction in risk of incident fractures and higher hip bone mineral density.

Greater Than Expected Increased Mortality Following Fragility Fractures in Women and Men with Rheumatoid Arthritis. Shreyasee Amin, Sherine E. Gabriel, Sara J. Achenbach, Elizabeth J. Atkinson and L. Joseph Melton III. Mayo Clinic, Rochester, MN

Background/Purpose: Women and men with RA are at an increased risk for fracture [fx] as well as greater overall mortality. It is recognized that in the general population, overall mortality among those with a fx is increased. We sought to determine whether an incident fx following the diagnosis of RA contributes to an excess mortality beyond what would be expected for an incident fracture in those without RA.

Methods: We studied a population-based inception cohort (age ≥18 yrs), who fulfilled 1987 American College of Rheumatology criteria for RA between 1955–2007, and an equal number of age- and sex-matched non-RA subjects from the same underlying population, who were followed until death or last available follow-up. All incident fxs were identified through a complete review (inpatient and outpatient) of medical records. We excluded from analyses pathologic fxs and fxs resulting from severe trauma (e.g. motor vehicle accidents, etc.). Cox proportional models were used to examine the risk for death following the first incident non-pathologic fracture resulting from no more than moderate trauma [moderate trauma fx] after RA diagnosis, or equivalent index date in non-RA subjects. All analyses were adjusted for age and sex, and fractures were modeled as a time-dependent covariate. In RA subjects, we also examined in separate analyses whether steroid use, being seropositive, or having nodules or erosions (modeled as time-dependent covariates) could account for the risk of death following fracture.

Results: In 1171 RA subjects, (822 women and 349 men, mean age at RA diagnosis ± SD: 56 ± 16 yrs and 58 ± 14 yrs, respectively), followed for 15,707 person-yrs [p-y], 440 had any moderate trauma fx, while 535 died over the available follow-up. In sex- and age-matched non-RA subjects, 374 had any moderate trauma fx and 441 died over 17,643 p-y follow-up. In RA subjects, a moderate trauma fx increased the risk for death (Hazard Ratio [HR], 2.2; 95% CI: 1.8, 2.6). An increased risk for death was also observed in non-RA subjects following a moderate trauma fx (HR: 1.5, 95% CI: 1.2, 1.9) although this risk was significantly lower (p = 0.04) than in RA. In RA subjects, any moderate trauma fracture remained a significant predictor of death even after adjusting for steroid use, being seropositive, or having nodules or erosions (HR: 1.9, 95% CI: 1.6, 2.3).

Conclusion: A moderate trauma fracture in RA is associated with a greater than expected excess mortality. Identifying characteristics or other co-morbidities among those with RA who fracture may help explain this excess risk of death following fractures.

Positive Effects of Tocilizumab On Bone Remodeling in Patients with Rheumatoid Arthritis. Karine Briot[1], Thierry Schaeverbeke[2], Fabien Etchepare[3], Philippe Gaudin[4], Aleth Perdriger[5], Muriel Vray[6], Stephanie Rouanet[7], Ghislaine Steinberg[7] and Christian Roux[1]. [1]Paris Descartes University, Paris, France, [2]Groupe Hospitalier Pellegrin, Bordeaux, France, [3]G.H. Pitié-Salpêtrière, Paris, France, [4]CHU Hôpital Sud, Grenoble Teaching Hospital, Echirolles, France, [5]Hôpital Sud, Rennes, France, [6]Paris, France, [7]Roche, Neuilly sur Seine, France

Background/Purpose: The anti-IL6-R antibody tocilizumab (TCZ) is an effective treatment of rheumatoid arthritis (RA). Previous studies showed that TCZ has a positive effect on bone turnover. However the effect of TCZ on bone mineral density (BMD) and regulators of bone remodeling pathways are limited. The objective of this ancillary study was to assess prospectively the TCZ effects on BMD and bone remodeling.

Methods: 103 patients with moderate to severe RA were treated with TCZ 8 mg/kg+ methotrexate (MTX) every 4 weeks in the Torpedo study during 12 months. Total hip and lumbar spine BMD were performed at baseline and after 48 weeks by dual energy X ray absorptiometry (DXA). Pro-collagen serum type I N-terminal propeptide (PINP), a marker of bone formation; serum C-terminalcross-linked telopeptide of type I collagen (CTX-I), a marker of bone resorption, and circulating levels of osteoprotegerin, receptor activator of nuclear factor-kappaB ligand, Wnt signalling pathway inhibitors Dickkopf-1 (Dkk-1) and sclerostin, were assessed at baseline, 12 and 48 weeks. Corticosteroid (CS) use was described using the

AUC (Area under the Curve) time weighted of cortisone intake (AUC-CS). Analysis was intent-to-treat. **Results** were presented in median and tested using the Wilcoxon paired signed-rank test.

Results: 103 patients (75 % women, 52±12 years) with active RA and a mean disease duration of 4 ±3 years were included. BMD was available for 73 patients at baseline and end of study. Serum PINP increased from baseline by 22 % (p≤0.001) and 19% (p≤0.001) at week 12 and week 48, respectively. By contrast CTX-I remained stable over the time which led to an improvement in PINP/CTX-I ratio of 14%, (p≤0.001) and 23 % (p≤0.001) at week 12 and 48, respectively. Serum DKK-1 significantly decreased from baseline by −31 % (p≤0.001) and −25 % (p=0.025) at week 12 and 48, respectively. The evolutions of DKK-1 and P1NP were not correlated. Evolutions of serum OPG and sclerostin were not significant over 48 weeks. There was no change in lumbar spine and hip BMD over 48 weeks. However in patients in the highest quartile of AUC-CS (>7.5mg/d), BMD significantly decrease at trochanter (p=0.016). CS dose was not a determinant of bone remodeling markers changes.

Conclusion: in these patients treated with TCZ in combination with MTX, we did not see the expected bone loss related to inflammation. DKK-1, a key determinant of the bone destructive pattern of RA, decreases in patients treated with TCZ which could participate to a rapid and positive effect on bone balance due to an increase in bone formation. From the results of this small sample of patients, it seems that there is no indication for prevention of CS-induced bone loss in patients receiving TCZ and low doses of corticosteroids.

824

Progressive Improvements in Cortical Mass and Thickness throughout the Hip Were Observed with Denosumab Treatment in the Freedom Trial. Ken Poole[1], Graham Treece[1], Andrew Gee[1].Jacques P. Brown[2], Michael R. McClung[3], Andrea Wang[4] and Cesar Libanati[4]. [1]University of Cambridge, Cambridge, United Kingdom, [2]CHUQ-CHUL Research Centre, Quebec City, QC, [3]Oregon Osteoporosis Center, Portland, OR, [4]Amgen Inc., Thousand Oaks, CA

Background/Purpose: Denosumab (a RANK ligand antibody) reduces remodeling, increases bone mineral density, and reduces cortical porosity in postmenopausal women with osteoporosis. In FREEDOM, denosumab treatment reduced the relative risk of hip fracture by 62% in those ≥ 75 years (Boonen et al, JCEM 2011). Bone strength at the hip, estimated by FEA from QCT scans, was significantly improved from baseline and compared with placebo (Keaveny et al, ASBMR 2010). To better characterize the changes, we used a novel cortical bone mapping technique on those same serial QCT scans, to determine the extent and distribution of mass and thickness changes at the proximal femur, a key skeletal site for fracture risk.

Methods: Eighty women age 74±5 years who participated in a FREE-DOM substudy underwent hip QCT scanning at baseline, and months 12, 24, and 36 during denosumab (60 mg SC Q6M) or placebo treatment; all subjects received calcium and vitamin D supplementation. For each femur, in addition to overall cortical density, the distributions of cortical mass (in mg per unit cm[2] of periosteal surface) and thickness were measured in a blinded-to-treatment manner. Distributed measures were transferred to an average femur by first registering each individual femur to this surface. Statistical parametric mapping was used to calculate significance of denosumab or placebo effects at each time point in relation to baseline, and between treatments. Distributed results were visualised as a color map over the average femur.

Results: In denosumab-treated women, there was a progressive increase in cortical mass over time, reaching a difference vs placebo of 6% at 3 years (p<0.0001) (Fig. 1). Approximately one-third of this increase was attributed to an increase in cortical density of 7.6±1.8 mg/cm[3]/year (p<0.0001), which in turn remained unchanged in placebo-treated subjects (p=0.62). With denosumab, cortical thickness was also significantly increased, which may represent in-filling of the cortical compartment. In contrast, average cortical mass and thickness decreased in subjects who received calcium and vitamin D alone. Mass color maps (Fig. 2) reveal the distribution of increases in cortical mass with denosumab, which were significant over an increasingly large area of the proximal femur.
Fig. 1. Mean change in cortical mass, as a percentage of baseline.

Error bars show 95% confidence intervals. *$p < 0.05$ compared with baseline. †$p < 0.05$ for denosumab compared with placebo. §Not all subjects had scans at each study time point.
Fig. 2. Additional cortical mass increase from baseline in Denosumab group compared with placebo group, as a percentage of baseline cortical mass.

Conclusion: In postmenopausal women with osteoporosis, administration of denosumab significantly and progressively increased cortical mass and thickness in regions of the proximal femur associated with hip fracture.

Rheumatoid Arthritis - Clinical Aspects II: Long-term Outcome of Rheumatoid Arthritis, Observational Studies
Sunday, November 11, 2012, 4:30 PM–6:00 PM

825

Osteoporosis and Vertebral Fractures Are Important Determinants of Cardiovascular Disease in Rheumatoid Arthritis. Ausaf Mohammad[1], Derek Lohan[1], Diane Bergin[1], Sarah Mooney[1], John Newell[2], Martin O'Donnell[1], Robert J. Coughlan[1] and John J. Carey[1]. [1]Galway University Hospitals, Galway, Ireland, [2]National University of Ireland, Galway, Ireland

Background/Purpose: Cardiovascular disease(CVD) represents a major comorbidity and the leading cause of mortality for Rheumatoid arthritis(RA) patients. Unfortunately traditional risk factors for CVD underperform in RA.

Enhanced risk stratification methods are needed. Recently a strong association between osteoporosis and CVD has been recognised in other populations. RA patients are also at increased risk of osteoporosis and thus may undergo DXA scanning as part of their usual care. DXA can diagnose osteoporosis by measuring BMD or by detecting vertebral fractures(VF) using VFA. We assessed the prevalence of osteoporosis by BMD criteria and VF in our RA cohort. We also determined whether osteoporosis increases the risk of CVD in RA patients compared to traditional CVD risk factors and RA disease activity.

Methods: A cross-sectional study of our RA cohort. We evaluated risk factors for, and details of CVD among patients ≥40 years who met 1987 ACR criteria for RA classification. Only those with a prior DXA and VFA scan available for analysis were included. Study was approved by local I.R.B. All scans were evaluated by two blinded musculoskeletal radiologists to determine the prevalence, number and severity of VF using Genant criteria. Patients were diagnosed as 'osteoporosis' using WHO DXA criteria. We compared the prevalence of osteoporosis and VF between RA patients with and without CVD, and using multivariate logistic regression analyses assessed whether VF, osteoporosis, traditional CVD risk factors and RA disease activity were independently associated with prevalent CVD.

Results: 603 patients met inclusion criteria: 74% female mean age 56 years, 76% seropositive. 230 subjects had 1 or more documented CVD event: MI 45, stent 145, CHF 33 and stroke 7. Subjects with CVD were twice as likely to have VF (24% Vs 12%) and 4 times as likely to have osteoporosis (60% Vs 15%) than those without CVD(p <0.05). Low BMD and VF were independently associated with CVD in multivariate regression analyses (P <0.05), and outperformed traditional risk factors for CVD and RA disease activity scores (Table 1).

Table 1. Age/gender adjusted OR for Osteoporosis, VF, RA Disease Activity and Traditional CVD Risk factors for CVD in RA Cohort

Variable	OR (95% Confidence Interval)	p Value
Diabetes Mellitus	1.61 (1.04–2.48)	<0.001
Smoking	1.18 (1.10–1.27)	0.042
Hypertension	1.58 (1.12–1.89)	0.001
Hyperlipidemia	1.02 (1.00–1.05)	0.041
CRP	1.73 (1.41–2.12)	<0.001
DAS28	1.63 (1.30–2.03)	0.001
Vertebral fracture	2.70 (1.50–4.75)	<0.001
Osteoporosis	2.67 (1.87–3.91)	<0.001

Conclusion: BMD and VF among RA patients should alert physicians not just to the presence of osteoporosis, but also to the possibility of CVD. Interventions to reduce the development of CVD in RA patients with osteoporosis may be warranted.

Predictors of Return to Work During 3 Years After Start of First Tumor Necrosis Factor Antagonist in a National Cohort of Biologics-Treated Patients with Rheumatoid Arthritis. Tor Olofsson[1], Ingemar F. Petersson[2], Jonas Eriksson[3], Martin Englund[2], Pierre Geborek[1], Lennart T.H. Jacobsson[4], Johan Askling[3] and Martin Neovius[3]. [1]Department of Clinical Sciences Lund, Section of Rheumatology, Lund University, Lund, Sweden, [2]Department of Orthopedics, Clinical Sciences Lund, Lund University, Lund, Sweden, [3]Clinical Epidemiology Unit, Department of Medicine, Karolinska Institutet, Stockholm, Sweden, [4]Department of Rheumatology and Inflammation Research, Sahlgrenska Academy at University of Gothenburg, Gothenburg, Sweden

Background/Purpose: To estimate predictors of return to work during 3 years following start of anti-TNF therapy in working-age RA patients with total work disability at treatment start.

Methods: RA patients aged 19–61y (n=753; mean age 53y; 80% women) starting their first anti-TNF therapybetween Jan 2006 and Dec 2009 and having total work disability at treatment start (90 days with sick leave or disability pension during the 3 months preceding anti-TNF start) were identified in the Swedish biologics register (ARTIS; 92% nationwide coverage). The mean/median disease duration at bio-start was 11y/8y, 77% were on ≥1 non-biological DMARD (corticosteroids excluded). Days of sick leave and disability pension were retrieved from the Social Insurance Agency

Sunday, November 11

S359

register covering all inhabitants in Sweden (data available until Oct 2010). Survival analysis was conducted with return to work ≥50% as outcome (defined as the first occurrence of a month with <15 days of sick leave or disability pension during follow-up). Baseline predictors including sex, age, education level, disease duration (counted from symptom onset), HAQ, CRP and use of non-biological DMARDs were estimated using Cox regression. The model was further adjusted for year of bio-start, health care region, unemployment status, depression and anxiety disorders, and malignancies. DAS28 was analysed in a separate model excluding HAQ (due to multi-collinearity) and CRP.

Results: During the 3-year observation period after start of anti-TNF treatment the overall cumulative probability of return to work ≥50% of monthly days was 21%. The corresponding probability for patients with disease duration <5y and ≥5y was 34% and 13%, respectively (Figure; unadjusted hazard ratio [HR] for return to work ≥50% 3.0, 95%CI 2.1–4.2; adjusted HR 2.4, 95%CI 1.5–3.7). Besides this, HAQ (HR 1.6, 95%CI 1.1–2.3, per unit decrease), age at bio-start (1.8, 1.4–2.2, per 10y decrease) and education level (2.1, 1.0–4.2, for >12y vs ≤9y) were also significant predictors in adjusted analysis. This was not the case for sex (p=0.08), CRP (p=0.34) or use of non-biological DMARDs (p=0.61) at bio-start. DAS28, analysed separately, was not a statistically significant predictor after adjustment (p=0.64).
Figure. Cumulative probability of work return ≥50% of monthly days for totally disabled RA patients (19–61 y) after start of first anti-TNF therapy (2006–2009) and 36 months forth, stratified on disease duration at treatment start.

Conclusion: The probability of return to work for totally disabled RA patients was higher for patients initiating anti-TNF therapy within 5 years of symptom onset. HAQ, age at bio-start and education level were also statistically significant predictors, while DAS28 and use of non-biological DMARDs were not. The results suggest that there might be a potential for increasing return to work if biological treatment was started earlier in the disease course in work disabled patients.

827

Sustained Development of Cardiovascular Disease in Rheumatoid Arthritis Despite Cardioprotective Treatment: The 10-Year Prospective Carre-Study. Alper M. van Sijl[1], Inge A.M. van den Oever[1], Mike J.L. Peters[2], Vokko P. van Halm[3], Alexandre E. Voskuyl[2], Yvo M. Smulders[2] and Mike T. Nurmohamed[1], [1]Jan van Breemen Research Institute | Reade, Amsterdam, Netherlands, [2]VU University Medical Center, Amsterdam, Netherlands, [3]Academic Medical Centre, Amsterdam, Netherlands

Background/Purpose: Rheumatoid arthritis (RA) is a chronic inflammatory joint disease which is associated with an increased cardiovascular (CV) risk. It is still unknown to what extent this is due to CV risk factors or the underlying inflammatory process in RA. With the advent of effective anti-inflammatory and cardioprotective treatment, this riskmight be mitigated or even reduced. The present study compared changes in CV risk factors, RA-related factors and medication use over time in RA-patients who did and did not develop CV disease during follow-up.

Methods: Starting from 2000–2001, 10-year incidence rate of CV disease, CV risk factors, RA-related factors and medication use were assessed in a prospective cohort of 353 RA patients at baseline, at 3-years and at 10-years of follow-up. Associations between the changes in RA related factors and development of CV disease were assessed using generalized estimating equation (GEE) analyses, while changes in all variables were assessed with general linear models (GLM).

Results: After 10 years, there were 58 CV events over 2361 patient years of follow-up, incidence rate (IR) of 25.3/1.000 patientyears. This was similar to the IR between 3-years and 10-years of follow-up: 22.8/1.000 patientyears. GLM analyses showed that use of antihypertensives, statins, TNF inhibitors and general CV risk increased significantly over time, while RA related factors improved significantly. GEE analyses showed that increased use of TNF inhibitors was positively associated with less incident CV disease.

Table 1. Changes in CV risk factors and RA-related factors during follow-up

	Baseline (n=353)	Change 0–3 years (n=226)	Change 3–10 years (n=164)
Changes in CV-risk factors			
Total cholesterol, in mmol/L	5.82 ± 1.11	−0.21	+0.05
LDL-cholesterol, in mmol/L	3.73 ± 1.03	+0.37 *	+0.07
HDL-cholesterol, in mmol/L	1.48 ± 0.48	+0.17 *	−0.07
Triglycerides, in mmol/L	1.3 (1.0–1.8)	0	0
Total-/HDL-cholesterol ratio	4.32 ± 1.48	−0.63 *	+0.10
Statins, %	9	+3 *	+5 *
Systolic BP, mmHg	141 ± 19	0	0
Diastolic BP, mmHg	81 ± 8	0	+5 *
Antihypertensives, %	24	+4	+11 *
Hypertension, %	59	−6 *	+3
DM, %	5	0	+4 *
Current smoking, %	27	−5	−10 *
Packyears	18 (1–34)	−1	+3
Body-mass index, kg/m2	26.7 ± 4.8	+0.4 *	+0.2 *
Markers for CV risk			
Intima-media thickness, mm	0.815 ± 0.136	+0.030	−0.006
10-year CV risk (SCORE)	5.0 (2.4–9.5)	+0.5	+4.4 *

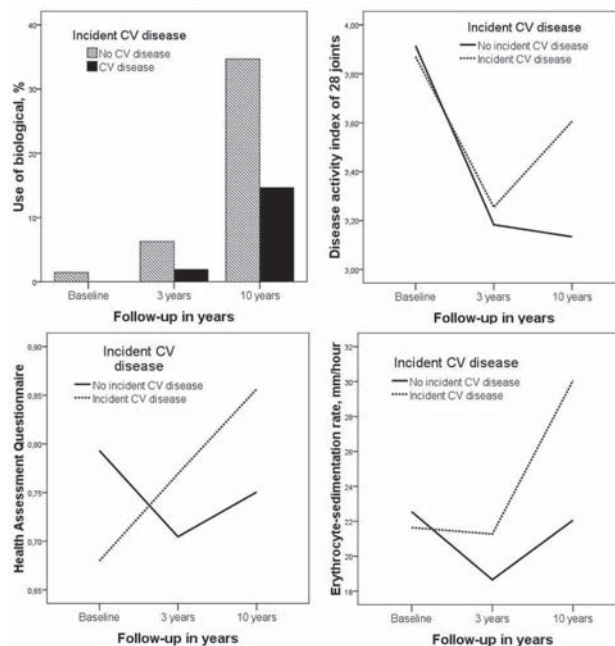
* p < 0.05. Changes in CV- and RA-related factors are investigated by General Linear Models


Figures 1–4. Changes in use of biologicals and RA factors over time stratified for incident CV disease

Conclusion: The risk of incident CV disease persists in patients with RA despite the advent of effective anti-inflammatory therapies and increased use of cardioprotective medication in recent years. Patients who used TNF inhibitors and, more indirectly, had a reduction in inflammation or disease activity, were less at risk of developinga CV disease. General CV risk and use of cardioprotective medications did not attenuate this association. A more aggressive cardioprotective and anti-inflammatory treatment of RA might mitigate the burden of CV disease in RA.

828

Association between Anti-Tumor Necrosis Factor Therapy and the Risk of Ischemic Stroke in Subjects with Rheumatoid Arthritis. Results From the British Society for Rheumatology Biologics Registers-Rheumatoid Arthritis (BSRBR-RA).

Audrey S. Low[1], Mark Lunt[2], Louise K. Mercer[1], James B. Galloway[1], Rebecca Davies[3], Kath D. Watson[4], British Society for Rheumatology Biologics Register (BSRBR) control centre consortium[1], Deborah P. Symmons[1], William G. Dixon[1], Kimme L. Hyrich[3] and On behalf of the BSRBR[5]. [1]Arthritis Research UK Epidemiology Unit, The University of Manchester, Manchester, United Kingdom, [2]University of Manchester, Manchester Academic Health Science Centre, Manchester, United Kingdom, [3]Arthritis Research UK Epidemiology Unit, Manchester, United Kingdom, [4]Arthritis Research UK Epidemiology Unit, University of Manchester, Manchester, United Kingdom, [5]British Society for Rheumatology, London, United Kingdom

Background/Purpose: Subjects with rheumatoid arthritis (RA) are at increased risk of cardiovascular (CV) morbidity and mortality, with some studies suggesting an increased risk of stroke (CVA). The aim of the analysis was to study the association of anti-TNF therapy with ischemic CVA (isCVA) in routine clinical practice.

Methods: The BSRBR-RA is an ongoing national prospective cohort study of subjects with RA recently started on anti-TNF therapy (etanercept, infliximab, adalimumab). A biologic-naïve comparator cohort of subjects with RA treated only with non-biologic disease modifying anti-rheumatic drugs (nbDMARDs) was also recruited. Both cohorts were recruited from 2001–2008 and were followed by physician and patient questionnaires every six months for the first three years and annual physician questionnaires thereafter, in which data on serious adverse events such as CVAs and drug therapy were reported. All subjects were also linked to the national death register. Further data about reported CVAs were collected from medical records and validated against the World Health Organization criteria for CVA. These were further classified as isCVA using CT brain reports or if isCVA was reported as the underlying cause of death from death certificates using International Classification of Diseases 10 (ICD-10) code I63. Only validated isCVAs were included in the analysis. Subjects with prior CVA were excluded. Subjects were censored at first isCVA, death or date of last physician follow-up, whichever came first. Risk of isCVA was compared between the nbDMARD cohort and subjects ever exposed to anti-TNF using a Cox regression model. Adjustment was made using propensity scores stratified by deciles, which included age, gender, ethnicity, BMI, DAS28, disease duration, HAQ, prior nbDMARD use, steroid use at baseline, year of entry to study, smoking, baseline drugs including NSAIDs, digoxin, warfarin, antiplatelet agents, statins, history of cancer, hypertension, ischaemic heart disease, diabetes, depression and chronic lung disease.

Results: To 10/31/2010, 130 verified incident isCVA (21 in 3271 nbDMARD subjects, 109 in 11642 anti-TNF subjects) occurred during 11973 and 61226 person-years (pyrs) of observation respectively (incidence rate 175 versus 178 per 100,000 pyrs). After adjustment, there was no association between ever exposure to anti-TNF and isCVA risk: hazard ratio (HR) 0.88 (95% CI 0.46, 1.71).

Table.

	nbDMARD (n=3271)	Anti-TNF (n=11642)
Age (years), mean (SD)	60 (12)	56 (12)
Female, %	74	77
Disease duration (years), median (IQR)	6 (1,15)	11 (6, 19)
Baseline DAS28, mean (SD)	5.3 (1.1)	6.6 (1.0)
Baseline HAQ, mean (SD)	1.5 (0.7)	2.0 (0.6)
Number of prior nbDMARDs, median (IQR)	2 (1, 3)	4 (3, 5)
Baseline steroid use, %	22	44
Baseline NSAID/COX2 use, %	55	63
Hypertension at baseline, %	31	30
Person-years of follow-up	11973	61226
Person-years of follow-up per person, median (IQR)	3.9 (2.1, 5.2)	5.6 (3.9, 6.9)
Number of incident fatal & non-fatal isCVA	21	109
Crude incidence rate of isCVA per 100,000 pyrs (95%CI)	175 (128, 297)	178 (151, 221)
Risk of isCVA in subjects ever exposed to anti-TNF therapy	–	–
Unadjusted HR (95% CI)	Referent	1.07 (0.67, 1.71)
Adjusted for age & gender (95% CI)		1.49 (0.92, 2.40)
Fully adjusted-stratified by deciles of propensity score (95%CI)		0.88 (0.46, 1.71)

Conclusion: Exposure to anti-TNF therapy does not appear to be associated with the risk of isCVA over the short term when compared to nbDMARD therapy. Further follow-up is needed to assess time-varying risk.

829

Subcutaneous Nodules Are Significantly Associated with Cardiovascular Events in Patients with Rheumatoid Arthritis: Results From a Very Large US Registry.

Prashant Kaushik[1], Susan P. Messing[2], Jyoti Arora[2], George Reed[3], Katherine C. Saunders[4], Jeffrey D. Greenberg[5] and Joel M. Kremer[6]. [1]Sratton VAMC, Albany, NY, [2]University of Rochester School of Medicine and Dentistry, Rochester, NY, [3]UMass Medical School, Worcester, MA, [4]CORRONA, Inc., Southborough, MA, [5]New York University School of Medicine, New York, NY, [6]Albany Medical College and The Center for Rheumatology, Albany, NY

Background/Purpose: Cardiovascular Disease (CVD) is now recognized to be a major comorbidity of patients with rheumatoid arthritis.Predictors of CVD have been shown to include a variety of measures of RA disease activity and severity (1). Although subcutaneous nodules (SQN) are associated with more severe RA, until this time there had been no clinical phenotypic characteristic which was immediately recognizable as a marker of increased risk for CVD in patients with RA.

Methods: Data are from the CORRONA database from Oct 2001 to Sept 2011 was evaluated.23327 patients with RA, including 182,201 individual visits who have an average of 3 years of follow-up dataand with 70455 patient-years and 795 CV events are included in this analysis. Presence or absence of SCN have been routinely collected over the entire 11 year history of the registry.CV events (ischemic heart disease including MI, stroke/TIA, CHF and CV death) were defined by MD reported events and exclusion of events not confirmed by the sites completing a follow up form.Cox regression models were used to estimate HR for time to first event with entry into CORRONA as the origin.Unadjusted and adjusted Hazard Ratios (HR) for SCN were estimated. A multivariable model was fit that considered the following factors as possible covariates: age, gender, age of onset of RA, presence of diabetes mellitus (DM), hypertension, smoking, alcohol consumption, use of a lipid lowering agent.Significant factors were retained in the model.

Results: Table 1 shows the estimated HR for SCN unadjusted and then adjusted with the covariates considered in the model. Unadjusted HR for SCN is 1.44, 95% CI: [1.23–1.67].Adjusted HR is 1.25 [1.07–1.46]. An interaction of age and gender provided a better fit of the model, females with a steeper increase in risk with age than males.

Table 1. CV risk associated with subcutaneous nodules adjusted and unadjusted Hazard Ratios (HR)

	HR	95% CI	p-value
Subcutaneous Nodules (unadjusted)	1.44	[1.23–1.67]	<0.0001
Multivariable Model			
Subcutaneous Nodules	1.25	[1.07–1.46]	0.0048
History of CVD	2.89	[2.40, 3.48]	<0.0001
Diabetes	1.72	[1.40,2.10]	<0.0001
Hx of Hypertension	1.47	[1.25, 1.73]	<0.0001
Current Smoker	1.39	[1.16, 1.66]	0.0003
Current Drinker	0.74	[0.63, 0.86]	0.0002
Age Onset of RA (per year)	1.004	[1.001, 1.007]	0.121
Lipids Measured	1.65	[1.21, 2.23]	0.0014
Age (Males)* (per year)	1.01	[1.00, 1.02]	0.049*
Age (Females)* (per year)	1.03	[1.02, 1.04]	
Females vs Males (at age 40)*	0.39	[0.26, 0.60]	
Females vs Males (at age 70)*	0.59	[0.50, 0.70]	

*Age-Gender interaction included in the model; p-value for test of interaction.

Conclusion: We report for the first time, from a very large US observational registry, that SCN confer a significantly increased likelihood of CVD in patients with RA followed for a period of > 3 years. While active RA is a risk factor for CVD the presence of subcutaneous nodules, an immediately assessable and accessible clinical phenotype, confers an increased risk for this major comorbidity.

Background/Purpose: To report the five-year outcome of a large national multicentre, longitudinal and prospective cohort of patients with very early arthritis and rheumatoid arthritis (RA), the so-called "ESPOIR cohort study".

Methods: Patients were recruited if they had early arthritis of less than 6 months disease duration, a high probability to develop RA, and if they were DMARD and steroids naïve. Patients have been followed every 6 months during the first 2 years then every year. Logistic regression analysis was used to determine predictive factors of outcome.

Results: 813 patients were included. The mean age was 48.1 ± 12.6 years, the main delay for referal was 103.1 ± 52.4 days. DAS28 score was 5.1 ± 1.3, HAQ DI was 1.0 ± 0.7. 44.2 % and 38.8 % had respectively IgM rheumatoid factor or anti-CCP antibodies. These rate remained stable during follow-up. 22 % of the patients had erosions on hand or feet at baseline. 78.5 % of the patients fulfilled the 2010 ACR/EULAR criteria for RA at baseline and 93.8 % during follow-up.573 patients were evaluated at the 5-year follow-up visit. The outcome was rather mild in most of the patients. Disease activity (median DAS28 score: 2.5) and HAQ DI (median: 0.3) were well controlled overtime. The annual rate of radiographic progression was low (2.9 modified Sharp score unit/year). A minority of the patients required joint surgery and no increased risk of co-morbidities was observed. During the 5-year follow-up, 82.7% of the patients received at least one DMARD, which was mainly MTX (n=536; 65.9 %) usually prescribed as monotherapy.18.3 % of the included patients were treated with a biological DMARD and almost 60 % of the whole cohort received at least once, prednisone with a mean dosage of 8.8 ± 7.7 mg/day. Anti-CCP antibodies were the best predictive factor of radiographic progression, prescription of both synthetic or biologic DMARDs or still being followed in the cohort at 5-year

Conclusion: The quite favourable 5-year outcome of this very early RA cohort highlights the need for early referral, early effective treatment and close monitoring in the management of patients with early arthritis in daily practice.

ACR Concurrent Abstract Session
Rheumatoid Arthritis Treatment - Small Molecules, Biologics and Gene Therapy: Efficacy and Safety of Novel Entities
Sunday, November 11, 2012, 4:30 PM–6:00 PM

A Randomized, Double-Blind, Placebo-Controlled, Multiple-Dose Study to Evaluate the Safety, Tolerability, and Efficacy of Brodalumab (AMG 827) in Subjects with Rheumatoid Arthritis and an Inadequate Response to Methotrexate. Karel Pavelka[1], Yun Chon[2], Richard Newmark[2], Ngozi Erondu[2] and Shao- Lee Lin[2]. [1]Institute and Clinical of Rheumatology, Charles University, Prague, Czech Republic, [2]Amgen Inc, Thousand Oaks, CA

Background/Purpose: A potential role for IL-17 in rheumatoid arthritis (RA) has been supported by data from clinical studies of inhibitors of the IL-17A ligand. To evaluate efficacy and safety of brodalumab (AMG 827), a human monoclonal antibody inhibitor of the IL-17 Receptor, in subjects with RA.

Methods: Subjects with RA who had an inadequate response to methotrexate (ie, continuing RA symptoms) and were biologic-naïve were randomized 1:1:1:1 to receive brodalumab (70, 140, or 210 mg) or placebo subcutaneously at day 1 and weeks 1, 2, 4, 6, 8, and 10 (Q2WK). Primary endpoint was proportion of subjects achieving an American College of Rheumatology (ACR) 50 response at week 12. Secondary endpoints included proportion with ACR 20 and 70 at week 12 and Disease Activity Score 28 joint (DAS28) at week 12. Safety was assessed by monitoring adverse events (AEs). Analyses were based on intent to treat using non-responder imputation.

Results: Two hundred fifty-two subjects were randomized; 189 to brodalumab and 63 to placebo. Two hundred forty-two subjects (183 [97%] AMG 827; 59 [94%] placebo) completed the study (defined as 16 weeks of study evaluations). Demographics and baseline characteristics were generally balanced among treatment groups. The majority ($> 75\%$) of subjects were female and white. In subjects treated with brodalumab and placebo, respectively, mean (SD) age was 50.6 (11.5) years and 53.3 (10.3) years, mean weight was 72.8 (15.1) kg and 74.8 (16.5) kg, mean duration of RA was 8.1 (7.9) years and 7.5 (6.9) years, mean Disease Activity Score 28 joint (DAS28) was 6.5 (0.8) and 6.4 (0.8), and mean C-reactive protein (CRP) was 12.8 (12.1) mg/L and 14.6 (17.6) mg/L.

ACR 50 at week 12 occurred in 16% (70 mg), 16% (140 mg), 10% (210 mg), and 13% (placebo; all non-significant vs placebo) of subjects. Differences in ACR 20 and 70 were non-significant ($p > 0.05$) for any treatment group as compared with placebo. Mean (SD) change from baseline in DAS28 at week 12 was −1.4 (1.3), −1.3 (1.2), −1.3 (1.2), and −1.3 (1.2) for the 70 mg, 140 mg, 210 mg and placebo groups, respectively. The p-values for DAS28 at week 12 in brodalumab treatment groups compared with placebo were all non-significant ($p > 0.05$). Mean (SD) percent CRP change was 97.5 (345.4), 50.7 (168.7), 45.1 (159.3), and 33.5 (170.3) for the 70 mg, 140 mg, 210 mg and placebo groups, respectively. No differences in efficacy outcomes for subgroup analyses based on sex, age, weight, or region were observed. Incidences of all AEs, including serious AEs (SAEs), were similar across treatment groups. A total of 7 subjects reported SAEs during the study (2 in the placebo group and 5 in the brodalumab groups), none of which was treatment related. There was 1 death (cardiopulmonary failure) 1 week after last dose in the 140 mg group.

Conclusion: There was no evidence of meaningful clinical efficacy or change in CRP with brodalumab treatment in subjects with RA who had an inadequate response to methotrexate. Short-term treatment was well tolerated across a dose range of 70 to 210 mg and these analyses did not suggest any safety risks with brodalumab administration. These preliminary results do not support further evaluation of brodalumab as a treatment for RA.

832

Peroxisome Proliferator-Activated Receptor Gamma Agonist Treatment for Rheumatoid Arthritis: A Proof-of-Concept Randomized Controlled Trial. Michelle J. Ormseth, Annette M. Oeser, Andrew Cunningham. Aihua Bian, Ayumi Shintani, S. Bobo Tanner and C. Michael Stein, Vanderbilt Medical Center, Nashville, TN

Background/Purpose: Rheumatoid arthritis (RA), a chronic inflammatory disease, is associated with insulin resistance.Experimental evidence indicates that the relationship between insulin resistance and inflammation is bi-directional: inflammation promotes insulin resistance, and insulin resistance promotes inflammation. Therefore, we examined the hypothesis that improving insulin sensitivity with pioglitazone, a thiazolidinedione PPAR-γ agonist, would decrease inflammation in patients with RA.

Methods: In a single center, randomized, double blind, placebo-controlled cross-over trial of 20 weeks duration, patients with RA (n=34) and moderate disease activity receiving stable disease modifying anti-rheumatic drug therapy were randomized to receive either pioglitazone 45mg daily (n=17) or matchingplacebo (n=17) for 8 weeks in addition to current therapy. This was followed by a 4 week wash-out period and then patients received the alternative regimen for the next 8 weeks.Primary outcome measures were change in DAS28 score; individual components of the DAS28 score including tender and swollen joint count, patient reported disease activity based on visual analog scale (VAS), and acute phase reactants; and change in insulin resistance determined by the homeostatic model assessment for insulin resistance (HOMA). Disease activity variables, inflammatory markers, and fasting insulin and glucose were measured. Analysis was by intention to treat and linear mixed effect models were used to determine the effect of pioglitazone on outcome measures.

Results: Patients had a median [IQR] age of 52.5 years [44.2–59.5 years], 82% were female and baseline median DAS28 CRP was 4.24 [3.62–5.6]. Compared to placebo, the addition of pioglitazone was associated with a 0.368 unit (95% CI, 0.0002–0.735) reduction in DAS28 CRP, (P=0.036), a 48.7% (28.5–63.1%) decrease in CRP (P<0.001), and a 23.7% (1.1–41.1%) decrease in insulin resistance as measured by HOMA (P=0.04). There was no significant reduction in swollen (P=0.83) or tender joint count (P=0.43), and a non-significant trend toward decreased patient reported disease activity VAS by 9.8mm (−0.1–19.7mm) (P=0.05). There was no significant change in ESR (p=0.27) or DAS28 ESR (P=0.92). Lower extremity edema was more common during pioglitazone (16%) treatment than placebo (0%); otherwise, adverse events occurred with similar frequency.

Conclusion: The addition of pioglitazone to current RA treatment improves insulin resistance and modestly reduces RA disease activity measured by DAS28 CRP and CRP levels.

A Phase 1, Randomized, Double-Blind, Placebo-Controlled Multiple-Dose Study of Intravenous Staphylococcal Protein A in Patients with Active Rheumatoid Arthritis On Methotrexate: Safety, Pharmacokinetics and Efficacy. Edward Bernton[1], Eduard Krantz[2] and William Gannon Jr.[3]. [1]Protalex Inc., Summit, NJ, [2]Parexel Clinical Pharmacology, Bloemfontein, South Africa, [3]Capital City Technical Consulting, Inc., Washington, DC

Background/Purpose: PRTX-100 is highly-purified GMP staphylococcal protein A (SpA) that binds with extremely high affinity to the Vh antibody framework region of Clade Vh3 immunoglobulins.SpA thus binds to human monocytes and Vh3 B-cells and, at concentrations of <50 ng/mL, SpA can inhibit their activation *in vitro*. In 1999 the FDA licensed an immunoabsorbent device for treatment of RA and subsequently it was demonstrated that these treatments exposed patients to low doses of SpA.Phase I studies have characterized the safety of single intravenous doses of SpA up to 0.45 μg/kg.

Methods: This phase I multicenter sequential dose-escalation study enrolled patients with active RA on methotrexate (mean DAS28-CRP of 5.78).Sequential cohorts were treated with 0.15, 0.45, 0.9 or 1.5 μg/kg of PRTX-100 or placebo, administered weekly for 4 weeks.Safety and disease activity were evaluated over 16 weeks following the first dose.The primary disease activity response endpoint was the number of patients with a DAS28-CRP <3.2 at Week 6.Pharmacokinetics were evaluated after the first and last dose.

Results: A total of 37 patients were enrolled.PRTX-100 was generally safe and well-tolerated; 3/29 PRTX-100-treated patients had mild to moderate infusion reactions, which were self-limiting and related to dosing rate.Transient flare of RA occurred in 4/29 of PRTX-100 patients.The relationship of dose to PRTX-100 C_{max} and AUC was linear, but clearance and AUC were extremely variable within dose cohorts.The mean C_{max} at 1.5 μg/kg was 51.9 ng/mL.PRTX-100 elicited anti-drug antibodies (ADAs) in the majority of patients but the incidence or titer of ADAs was not dose-dependent.Higher titer ADAs were associated with an increased plasma clearance after the fourth dose.The development of ADAs did not appear to preclude an effect of PRTX-100 on measures of disease activity. The endpoint of DAS28-CRP <3.2 at Week 6 was met by 3/29 PRTX-100 and 0/8 placebo patients.PRTX-100 treatment did not decrease CRP, even in patients whose swollen and tender joint count and global VAS decreased to low levels after treatment.A post-hoc analysis was performed examining changes in CDAI scores in all patients to remove the influence of the CRP component.At baseline the mean CDAI score for study patients was 36.8.In the placebo, 0.15 μg/kg and 0.45 μg/kg PRTX-100 groups, 1/8 patients attained low disease activity (CDAI ≤10) on two or more consecutive visits.Two of eight and 2/5 patients in the 0.9 and 1.5 μg/kg PRTX-100 groups, respectively, attained this same endpoint and maintained CDAI ≤10 for 12 weeks after the end of treatment.Of the 4/5 responders in the 1.5 μg/kg group, two attained a CDAI ≤6 (remission), one attained a CDAI ≤10 (low activity), and one attained a CDAI of 10.1 over the course of the study.The mean time to peak response in this group was 70 days.

Conclusion: Four weekly doses of intravenous PRTX-100 demonstrated an acceptable safety profile and, at the higher doses, decreased RA activity as scored by CDAI.Results of this pilot study support further clinical trials of PRTX-100 at doses of 1.5 μg/kg and higher.

Cetrorelix, a Gonadotropin-Releasing Hormone Antagonist, Significantly Reduces Tumour-Necrosis-Factor-Alpha and Demonstrates Efficacy in Patients with Active Rheumatoid Arthritis: A Proof-of-Concept, Double-Blind, Randomised Trial. Anita Kåss[1], Øystein T. Førre[2], Morten Fagerland[2]. Hans Christian Gulseth[3], Peter Torjesen[4] and Ivana Hollan[5], [1]University of Oslo, Oslo, Norway, [2]Oslo University Hospital, Oslo, Norway, [3]Betanien Hospital, Skien, Norway, [4]Oslo University Hospital, Norway, [5]Lillehammer Hospital for Rheumatic Diseases, Lillehammer, Norway

Background/Purpose: The pathogenesis of rheumatoid arthritis (RA) is unclear, and treatment options can be improved. Gonadotropin-releasing hormone (GnRH) stimulates immune responses (1) and therefore might be pro-inflammatory in RA. We investigated the short-term effects of a GnRH-antagonist, cetrorelix (which rapidly decreases luteinizing hormone [LH] and follicle-stimulating hormone [FSH]), in a proof-of-concept study in RA.

Methods: In this double-blinded, single-site study in Norway (ClinicalTrials.gov NCT00667758), 99 patients with active longstanding RA, were randomised to predefined intention-to-treat populations using computer-generated allocation (1:1) in dynamic blocks stratified for sex. Patients were assigned to subcutaneous cetrorelix (n=48) (5 mg days 1–2, 3 mg days 3–5) or placebo (n=51). The primary endpoint was the change in disease activity score (DAS28CRP) by day 5, when the greatest LH and FSH suppression was anticipated. Secondary endpoints included change in tumour necrosis factor-α (TNF-α), American College of Rheumatology (ACR) responses, and DAS28CRP<2.6 remission by day 5. Patients were followed up on days 10 and 15.

Results: By day 5, the change in DAS28CRP was −0.82 (95% CI –1.06, –0.58) in the cetrorelix group and –0.57 (–0.76, –0.37) in the placebo group, between-group difference 0.26 (–0.04, 0.57, p=0.091).By day 5, TNF-α (log pg/mL) was significantly decreased in the cetrorelix group (–0.58) compared with the placebo group (–0.02; difference 0.55 [0.08, 1.01], p=0.023), and more patients on cetrorelix achieved ACR20 responses (40% *vs* 18%; p=0.015) and DAS28CRP<2.6 remission (13% *vs*0%; p=0.009). Serum CRP levels were clinically relevantly reduced in the cetrorelix group versus placebo (−0.28 vs. 0.045mg/dL, p=0.060); followed by a reduction in ESR levels by day 15 (−1.06 vs. 5.04, p=0.051). Disease activity markers rebounded towards baseline after cetrorelix withdrawal, except erythrocyte sedimentation rate, which is slower to change. Adverse event rates were similar between groups.

Conclusion: This study demonstrates antagonizing GnRH with cetrorelix lowers TNF-α, and improves signs and symptoms of RA. The novel association between GnRH and TNF-α may improve insights into the pathogenesis and treatment of RA, and potentially other autoimmune diseases. Larger, long-term studies on the efficacy and safety of GnRH antagonists in RA patients are warranted.

Low Doses of Ocaratuzumab, a Fc- and Fab-Engineered Anti-CD20 Antibody, Result in Rapid and Sustained Depletion of Circulating B-Cells in Rheumatoid Arthritis Patients. Adrienne O'Reilly, Tracy Davis and Vinay Jain. Mentrik Biotech, Dallas, TX

Background/Purpose: B-cell depletion provides therapeutic benefits for patients with rheumatoid arthritis (RA). Ocaratuzumab, previously known as AME-133v, is a Fc- and Fab-engineered, humanized, anti-CD20 monoclonal antibody designed for optimized affinity to the CD20 antigen as well as to the CD16 (FcγRIIIa) receptor on effector cells. It demonstrates 13–20 fold higher affinity for CD20 and 6-fold higher antibody-dependent cellular cytotoxicity as compared to rituximab, which is currently approved for RA. Because patients with low affinity FcγRIIIa receptors historically have poor B-cell depletion with rituximab, there is a need for monoclonal antibodies that improve the rate of B-cell depletion in these patients. The ability of ocaratuzumab to deplete B-cells in patients with RA was studied in a dose escalation phase I study.

Methods: Five RA patients were treated with a single intravenous (IV) dose of 5 mg of ocaratuzumab, and three patients received 7.5 mg IV of ocaratuzumab. Patients were followed for B-cell depletion and recovery.

Results: Rapid B-cell depletion was seen in all patients in both the 5 mg and 7.5 mg cohorts (Figure 1). This depletion, with CD20+ cells either absent or very low, was seen as early as 3 hours after the start of infusion. Although most patients began to recover their B-cell counts within seven days of the infusion, at two months, the circulating B-cell counts were less than 50% of baseline in 5 of the 8 patients treated with ocaratuzumab.
Figure 1. B-cell depletion with a single 7.5 mg IV dose of ocaratuzumab

The subjects were followed beyond the Day 85 visit to monitor the recovery of their B-cells. Four patients had follow-ups up to 3 months after Day 85, two patients up to four months, and two patients up to 6 and 13 months, respectively. Based on review of the adverse events, no suggestion of susceptibility to infection was seen.

As expected, administration of the larger dose led to a greater C_{max}. In the 7.5 mg cohort, C_{max} was 1720 ng/mL and 1620 ng/mL in the 5 mg cohort. The AUC of the drug was 24,000 ng·hr/mL in the 7.5 mg cohort and 4160 ng·hr/mL in the 5 mg cohort.

Conclusion: Even when administered at doses that are less than 100 fold that of rituximab, ocaratuzumab demonstrates rapid and prolonged B-cell depletion in RA patients. The majority of the patients treated with very low doses of ocaratuzumab demonstrated protracted B-cell depletion lasting for three months, with one patient recovering B-cells more than one year after receiving 7.5 mg of drug. Ocaratuzumab may provide a therapeutic option for patients with autoimmune diseases, especially those with the low affinity FcγRIIIa phenotype, who have not received optimal benefit from conventional monoclonal antibodies. Furthermore, ocaratuzumab can potentially be given at doses much smaller than that of the conventional antibodies, possibly permitting subcutaneous administration.

Clinical Responses and Patient Reported Outcomes to NNC0109-0012 (anti-IL-20 mAb) in RheumatoidArthritis (RA) Patients Following 12-Weeks Dosing and 13 Weeks Follow up: Results From a Phase 2a Trial. Ladislav ŠEnolt[1]. Marie Göthberg[2], Xavier Valencia[3] and Eva Dokoupilova[4], [1]Institute of Rheumatology, Prague, Czech Republic, [2]Novo Nordisk, A/S, Soeborg, Denmark, [3]Novo Nordisk, Inc., Princeton, NJ, [4]Medical Plus s.r.o, Uherske Hradiste, Czech Republic

Background/Purpose: NNC0109-0012 (anti-IL-20 mAb) is a novel human monoclonal IgG$_4$ antibody which binds to and neutralizes the activity of IL-20. Data from a phase 1 single-dose trial in healthy volunteers and RA patients, and a multiple-dose trial in RA patients, did not raise any safety concerns. NNC0109-0012 has linear pharmacokinetics in the investigated dose range (1–3 mg/kg) and signs of reduced disease activity were shown in RA patients. Objectives of this phase 2a trial were to evaluate changes in disease activity in RA patients with active disease using the following endpoints: DAS28-CRP, ACR20/50/70, and the patient-reported outcomes physical function (HAQ-DI), pain (Pain VAS) and global disease activity (PtGA VAS) after 12 weeks of treatment and during a 13-week follow up period.

Methods: A total of 67 RA patients (51 females:16 males) with active disease (DAS28 (CRP) >4.5, $\geq$5 swollen and $\geq$5 tender joints) were randomized in a 2:1 ratio (45 NNC0109-0012: 22 placebo) in a multicenter, double-blind, placebo-controlled, parallel group trial. Patients were dosed once-weekly s.c. with 3 mg/kg NNC0109-0012 or placebo for 12 weeks and followed for an additional 13 weeks. Patients were 18 to 75 years old with active RA and on stable methotrexate (MTX) treatment (>7.5 to <25 mg/week for at least 4 weeks). The primary endpoint was change in DAS28 (CRP) at Week 12.

Results: DAS28 (CRP) was significantly decreased compared to placebo at Weeks 12 and 16, and through Weeks 12 – 25 for seropositive (RF and anti-CCP positive) patients (n=29 and 14; 3 mg/kg and placebo, respectively). Significantly more NNC0109-0012 treated seropositive patients compared to placebo achieved ACR20/50 at Week 12 and ACR70 at Weeks 12, 16 and 20. Physical function, pain and global disease activity were significantly improved compared to placebo for seropositive patients for Weeks 12 – 25. Similar trends in NNC0109-0012 effects on most of the secondary endpoints for disease activity were observed in all randomized patients, although not all changes were significant. No deaths, serious adverse events or dose limiting toxicities were reported.

	Week 12	Week 16	Week 20	Week 25
DAS28 (CRP)[a]	−0.88*	−0.72*	−0.51	−0.60
DAS28 (CRP), S+	−1.66†	−1.55†	−1.26**	−1.24**
ACR20 (%), S+	58.6/21.4*	62.1/35.7	58.6/28.6*	58.6/35.7
ACR50 (%), S+	48.3/14.3*	44.8/14.3	44.8/21.4	44.8/21.4
ACR70 (%), S+	34.5/0*	34.5/0*	31.0/0*	31.0/7.1

Pain (VAS), S+	−30†	−28**	−25**	−29†
PtGA (VAS), S+	−28†	−29†	−25**	−28†

DAS28 (CRP), HAQ-DI, pain (VAS), PtGA (VAS) shown as mean difference for NNC0109-0012 μ placebo; Proportion with ACR20/50/70 for NNC or placebo shown as NNC/placebo. VAS = visual analogue scale (mm).[a]All randomized patients; S+=seropositive; * = p<0.05, ** = p<0.01,† = p<0.001

Conclusion: This phase 2a trial investigating NNC0109-0012 (anti-IL-20 mAb) in patients with RA met its primary endpoint, showing significant improvement in DAS28 (CRP) after 12 weeks. For the sub-group of RF/anti-CCP-positive patients, the treatment effects of NNC0109-0012 on all disease parameters were significantly larger than for all randomized patients at week 12 and were sustained during the 13 weeks after stopping study drug administration. Treatment with NNC0109-0012 revealed no safety concerns. The data from this trial support further clinical development of NNC0109-0012 (anti-IL-20 mAb) in RA.

Response to MMF Therapy for Lupus Nephritis Is Independent of Genetic Variation of Inosine Monophosphate Dehydrogenase. Noa Schwartz[1], Tejaskumar Patel[1], Ellen M. Ginzler[2], Neil Solomons[3], Jill P. Buyon[4] and Robert M. Clancy[1]. [1]New York University School of Medicine, New York, NY, [2]SUNY-Downstate Medical Center, Brooklyn, NY, [3]Vifor Pharma, [4]NYU School of Medicine, New York, NY

Background/Purpose: The Aspreva Lupus Management Study (ALMS) demonstrated the efficacy of mycophenolate mofetil (MMF-a prodrug of MFA, mycophenolic acid) for both induction and maintenance of response in lupus nephritis. However, response is not uniform and it remains unresolved whether this relates to genetic variation in inosine monophosphate dehydrogenase (*IMPDH*).SNPs in *IMPDH1* (rs2278294) and *IMPDH2* (rs11706052) confer a higher risk of acute rejection in renal transplant recipients, and lymphocytes of mutant carriers (rs11706052) yieldan antiproliferative effect which is half that of subjects who are homozygous common. In addition, the ability of MMF to reduce pathogenic nitric oxide (NO) is attenuated in subjects carrying variant forms of *IMPDH*. Accordingly, this study was initiated to determine whether the clinical response of MMF and phenotype (NO levels) in ALMS associates with variants of I*MPDH*.

Methods: Subjects were 62 ALMS patients randomized to MMF in induction and/or maintenance.DNA and blood samples were obtained for evaluation of genetic variation and serum NO levels (colorimetric method, NO = nitrite + nitrate).Genotyping assignments were made based on a postread of the amplified genomic patient DNA by allelic discrimination and use of probes for *IMPDH1* rs2278294 and *IMPDH2* rs11706052 (Applied Biosystems).The allele calling rate of 62 DNA samples was 98% for rs2278294 and 100% for rs11706052.Assignments were verified by PCR amplification and direct sequencing.Both rs11706052 (*IMPDH2*) and rs2278294 (*IMPDH1*) were tested for departure from Hardy-Weinberg equilibrium (HWE) expectations.

Results: Representation of the two candidate SNPs had no HWE deviation; the relatively frequent minor alleles were comparable to those in the dbSNP database and in agreement with allelic discrimination and direct sequencing.Patients were stratified into two groups: Group I defined as responders to MMF at induction and non-treatment failures at maintenance, and Group 2 non-responders at induction and treatment failures at maintenance.For the *IMPDH2*, rs11706052, the distribution of variant alleles was similar for subjects in both groups (10.5%vs 13.9% MAFfor Groups 1 (N=18) and 2 (N=19), respectively). Similar results were observed when the analysis was restricted to Hispanics (largest ethnic group). For the *IMPDH1,*rs2278294, no association was observed between groups (44.4%vs 44.7% MAF, Groups 1 vs Groups 2).With regard to NO, there was no association between genotypes at rs2278294 and levels (14.5±2.6 uM vs 20.4±2.8, P=0.30, homozygous variant (N=9) versus heterozygous + homozygous common (N=33), respectively).

Conclusion: In distinction to renal transplant, genetic variation at *IMPDH1* and *IMPDH2* does not account for variability in the clinical response to MMF or levels of NO. These results should allay concerns regarding genetic testing of these alleles to predict efficacy of MMF in lupus.

838

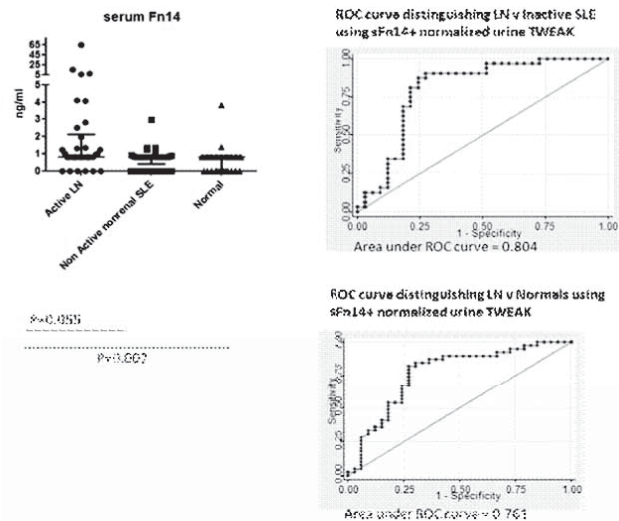
Association of Urinary and Serum Soluble Fn14 Levels and TWEAK Levels with Lupus Nephritis Disease Activity. Irene Blanco[1], Ping Wu[2], Timothy S. Zheng[3], Shawn Weng[4], Jennifer S. Michaelson[5], Linda C. Burkly[5] and Chaim Putterman[1]. [1]Albert Einstein College of Medicine, Bronx, NY, [2]Biogen Idec, Inc, Cambridge, MA, [3]Biogen Idec Inc, Cambridge, MA, [4]Biogen Idec, Inc., Cambridge, MA, [5]Biogen Idec, Cambridge, MA

Background/Purpose: We have showed that the cytokine TWEAK is a biomarker for lupus nephritis (LN). However, soluble receptors for key immune pathways are also potential biomarkers of inflammatory diseases, including SLE. Thus, we hypothesized that a soluble form of TWEAK receptor, Fn14, might be present in human serum or urine and could be a biomarker for LN.

Methods: Serum and urine from 67 patients from the Einstein Lupus Cohort were included in this study. 34 had active LN (renal SLEDAI≥4) and 33 had inactive, non-LN SLE (general SLEDAI≤2). Healthy normals (n=39), age and race matched, were also evaluated. ELISAs were performed on serum and urine samples to determine soluble Fn14 and TWEAK levels.All data was analyzed using STATA 10.1

Results: Of the 106 patients, 47% were Black, 47% were Hispanic and 6% were of another race/ethnicity. 79% were female with a median age of 43y. For the SLE patients the median disease duration was 6.0y. As expected LN patients had higher median protein to creatinine ratios as compared to both inactive SLE patients and normals (1.22 v 0.11 v 0.09, p<0.001).Although the normal group had a higher median GFRs overall, all groups had normal median values (90 v 89 v 115, p=0.02)

Serum Fn14 (sFn14) levels were significantly higher in LN compared to normals (p=0.002) and trended toward significance when comparing LN to the inactive SLE group (p=0.06). Median urine Fn14 levels tended to be higher in the LN group as compared the inactive SLE (p=0.06) and normals (p=0.05) but did not achieve significance with normalization to urine creatinine (p=0.06 and 0.12 for comparison to inactive SLE and normal, respectively). While there was no significant difference between the groups with regard to serum EAK, as previously shown, median urinary TWEAK levels were significantly elevated in the LN group compared to inactive SLE and normal groups when normalized to urine creatinine concentration (LN v inactive SLE (p=0.002) and LN v normal (p=0.002).

We performed an ROC analysis to determine the capability of sFn14 to distinguish between LN and inactive SLE as well as LN and normals. The AUC for sFn14 by itself was fair (LN v inactive SLE, AUC: 0.63; LN v normals, AUC: 0.70) while that of normalized uTWEAK was good (LN v inactive SLE, AUC: 0.77; LN v normals, AUC: 0.72). However, when the AUC for sFn14 and uTWEAK were combined the AUC was increased (LN v inactive SLE, AUC: 0.80; LN v normals, AUC: 0.76).


Conclusion: sFn14 levels are significantly elevated in patients with LN. This novel finding contributes to our previous observations that urinary TWEAK is elevated in this patient population. Adding sFN14 levels to urinary TWEAK levels as a combined biomarker has a higher capacity than each alone to distinguish between LN and inactive SLE as well as LN and normals. sFn14 is a promising novel biomarker in LN, further underscoring the TWEAK/Fn14 pathway as a potential therapeutic target that warrants further study.

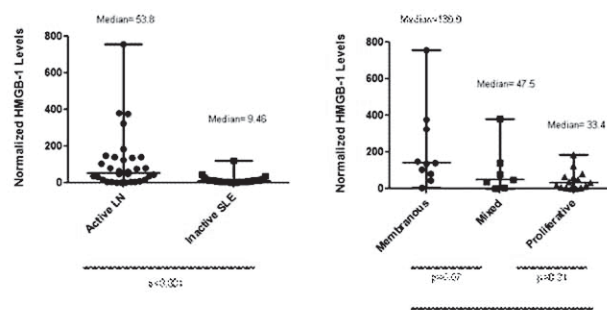
839

Urinary Levels of High Mobility Group Box 1 Protein Are Elevated in Patients with Active Lupus Nephritis, and Correlate with Renal Histopathology. Irene Blanco[1], Neelakshi Jog[2], Chaim Putterman[1], Iris Lee[2] and Roberto Caricchio[3]. [1]Albert Einstein College of Medicine, Bronx, NY, [2]Temple University, Philadelphia, PA, [3]Temple Univ Med Office Bldg, Philadelphia, PA

Background/Purpose: High mobility group box 1 protein (HMGB-1) had been implicated in the pathogenesis of SLE and potentially lupus nephritis (LN).There is increased expression in the both the glomerulus and mesangium and is found to be increased in the serum of LN patients compared to controls. To further investigate what happens locally in the kidney, we analyzed the urine of active LN patients for HMGB-1.

Methods: Urine from 61 Einstein Lupus Cohort patients was included in this study. 32 patients had active, biopsy-proven LN, (15 class III or IV, 7 mixed class III/IV+V, 10 class V; all had renal SLEDAI $\geq$4)and 29 had inactive, non-LN SLE (general SLEDAI$\leq$2). HMGB-1 was detected by western blot using a polyclonal antibody against it. Band intensities were measured with ImageJ software and HMGB-1 was normalized to albumin for each sample. Urine was then normalized to urine creatinine to account for the volume of each specimen.All data was analyzed using STATA 10.1

Results: Of the 61 patients, 90.2% are female and 9.8% are male.47.5% are Hispanic, 45.9% are Black and 6.6% are of another race/ethnicity. The median age and disease duration were 39y and 7.5y respectively. Overall, LN patients have lower median serum albumin levels (3.6 v 4.1, p<0.001) and higher median protein to creatinine ratios ("uP/C", 1.22 v 0.11, p<0.001), but there was no statistically significant difference in serum creatinine or GFR when compared to those with inactive SLE.

Median normalized urine HMGB-1 was significantly elevated in LN patients compared to inactive SLE (53.81 v 9.46, p<0.001). A difference in median levels was also seen between the classes.There was a significant difference between proliferative and membranous disease (33.4 v 138.8, p=0.003) and there seemed to be increased levels between mixed and membranous disease (47.5 v 138.8, p=0.07). However there was no significant difference between proliferative and mixed LN (33.4 v 47.5, p=0.21)


uP/C was associated with urinary HMGB-1 (r=0.52, p<0.001), but across the classes this was true only for membranous disease (r=0.71, p=0.022, proliferative, p=0.63; mixed, p=0.34). This is despite the fact that median uP/C was highest in mixed disease as compared membranous and proliferative (2.82 v 1.75 v 0.70, p=0.06).

Conclusion: This is the first study to look at urinary HMGB-1 levels in lupus nephritis. Levels are significantly higher in active LN patients compared to inactive SLE. Levels may be associated with class where the highest levels were seen in membranous disease. While this was correlated to uP/C in the membranous group, it was neither correlated in the mixed group, despite having higher levels of proteinuria, nor in the proliferative group, where there was also elevated urinary protein though not to the level of the other groups. Therefore it is possible that the same process that drives proteinuria in membranous disease is driving elevated HMGB-1 levels.

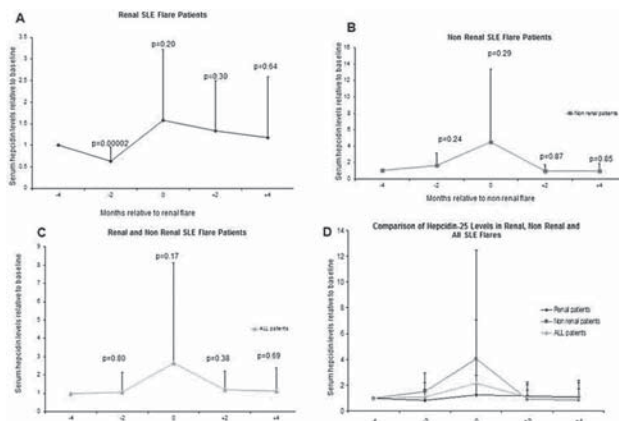
Do Serum Hepcidin 25 Levels Predict SLE Renal or Non-Renal Flares? Alexandra Friedman[1]. Nicholas Young[1], Paul Jensen[2], Xiaolin Zhang[2], Wael N. Jarjour[3], Brad H. Rovin[2], Daniel Birmingham[2], Lee Hebert[2] and Stacy P. Ardoin[3]. [1]The Ohio State University Medical Center, Columbus, OH, [2]Ohio State University Medical Center, Columbus, OH, [3]Ohio State University, Columbus, OH

Background/Purpose: Biomarkers are needed which can accurately predict systemic lupus erythematosus (SLE) flare, allowing tailoring of immunosuppressive therapy to minimize disease damage and medication toxicity. Urinary hepcidin-25 levels have been shown to decrease 2 months prior to renal SLE flare and show promise as a biomarker of lupus nephritis flare.This study assessed serum hepcidin-25 levels before, during and after renal and non-renal SLE flares.

Methods: As part of the Ohio SLE Study (OSS), serum and urine were obtained in SLE patients prospectively at every 2 month intervals.We identified 34 renal flare cycles in 21 patients and 22 non renal flare cycles in 17 patients. We measured serum 25 hepcidin levels at baseline, at time of flare and at 2 and 4 month intervals prior to flare and after flare.Renal and non-renal flares were defined and adjudicated by OSS protocol. Serum hepcidin-25 was measured in duplicate by enzyme immune assay kits (Bachem).Descriptive statistics were performed.

Results: Serum hepcidin-25 levels showed substantial inter-patient variability and were presented relative to normalized baseline levels.As shown in Figure 1, serum hepcidin 25 levels decreased significantly 2 months prior to renal flares but did not decrease prior to non renal flares.


Conclusion: Serum hepcidin-25 levels decrease 2 months prior to renal SLE flare but not prior to non-renal SLE flare. To our knowledge, this is the first study to show that serum hepcidin 25 levels may predict renal SLE flare.These findings need to be confirmed in larger prospective cohorts but support previous evidence that hepcidin 25 may be a biomarker for renal SLE flares.

Effect of Partial and Complete Proteinuria Recovery in Lupus Nephritis On Long Term Outcomes. Zahi Touma, Murray B. Urowitz, Dominique Ibanez and D. D. Gladman. Toronto Western Hospital and University of Toronto, Toronto, ON

Background/Purpose: The identification of partial proteinuria recovery (PPR) of$\geq$ 50% allows for the detection of an additional number of patients who improve their proteinuria on standard of care treatment.The long term outcome of patients with$\geq$ 50% PPR at 1 year is not well studied.

To determine the prognostic value of PPR and complete proteinuria recovery (CPR) at 1 year on long term outcomes compared to patients who did not recover proteinuria$\geq$ 50% on standard of care therapy.

Methods: All active lupus nephritis (LN) patients registered at a large lupus clinic from 1970–2011. Proteinuria was defined as >0.5g/24 hours based on a 24 hour urine collection. Patients with proteinuria and at least one of the urinary sediments (hematuria, pyuria or casts) present at entry into the study and persistent on 2 consecutive visits were enrolled.

CPR was defined as proteinuria <0.5g/24 hours based on SLEDAI-2K. PPR was a decrease of $\geq$ 50% in the level of proteinuria from baseline as defined by SLEDAI-2K responder index-50 (SLEDAI-50-RI). Not recovered was defined as less than 50% recovery.Proteinuria recovery was identified if present on 2 consecutive visits within 1 year.

The long term outcomes (death, eGFR<15, dialysis or kidney transplant, SLICC Damage Index (SDI)>0, SDI>3) occurring after the identification of proteinuria related to LN at entry into the study were studied. The mean time to long term outcome was determined

Proportional hazard models were used to determine the hazard ratio (HR) for long term outcomes for the different recovery definitions.

Results: 217 patients (81.8% female) were identified. At 1 year: 45 patients achieved PPR, 48 CPR and 124 not recovered.

Long term outcomes: eGFR< 15 was identified in 14.3% of the patients, dialysis or kidney transplant in 12.8%,.18% of the patient died and 56% developed damage (SDI>0) with 30.7% with SDI >3.

The mean time to event from 1st visit in the study were:7.0 ± 8.3 years for death (n=39),3.7 ± 3.7 years for eGFR< 15 (n=30), 5.5 ± 6.0 for dialysis or kidney transplant (n=20), 3.6 ± 5.6 years for SDI>0 (n=75) and 6.1 ± 7.3 years for SDI>3 (n=57).

Achieving a PPR at 1 year protects from the development of eGFR<15; HR=0.29. Achieving a CPR at 1 year protects from the development of eGFR<15 (HR=0.25), accrual of damage with SDI>3 (HR=0.23) and none with CPR at 1 year subsequently went on to dialysis or transplant. (Table 1).

Table 1. Time to development of event in patient who achieved CPR and PPR at 1 year compared to patients without proteinuria recovery

Outcomes	PPR HR (p-value)	CPR HR (p-value)
Death	0.88 (0.75)	0.35 (0.05)
eGFR<15	0.29 (0.04)	0.25 (0.02)
Dialysis or Kidney Transplant	0.42 (0.17)	No event
SDI>0	1.05 (0.86)	0.70 (0.22)
SDI>3	0.73 (0.35)	0.23 (0.002)
Atherosclerotic events	1.07 (0.93)	0.84 (0.79)

Conclusion: Achieving complete recovery from proteinuria in patients with active lupus nephritis at 1 year from the onset of lupus nephritis protects against comorbidities including end stage kidney disease, dialysis and transplant, organ damage and death. Nonetheless, achieving at least partial recovery in proteinuria, ≥ 50%, at year 1 from the onset of lupus nephritis protects against the development ofeGFR<15.

Partial and Complete Recovery From Proteinuria in Lupus Nephritis Patients Receiving Standard of Care Treatment. Zahi Touma, D. D. Gladman, Dominique Ibanez and Murray B. Urowitz. Toronto Western Hospital and University of Toronto, Toronto, ON

Background/Purpose: In the majority of trials on lupus, partial proteinuria recovery (PPR) (≥ 50% decrease in the proteinuria level) is a component of the composite outcome of partial renal remission.

To determine the percentage of patients who achieve complete proteinuria recovery (CPR), PPR and CPR and/or PPR in lupus nephritis (LN) patients receiving standard treatment at 6 months, 1 year and 2 years. The am of this study was to determine if the initial level of proteinuria predicts recovery from proteinuria.

Methods: We studied all active LN patients registered at the Lupus Clinic (1970–2011).Proteinuria was defined as >0.5g/24 hours based on a 24 hour urine collection. Patients with proteinuria and at least one of the urinary sediments (hematuria, pyuria or casts) present at the entry of the study and persistent on 2 consecutive visits were enrolled. Patients were grouped into: group 1 as 0.5–0.9g/day, group 2 as 1–2g/day and group 3 as ≥2g/day.

CPR was defined as proteinuria <0.5g/24 hours based on SLEDAI-2K. PPR was a decrease of ≥ 50% in the level of proteinuria from baseline as defined by by SLEDAI-50 responder index (SLEDAI-50-RI).

We determined the percentage of PPR, CPR and PPR and/or CPR achieved: 1) on 1 visit at 6 months, 1 year and 2 years 2) persistent on 2 consecutive visits at 6 months, 1 year and 2 years. The percentage of patients who recovered from proteinuria was evaluated based on initial proteinuria levels with the Kaplan-Meier estimator.

Results: 217 patients (81.8% female) were identified. The age and duration of lupus at the start of the study was 34.2 ± 12.4 and 5.7 ± 6.3 years.

PPR was achieved by 27% of patients at 6 months, 48.3% at 1 year and 69.4% at 2 years. PPR and/ or CPR was achieved by 31.8% of patients at 6 months, 57.6% at 1 year and 79.3% at 2 years. CPR was achieved by 8.8% of patients at 6 months, 35.2% at 1 year and 60.2% at 2 years (table 1). The percentage of PPR, CPR and PPR and/or CPR decreased when proteinuria recovery was required on 2 consecutive visits (Table 1) (Figure 1).

Based on the level of proteinuria, in group 1, 2 and 3 more patients achieved at least PPR compared to CPR at 6 months (p=0.81), 1 and 2 years (p<0.05).

Table 1. Percentage of PPR, CPR, and PPR or CPR using 1 visit or 2 visits what does this mean

	Percent of patients who have proteinuria recovery					
	@ 6 months		@ 1 year		@ 2 years	
Definitions	1 visit	2 visits	1 visit	2 visits	1 visit	2 visits
Partial recovery	27%	21%	48.3%	35.8%	69.4%	50.9%
Complete recovery	8.8%	6.9%	35.2%	24.8%	60.2%	45.7%
Partial or complete recovery	31.8%	25.5%	57.6%	46.4%	79.3%	65.9%
Figure 1. Comparing Complete, Partial, Partial and/or Complete – All Patients— 1 Visit Definition

Conclusion: The identification of partial proteinuria recovery allowed the detection of additional patients who improved their proteinuria on standard of care treatment. 58% of patients achieved at least partial while only 35% achieved CPR at year 1. PPR can serve as an important primary endpoint in research studies and trials.

Background/Purpose: Powerful evidence suggests that Systemic lupus erythematous (SLE or lupus) autoimmunity is mediated by disregulation of the IRF5-NFκB signaling pathway. The interferon regulatory factor 5 (IRF5) genomic locus is associated with lupus and seven other autoimmune diseases

in populations of each of the major ancestral groups. While the association of lupus with the IRF5 region has been extensively confirmed, previous publications have not presented a comprehensive analysis of the complete genetic variation of the entire locus including the juxtaposing gene TNPO3.

Methods: In order to fine map the entire IRF5/TNPO3 region, we used an Illumina iSelect custom array to genotype 107 single nucleotide polymorphisms (SNPs) in 8,395 SLE cases and 7,367 controls of European, African American, Asian, Hispanic, and Native American ancestry. Additionally, we imputed genetic variants spanning the IRF5/TNP03 region and performed targeted deep sequencing of lupus cases and controls to identify over 7,000 variants in the region.

Results: Through direct genotyping, imputation, and deep sequencing, we have accounted for all variation within the IRF5/TNPO3 region and identified a set of variants that includes the causative polymorphism(s). In each ancestry group, we confirmed strong association of variants located in the promoter region of IRF5. Furthermore, in Europeans and populations with European admixture, we also observed a strong independent association that spans the IRF5 and TNPO3 genes marked by a large haplotype.Through step-wise conditional analysis of the variation, our model of association using these two independent effects is able to explain the entire association of the IRF5/TNPO3 region. Using an iterative strategy, we limited the list of possible causal polymorphisms to those present in the genetic models with the strongest lupus associations.We further demonstrated evidence for over-transmission of European-derived variants to African American cases by using global and local admixture analysis.

Conclusion: IRF5 association reflects a crucial component in the pathogenesis of lupus in multiple ancestral groups.With these studies, we present a model of association that is superior to other genetic models published to date: we show two distinct and independent effects within the IRF5/TNPO3 locus. Being convinced that we have identified all of the genetic variation relevant to the IRF5 association in the region of IRF5/TNPO3, we have therefore captured the causal variant(s). Identifying the independent genetic effects allows for the separate pursuit of causal polymorphisms within this defined variation and disease mechanisms yet to be described.

Toll-Like Receptor 9-Independent and Immune Complex-Independent Interferon-α Production by Neutrophils Upon Netosis in Response to Circulating Chromatin. Dennis Lindau[1], Julie Mussard[2], Armin Rabsteyn[1], Matthieu Ribon[2], Ina Kötter[3], Annette Igney[3], Gosse Adema[4], Marie-Christophe Boissier[5], Hans-Georg Rammensee[1] and Patrice Decker[2]. [1]University of Tübingen, Institute for Cell Biology, Tübingen, Germany, [2]University of Paris 13, Sorbonne Paris Cité, Bobigny, France, [3]Department of Internal Medicine II, Rheumatology Division, Tübingen, Germany, [4]Nijmegen Centre for Molecular Life Sciences, Nijmegen, Netherlands, [5]Avicenne Hospital, Rheumatology Department, Bobigny, France

Background/Purpose: Chromatin (which is composed of DNA and histones) represents a major autoantigen in systemic lupus erythematosus (SLE). Interferon-α (IFN-α) plays an important role in lupus development. Although activated plasmacytoid dendritic cells (pDC) are believed to be the main producers of IFN-α in SLE, pDC represent a minor cell population. On the other hand, neutrophils represent 50 % of total blood leukocytes and are activated in SLE, especially by chromatin. Moreover, neutrophils form immunogenic neutrophil extracellular traps (NET) in SLE. Toll-like receptor (TLR) 9 recognizes certain forms of DNA but its role in SLE is still not elucidated. We therefore sought to determine the cellular source of IFN-α as well as the natural stimuli in SLE, the mechanism and the impact of TLR9.

Methods: Chromatin (mono-nucleosomes) was purified from calf thymus. PBMC and neutrophils were isolated from healthy individuals and SLE patients. Mouse neutrophils were purified from the bone marrow. Cells were activated with different stimuli and IFN-α production/secretion was estimated by flow cytometry, ELISA and a bioassay. Gene expression was analyzed by qRT-PCR. Neutrophil activation was verified by flow cytometry and ELISA. NET induction was estimated by confocal microscopy.

Results: Isolated neutrophils produce IFN-α upon stimulation with chromatin. IFN-α secretion by neutrophils was observed with steady-state neutrophils, and not pro-inflammatory neutrophils, from both healthy donors and SLE patients whereas pDC were less efficient. Neutrophil-derived IFN-α was detected in response to free chromatin, and not chromatin-containing immune complexes, as well as TLR9 agonists. Nucleosome-induced IFN-α production by neutrophils was associated with IL-8 secretion, CD66b up-regulation, ROS production and NET formation (NETosis). Neutrophil priming is not required. In low-responders, autologous PBMC sustain IFN-α secretion by chromatin-activated neutrophils in co-cultures. In contrast to TLR9 agonists, chromatin-induced IFN-α secretion occurs independently of TLR9 since neutrophils isolated from both wild-type and TLR9-deficient mice were activated. Finally, chromatin increases gene expression levels of IFN-α and several DNA sensors, e.g. AIM2 and STING.

Conclusion: Neutrophils represent also an important source of IFN-α. IFN-α was detected at the mRNA and protein levels and in an active and secreted form. This is the first report showing both that steady-state neutrophils can secrete IFN-α and identifying a natural lupus stimulus involved. Since both normal and lupus neutrophils have the capability of producing IFN-α, a key event is thus the presence of increased concentrations of circulating nucleosomes in SLE patients. Chromatin-activated neutrophils (in addition to pDC and low-density granulocytes) may secrete IFN-α early during the lupus disease, before immune complexes are produced. The generation of NET and the expression of genes involved in the recognition of DNA may strengthen pDC activation and DNA-mediated activation.

Systemic Lupus Erythematosus Immune Complexes Upregulate the Expression of CD319 and CD229 On Plasmacytoid Dendritic Cells. Niklas Hagberg[1], Jakob Theorell[2], Gunnar V. Alm[3], Maija-Leena Eloranta[1], Yenan Bryceson[2] and Lars Rönnblom[1]. [1]Section of Rheumatology, Uppsala University, Uppsala, Sweden, [2]Center for Infectious Medicine, Karolinska Institutet, Stockholm, Sweden, [3]Swedish University of Agricultural Sciences, Uppsala, Sweden

Background/Purpose: Patients with SLE have an activated type I interferon (IFN) system due to an ongoing IFN-alpha synthesis by plasmacytoid dendritic cells (pDCs) stimulated by endogenous nucleic-acid containing immune complexes (ICs). The IFN-alpha production by pDC is strongly promoted by NK cells via MIP-1beta and LFA-1-mediated cell contact. In this study we aimed to further identify molecules of importance in the pDC-NK cell cross-talk.

Methods: Healthy donor PBMC were stimulated with medium or IC consisting of purified SLE-IgG and U1snRNP particles (SLE-IC) for 6 h. Surface expression of 45 different molecules was determined on pDCs, CD56[dim] and CD56[bright]NK cells by flow cytometry. Regulation of CD319 (CRACC) and CD229 (LY9) was analyzed in isolated or cocultured pDCs and NK cells. Intracellular IFN-alpha was correlated to the expression of CRACC and LY9 on pDCs and the expression of these molecules on different immune cells was compared between SLE patients and healthy controls. Expression of the adaptor molecules SAP and EAT-2 was determined by western blot. The functional role of CRACC and LY9 in pDC and NK cells was investigated.

Results: SLE-IC induced expression of CRACC and LY9 on pDCs, and CRACC on CD56[dim] NK cells in PBMC (Mean fold increased MFI 3.7, 2.2 and 2.0, respectively). CRACC and LY9 were not regulated in purified pDC but addition of NK cells restored the up-regulation on pDCs. IL-3 or GM-CSF increased the expression of CRACC and LY9 on SLE-IC-stimulated pDCs as efficiently as NK cells. IFN-alpha producing pDCs had a higher expression of CRACC and LY-9 compared to IFN-alpha negative pDCs. Patients with SLE displayed an increased frequency of CRACC+ CD56[bright] NK cells and B cells (p=0.03; 17±2% vs. 10±2% and p<0.001; 10±3% vs 3±0.3%, respectively, (mean±SEM)) and a decreased frequency of CRACC+ CD56[dim] NK cells (p=0.01; 59±5% vs. 76±3%, (mean±SEM)). No expression of SAP or EAT-2 was found in pDCs, while NK cells expressed both molecules. Cross-linking CRACC or LY9 by plate-bound mAbs did not affect IFN-alpha production by SLE-IC-stimulated pDCs. Cross-linking CRACC in a redirected cytotoxicity assay resulted in a low frequency of degranulating NK cells, whereas co-ligation of CRACC together with DNAM-1 (CD226) significantly increased the degranulation (4% and 29% CD107a+ CD56[dim]NK cells, respectively).

Conclusion: SLE-ICs up-regulates the expression of the costimulatory molecules CRACC and LY9 on pDCs and these molecules also have an increased expression on IFN-alpha producing pDCs. Because these SLAM molecules are self-ligands and involved in the activation of several types of immune cells, the expression on both pDCs and NK cells might facilitate the pDC-NK cell interaction and the function of these cells. In contrast to the positive signal delivered by CRACC and LY9 to NK cells, the lack of SAP and EAT-2 adaptor molecules in pDCs suggests an inhibitory function in these cells. The precise roles of CD319 and LY9 in the autoimmune disease process remains to be established, but are important to clarify given the altered expression of CRACC in SLE on both B cells and NK cells.

Preferential Binding to Elk-1 by SLE-Associated *IL10* Risk Allele up-Regulates *IL10* Expression.
Daisuke Sakurai[1], Jian Zhao[1], Yun Deng[1], Jennifer A. Kelly[2], Kathy Moser Sivils[2], Kenneth M. Kaufman[3], Elizabeth E. Brown on behalf of PROFILE[4], Marta E. Alarcón-Riquelme on behalf of BIOLUPUS and GENLES network[5]. John B. Harley[6], Sang-Cheol Bae[7], Chaim O. Jacob[8], Timothy J. Vyse[9], Timothy B. Niewold[10], Patrick M. Gaffney[11], Judith A. James[12], Robert P. Kimberly[4], Gary S. Gilkeson[13], Diane L. Kamen[14], Carl D. Langefeld[15], Deh-Ming Chang[16], Yeong Wook Song[17], Weiling Chen[1], Jennifer M. Grossman[1], Bevra H. Hahn[1] and Betty P. Tsao[1], [1]David Geffen School of Medicine University of California Los Angeles, Los Angeles, CA, [2]Oklahoma Medical Research Foundation, Oklahoma City, OK, [3]Cincinnati Children's Hospital Medical Center, Cincinnati, OH, [4]University of Alabama at Birmingham, Birmingham, AL, [5]Centro de Genómica e Investigación Oncológica Pfizer-Universidad de Granada-Junta de Andalucía (GENYO), Granada, Spain and Oklahoma Medical Research Foundation, Oklahoma City, OK, [6]Cincinnati Children's Hospital Medical Center; US Department of Veterans Affairs Medical Center, Cincinnati, OH, [7]Hanyang University Hospital for Rheumatic Disease, Clinical Research Center for Rheumatoid Arthritis (CRCRA), Seoul, [8]Keck School of Medicine, University of Southern California, Los Angeles, CA, [9]King's College London, London, United Kingdom, [10]University of Chicago, Chicago, IL, [11]Arthritis & Clinical Immunology Program, Oklahoma Medical Research Foundation, Oklahoma City, OK, [12]Oklahoma Medical Research Foundation and Oklahoma University Health Sciences Center, Oklahoma City, OK, [13]Medical University of South Carolina, Charleston, SC, [14]Arthritis & Clinical Immunology Program, Oklahoma Medical Research Foundation, Charleston, SC, [15]Department of Biostatistical Sciences, Wake Forest University Health Sciences, Winston-Salem, NC, [16]National Defense Medical Center, Taipei, [17]Seoul National University Hospital, Seoul, South Korea

Background/Purpose: The established association between *IL10* and multiple autoimmune diseases including SLE and elevated levels of IL-10 in SLE patients correlating with disease activity led us to fine-map the *IL10* family locus (*IL10-IL19-IL20-IL24)* to evaluate SLE-associated SNPs for their potential functions in multiple ancestries.

Methods: We genotyped 19 tag SNPs of the 154 kb *IL10* family locus in 15533 subjects including European Americans (EA, 3820 cases vs 3412 controls), African Americans (1670 vs 1904), Asians (1252 vs 1249) and Hispanics (1445 vs 781), and imputed an additional 109 SNPs in EA. Each SNP was assessed for association with SLE, and haplotype-based conditional testing was conducted to distinguish independent signals. Transcript and protein levels of IL-10 were measured by real-time PCR and ELISA. EMSA was performed using nuclear lysates of SLE PBLs to assess differential binding to SLE-associated SNP alleles that might regulate IL-10 expression. Elk-1 activation was detected by Western blot, and co-localization of IL-10 and phospho-Elk-1 by flow cytometry.

Results: Among 19 genotyped SNPs, the 3'UTR downstream SNP of *IL10*, rs3024505, exhibited the strongest independent association with SLE susceptibility in EA only ($P = 2.67 \times 10^{-8}$, OR [95%CI] =1.30 [1.19–1.43]). Lower allelic frequencies of this SNP and lack of other association signals in non-EA led us to focus on EA for imputation, showing association with SLE of 3 additional SNPs: rs3122605 (10kb 5' upstream), rs3024493 (intron3) and rs3024495 (intron4) tagged by rs3024505 ($r^2>0.91$). SLE patients carrying risk-alleles of these 4 SNPs had higher IL10 expression at mRNA ($P=3.8 \times 10^{-6}$) and protein level ($P=4.2 \times 10^{-5}$) than those carrying non-risk alleles. Only the risk allele of rs3122605 exhibited binding to nuclear extracts from SLE PBLs using EMSA. This risk allele was predicted to preferentially bind to transcription factor Elk-1, and was validated by supershift in the presence of ELK-1 antibodies, suggesting it is the likely causal variant. Upon

activation, cytoplasmic Elk-1 is known to be phosphorylated and translocated into the nucleus inducing transcription. Phospho-Elk-1 was detected in nuclear extracts from SLE but not normal PBMCs, and appeared higher in patients with increasing SLEDAI scores (Figure). Co-expression of phospho-Elk-1 and IL-10 in PBLs was elevated in SLE than controls ($P = 0.005$) and active than inactive patients ($P < 0.05$).
Conclusion: We identified GWAS level association ($P<5\times10^{-8}$) of 4 *IL10* SNPs with SLE in EA. The risk allele of 5' upstream rs3122605 preferentially binding to ELK-1 was associated with elevated IL10 levels. Nuclear localization of activated phospho-Elk-1 was elevated in SLE PBLs that also expressed IL-10, especially during active disease. Taken together, the SLE-associated rs3122605 C allele conferred SLE risk by upregulating ELK-1-mediated IL-10 expression.

Enhanced ROCK Activation in Patients with Systemic Lupus Erythematosus.
Josephine Işgro[1], Sanjay Gupta[2], Tanya M. Pavri[2], Roland Duculan[2]. Kyriakos A. Kirou[2], Jane E. Salmon[2] and Alessandra B. Pernis[2], [1]Morgan Stanley Children's Hospital of New-York Presbyterian, Columbia University Medical Center, New York, NY, [2]Hospital for Special Surgery, New York, NY

Background/Purpose: The Rho GTPases, Rac and RhoA, play a key role in immune responses by regulating both cytoskeletal reorganization and gene expression. RhoA exerts many of its effects by activating Rho kinases (ROCKs). Aberrant ROCK activation has been implicated in the pathogenesis of various cardiovascular, renal, and neurological disorders. As such, ROCK inhibitors have emerged as potential treatments for these diseases. Recent studies have demonstrated that, in T cells, Rho kinases can regulate the production of IL-17 and IL-21, two cytokines associated with the development of multiple autoimmune disorders including Systemic Lupus Erythematosus (SLE). ROCK inhibition has previously been shown to ameliorate the cytoskeletal abnormalities of SLE T cells suggesting that SLE patients may exhibit aberrant ROCK activation. The goal of this study was to measure ROCK activity in SLE patients and its relationship with clinical and immunological aspects of SLE.

Methods: We performed a cross sectional study of 28 SLE patients and 25 healthy controls matched for age (31.1 ± 9.1 years vs (31.8 ± 8.2), gender (79% female vs 92%) and race. Mean SLEDAI 4.0 ± 2.4 (Range: 0–10) and physician global assessment 0.8 ± 0.7 (Range: 0–2). Peripheral blood mononuclear cell (PBMC) lysates were used for ROCK kinase activity assays. Cytokine and chemokine profiles in plasma were analyzed via ELISA.

Results: PBMCs from SLE patients expressed significantly higher levels of ROCK activation compared to healthy controls, 1.251 (IQR 0.5–1.6) vs. 0.5645 (IQR 0.5–0.6), respectively (p=0.0015). There were two distinct subgroups of SLE patients: those with high (ROCK^high) and low (ROCK^low) ROCK levels; 16/28 (57%) patients were in the ROCK^high group. Using linear regression models, disease duration, lymphocyte count, and azathioprine use were identified as independent predictors of ROCK activity (p≤0.02). There was no significant difference in IL-17 and IL-21 plasma levels between SLE patients and healthy controls.CCL20 levels from SLE patients were, however, significantly elevated compared to healthy controls, 16.1 pg/ml (IQR 10–23) vs. 10.2 pg/ml (IQR 7.1–15.5), respectively

(p=0.02). Consistent with previous studies, SLE patients expressed significantly higher BAFF levels when compared to controls, 1144 pg/ml (IQR 706–1609) vs. 762.8 pg/ml (IQR 661–829), respectively (p=0.009). There was no correlation between ROCK levels and SLEDAI, cytokine profiles, autoantibodies, or renal disease.

Conclusion: Enhanced ROCK activity was seen in a subgroup of SLE patients and was associated with disease duration, lymphocyte count, and azathioprine use. Given the multiple links between CCL20 and Th17 cells, the elevated levels seen in SLE suggest a role for Th17 cells in the pathogenesis of SLE. These data support the concept that the RhoA/ROCK pathway could represent an important therapeutic target for the treatment of SLE and that measurement of ROCK activation in SLE patients may be utilized to assess the efficacy of therapies, such as ROCK inhibitors, aimed at inhibiting this pathway. Following SLE patients prospectively is necessary to further characterize ROCK levels over time and establish their relationship with disease activity and/or medications.

Targeting Glycosphingolipid Biosynthesis Normalises T Lymphocyte Function in Patients with Systemic Lupus Eyrthematosus.

Georgia McDonald[1], Laura Miguel[1], Cleo Hall[1], David A. Isenberg[1], Anthony I. Magee[2], Terry Butters[3] and Elizabeth C. Jury[1]. [1]University College London, London, United Kingdom, [2]Imperial College London, London, United Kingdom, [3]University of Oxford, Oxford, United Kingdom

Background/Purpose: Patients with systemic lupus erythematosus (SLE) are characterised by hyperactive T-cells that provide help to autoreactive B-cells. Underlying this hyperactivity are alterations in the lipid and protein composition of membrane lipid microdomains (lipid rafts) that influence the nature, duration and outcome of immune synapse formation between T-cells and antigen presenting cells including B-cells. We examined the profile of lipid raft-associated glycosphingolipids (GSL) in T-cells, the mechanisms underlying their abnormal expression in patients with SLE and whether by normalising GSL expression, T-cell function could be restored in patients.

Methods: High performance liquid chromatography and flow cytometry were used to assess the GSL profile and phenotype of T-cells from 98 patients with SLE compared with 82 healthy controls and 23 patients with other autoimmune rheumatic disease. Western blotting, quantitative PCR and confocal microscopy using fluorescently-labelled GSLs were used to assess levels of proteins controlling GSL expression and GSL location within T-cells. T-cell function was assessed by measuring phosphorylation of proximal and downstream signalling molecules, proliferation and cytokine production.

Results: The expression levels of lipid raft-associated GSL lactosylceramide (LC), Gb3 and GM1 were significantly increased in T-cells from patients with SLE compared to healthy and disease controls. In healthy donors LC^+, $GM1^+$ and $Gb3^+$ T-cells had an activated phenotype, increased expression of proliferation marker Ki-67 and transcription factor RORgT, however, raised GSL expression was not associated with a specific T-cell phenotype in patients with SLE. Increased GSL expression in T-cells from SLE patients was not associated with altered levels of enzymes controlling GSL biosynthesis but was associated with increased GSL recycling from the plasma membrane to intracellular compartments. T-cells from patients with SLE incorporated fluorescently-labelled-LC into intracellular vesicles more rapidly compared to T-cells from healthy controls and this was accompanied by increased expression of the Niemann-Pick 1 and 2 genes that control GSL recycling. *In vitro* culture of T-cells from SLE patients with direct inhibitors of GSL biosynthesis normalised GSL membrane expression and restored their function in terms of lipid raft-associated T-cell signalling, proliferation and cytokine production.

Conclusion: We show that targeting lipid biosynthesis pathways using clinically approved inhibitors can rectify hyperactivity in autoimmune T-cells and restore their function.

The Risk of Cardiovascular Disease in Systemic Sclerosis: A Population-Based Cohort Study.

Ada Man[1], Yanyan Zhu[1], Yuqing Zhang[2], Maureen Dubreuil[1], Young Hee Rho[1], Christine Peloquin[1], Robert W. Simms[1] and Hyon K. Choi[3]. [1]Boston University School of Medicine, Boston, MA, [2]Boston University, Boston, MA, [3]Boston University School of Medicine, University of British Columbia, Arthritis Research Centre of Canada, Boston, MA

Background/Purpose: Recent studies show that the prevalence of subclinical atherosclerosis is increased in individuals with systemic sclerosis (SSc). An accurate understanding of cardiovascular disease (CVD) risk is crucial in improving the overall outcomes of SSc, a disease associated with high mortality. To further elucidate the association between SSc and CVD, we evaluated the future risk of incident myocardial infarction (MI), stroke, and peripheral vascular disease (PVD) in individuals with SSc in a general population context.

Methods: We conducted a matched cohort study using The Health Improvement Network database, which is derived from electronic medical records from general practices in the UK from 1986 to 2011. SSc diagnoses, covariates, and cardiovascular outcomes were identified from the records. We conducted two cohort analyses: 1) MI and stroke, and 2) PVD, excluding individuals with prevalent disease from each analysis. PVD specifying the upper extremities was not included. We estimated hazard ratios (HRs) using Cox proportional hazards regression models, comparing SSc with age-, sex-, and entry time-matched comparison cohorts, adjusting for BMI, smoking, diabetes, hyperlipidemia, hypertension, atrial fibrillation, aspirin, oral glucocorticoid, and NSAID use. We then estimated the cumulative incidence of each outcome accounting for the competing risk of death.

Results: Mean follow-up time was 5.2 years in the SSc cohorts and 6.0 years in the comparison cohorts. Among 865 individuals with SSc (85.8% female, mean age 58.7 years), the incidence rates (IRs) of MI and stroke were 4.4 and 4.8 per 1000 person-years (PY), versus 2.5 and 2.5 per 1000 PY in the comparison cohort, respectively. The corresponding adjusted HRs were 1.80 (95% CI 1.07 to 3.05) for MI and 2.61 (95% CI 1.54 to 4.44) for stroke. Among 858 individuals with SSc (85.3% female, mean age 58.9 years), the IR of PVD was 7.6 per 1000 PY versus 1.9 per 1000 PY in the comparison cohort, with an adjusted HR of 4.35 (95% CI 2.74 to 6.93).
Figure 1. Cumulative incidence of myocardial infarction or stroke in 865 individuals with systemic sclerosis (SSc) as compared to 8643 age-, sex-, entry time-matched, non-SSc individuals. Estimates accounted for the competing risk of death.
Figure 2. Cumulative incidence of peripheral vascular disease in 858 individuals with incident systemic sclerosis (SSc) as compared to 8580 age-, sex-, entry time-matched, non-SSc individuals. Estimates accounted for the competing risk of death.

Conclusion: These findings provide the first general population-based evidence that SSc is associated with an increased risk of developing MI, stroke, and PVD.Increased awareness of CVD in individuals with SSc is warranted.Further insight into the etiology of CVD in SSc, including the relative contributions of microvascular and macrovascular pathology, as well as how anti-platelet or vasodilating medications may alter this pathology, is needed.

Elevation of KL-6 At Early Disease Course Predicts Subsequent Deterioration of Pulmonary Function in Patients with Systemic Sclerosis and Interstitial Lung Disease. Masataka Kuwana[1], Tsutomu Takeuchi[1] and Junichi Kaburaki[2]. [1]Keio University School of Medicine, Tokyo, Japan, [2]Shinakasaka Clinic, Tokyo, Japan

Background/Purpose: Interstitial lung disease (ILD) is the leading cause of morbidity and mortality in patients with systemic sclerosis (SSc). However, only a subset of SSc patients with ILD develops end-stage lung disease (ESLD). The presence of significant fibrosis on high-resolution computed tomography and percent predicted forced vital capacity (%FVC) <70% were shown to be variables associated with a greater decline in pulmonary function, but these findings are rarely detected in patients with early SSc. In our institution, we principally did not treat ILD in SSc patients before 2000. Therefore, our cohorts of untreated patients are extremely useful in assessing the natural history of pulmonary function in SSc patients with ILD. Using this cohort, we evaluated initial factors that predict development to ESLD.

Methods: We enrolled 50 patients with SSc, who were diagnosed as having SSc between 1980 and 1995. These patients were selected from our database based on the following criteria: they had ILD as determined by chest radiographs at diagnosis, had disease duration <3 years at diagnosis, were followed for 10 or more years unless death due to ILD-related causes, had at least 4 serial pulmonary function tests, and had never received immunosuppressants, >10 mg daily prednisolone, or other potential disease-modifying drugs. ESLD was defined as having at least one of the following: <50% FVC, required oxygen supplementation in the absence of pulmonary hypertension, or death due to ILD-related causes. We performed statistical analyses stratified by development to ESLD and multivariate analysis to assess factors that predict the ESLD development. Survival analysis was performed using the Kaplan-Meier method combined with log-rank test.

Results: Disease duration at diagnosis was 14.2 ± 7.2 months and %FVC was 83.7 ± 14.2%. The patients were followed for 173.5 ± 64.7 months, and 16 patients (32%) developed ESLD. The decline in %FVC during the 12-month period was 4.6 ± 2.4% in patients who developed ESLD and 0.5 ± 0.8% in patients who did not ($P < 0.0001$). Cumulative survival rates were significantly worse in patients who developed ESLD than in those who did not ($P < 0.0001$). Initial characteristics associated with development to ESLD included diffuse cutaneous SSc ($P = 0.006$), anti-topoisomerase I antibody ($P = 0.004$), exertional dyspnea ($P = 0.03$), elevated KL-6 ($P < 0.0001$), reduced %FVC ($P = 0.007$), and reduced %DLco ($P = 0.001$). Multivariate analysis revealed that elevated KL-6 at diagnosis was the sole parameter independently associated with the ESLD development ($P = 0.0002$, odds ratio = 88). Cumulative rates free of ESLD and death were significantly greater in patients with normal KL-6 than in those with elevated KL-6 ($P < 0.0001$ for both comparisons). Finally, the rate of decline in %FVC was negatively correlated with KL-6 at diagnosis ($r = 0.71$, $P < 0.0001$).

Conclusion: SSc patients with ILD are heterogeneous in terms of deterioration of pulmonary function. Elevated KL-6 at baseline is an independent predictor of %FVC decline and mortality. SSc patients with ILD and elevated KL-6 at early disease course are candidates for aggressive therapeutic intervention.

An Evidence-Based Screening Algorithm for Pulmonary Arterial Hypertension in Systemic Sclerosis. James R. Seibold[1], Christopher D. Denton[2], Ekkehard Grünig[3], Diana Bonderman[4], Oliver Distler[5], Dinesh Khanna[6], Ulf Müller-Ladner[7], Janet E. Pope[8], Madelon C. Vonk[9], Martin Doelberg[10], Harbajan Chadha-Boreham[10], Harald Heinzl[4], Daniel M. Rosenberg[10], Vallerie McLaughlin[6] and John G. Coghlan[2]. [1]Scleroderma Research Consultants LLC, Avon, CT, [2]Royal Free Hospital, London, United Kingdom, [3]University Hospital, Heidelberg, Germany, [4]Medical University of Vienna, Vienna, Austria, [5]University Hospital Zurich, Zurich, Switzerland, [6]University of Michigan, Ann Arbor, MI, [7]Kerckhoff-Klinik GmbH, Bad Nauheim, Germany, [8]Western University of Canada, St. Joseph's Health Care, London, ON, [9]Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands, [10]Actelion Pharmaceuticals Ltd, Allschwil, Switzerland

Background/Purpose: Pulmonary arterial hypertension (PAH) is a leading cause of mortality and late-stage morbidity in systemic sclerosis (SSc). Current PAH screening recommendations are consensus-based and their clinical application results in high false positive rates. The rate of missed diagnoses has never been determined. The DETECT study aimed to develop an evidence-based screening algorithm for PAH in SSc patients that would limit the number of missed PAH diagnoses.

Methods: In this prospective, multicenter, cross-sectional observational cohort study [NCT00706082], adult patients with SSc for >3 years, a diffusing capacity of the lung for carbon monoxide (DLCO) <60% of predicted, and no previous diagnosis of pulmonary hypertension underwent multiple non-invasive screening tests followed by diagnostic right heart catheterization (RHC). Univariable and multivariable analyses selected the best discriminatory variables for identifying PAH, which were assessed for clinical plausibility and feasibility and incorporated into a two-step internally validated screening algorithm.

Results: Of 466 SSc patients, 19% (n=87) had RHC-confirmed PAH and 69% (n=321) had normal pulmonary arterial pressure (PAP). PAH was mild (mean PAP 32.5 [30.7–34.3] mm Hg; 64.4% WHO functional class I or II). Six simple screening tests (forced vital capacity [% predicted]/DLCO [% predicted]; current/past telangiectasias; anti-centromere antibody; N-terminal pro-brain natriuretic peptide; uric acid; right axis deviation on electrocardiography) were used in step 1 of the algorithm to derive a risk prediction score with pre-defined high sensitivity (to minimize the rate of missed PAH diagnoses) and to inform a decision to refer to echocardiography. Right atrial area and tricuspid regurgitation jet velocity were added in step 2 (with pre-defined low specificity) to determine referral to RHC. The DETECT algorithm, with step 1 sensitivity 97% and step 2 specificity 35%, resulted in a rate of missed PAH diagnoses of 4% requiring RHC in 62% of patients. When the current ERS/ESC screening recommendations were applied, the missed diagnoses and the RHC referral rates were 29% and 40%, respectively.

Conclusion: The two-step algorithm is a sensitive non-invasive screening tool for detection of PAH in SSc which addresses resource utilization of RHC, identifies less advanced disease and, most importantly, minimizes missed diagnoses. This is an evidence-based approach to revise standards of care in SSc patients.

C-Reactive Protein Predicts Long-Term Progression of Interstitial Lung Disease and Survival in Patients with Early Systemic Sclerosis. Xiaochun Liu[1], Maureen D. Mayes[1], John D. Reveille[2], Emilio B. Gonzalez[3], Brock E. Harper[3], Hilda T. Draeger[4] and Shervin Assassi[5]. [1]University of Texas Health Science Center at Houston, Houston, TX, [2]Univ of Texas Health Science Center at Houston, Houston, TX, [3]University of Texas Medical Branch, Galveston, TX, [4]Univ of TX Health Sci Ctr, San Antonio, TX, [5]Univ of Texas Health Science Houston, Houston, TX

Background/Purpose: The currently available clinical markers are not reliable predictors of long-term progression of interstitial lung disease (ILD) in patients with systemic sclerosis (SSc). In a previous study conducted in the GENISOS (Genes versus Environment in Scleroderma Outcome Study) cohort, none of the baseline clinical variables (including serology and disease type) was predictive of long-term decline in forced vital capacity (FVC). Elevated C-reactive protein (CRP) levels have been reported in a subset of patients with SSc and correlated with disease severity as well as shorter survival. Herein, we examine the predictive significance of CRP for progression of ILD (based on longitudinally obtained serial FVC) and survival in a large early SSc cohort.

Methods: We compared the plasma CRP levels in 266 SSc patients enrolled in the GENISOS cohort (mean disease duration at enrollment 2.5 years, 59% diffuse cutaneous involvement) to that of 97 age, gender and ethnicity-matched controls. Subsequently, the correlation between the plasma CRP levels and concomitantly obtained markers of disease severity was assessed. The primary outcome was decline in FVC over time. A total of 1,016 FVC measurements fulfilled the American Thoracic Society/European Respiratory Society criteria and were included in the analysis. The mean follow-up time was 4.4 years. The predictive significance for long-term change in FVC was investigated by a joint analysis of longitudinal measurements (sequentially obtained % predicted FVC) and survival data. This approach allows inclusion of all FVC measurements and accounts it for survival dependency.

Results: We confirmed that the baseline plasma CRP levels were significantly higher in SSc patients than matched controls (p=0.027). In addition to body mass index and age at baseline, the plasma CRP levels were associated with absence of anti-centromere antibodies ($p=0.043$). Also consistent with previous reports, plasma CRP levels correlated with the concomitantly obtained joint, skin and lung components of the Medsger Severity Index, as well as, FVC, DLco, mRSS. More importantly, baseline CRP levels correlated with shorter survival ($p<0.001$) and predicted the long-term decline in % predicted FVC ($\beta = -0.35$, 95% CI: $-0.61 - -0.09$, $p = 0.006$).The predictive significance of CRP for ILD progression was independent of potential confounders (age at baseline, gender, ethnicity, body mass index, and treatment with immunosuppressive agents) in the multivariable model ($\beta = -0.37$, 95% CI: $-0.63 - -0.11$, $p=0.005$).

Conclusion: In the present study, we show for the first time that the baseline CRP levels are predictive of long-term ILD progression. High CRP levels can identify the subgroup of patients that would benefit from more intensive monitoring and treatment.

Systemic Sclerosis Classification Criteria: Developing Methods for Multi-Criteria Decision Analysis. Sindhu R. Johnson[1], Raymond P. Naden[2], Jaap Fransen[3], Frank H.J. van den Hoogen[4], Janet E. Pope[5], Murray Baron[6], Alan G. Tyndall[7], Marco Matucci-Cerinic[8] and Dinesh Khanna on behalf of ACR/EULAR Classification Criteria SSc[9]. [1]Toronto Western Hospital, Toronto, ON, [2]Auckland City Hospital, Auckland, New Zealand, Austria, [3]Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands, [4]Department of Rheumatology, Sint Maartenskliniek, Nijmegen, Netherlands, [5]St. Joseph Health Care London, London, ON, [6]Jewish General Hospital, Montreal, QC, [7]University of Basel, Basel, Switzerland, [8]Univ Florence, Firenze, Italy, [9]University of Michigan, Ann Arbor, MI

Background/Purpose: Classification criteria for systemic sclerosis (SSc) are being developed. Twenty-three candidate criteria have been identified, but need to be reduced. The objectives of this study were to: 1) develop a SSc-specific instrument for use in a forced-choice study and evaluate its sensibility (comprehensibility, clarity, face and content validity, and feasibility); 2) use forced-choice methods to reduce and weight criteria; and 3) explore the agreement between SSc experts on the probability that cases were classified as SSc.

Methods: A standardized instrument was tested for attributes of sensibility. The instrument was applied to cases of SSc from 20 cohorts covering a range of probabilities that each case had SSc (very likely to not at all). SSc experts rank-ordered cases from 1 (highest probability) to 20 (lowest probability). Experts then reduced and weighted the 23 criteria using forced choice-conjoint analytic methods and subsequently re-ranked the cases. Consistency in both rankings was evaluated using an intraclass correlation coefficient (ICC).

Results: Experts endorsed clarity of the form (83%), comprehensibility of the instructions and response option (100%), face and content validity (100%) and feasibility. Experts identified 'skin thickening of the fingers and proximal to the metacarpophalangeal joints' as a sufficient criterion for SSc classification. Other criteria were reduced and weighted (weight in points): skin thickening of the fingers (14–22), finger tip lesions (9–21), finger flexion contractures (16), telangiectasia (10), abnormal nailfold capillaries (10), puffy fingers (5), calcinosis (12), Raynaud's phenomenon (13), tendon/bursal friction rubs (21), pulmonary fibrosis/pulmonary hypertension (13), renal crisis (11), esophageal dilation (7) and SSc-related antibodies (15). The ICC for agreement across experts was 0.73 (95% CI 0.58, 0.86) and improved to 0.80 (95%CI 0.68, 0.90).

Conclusion: Our SSc-specific instrument for classification has demonstrable sensibility. The number of criteria were reduced by 35% (from 23 to 15) and weighted. The experts had substantial agreement in rank order. The next phase of criteria development will evaluate a threshold. Our methods reflect the rigors of modern psychometric science, and serves as a template for developing classification criteria in other diseases.

Anti-EIF2B: A Novel Interstitial Lung Disease Associated Autoantibody in Patients with Systemic Sclerosis. Zoe Betteridge[1], Felix Woodhead[2], Christopher Bunn[3], Christopher D. Denton[4], David J. Abraham[5], Sujal Desai[6], Roland du Bois[7]. Athol U. Wells[8] and Neil McHugh[1], [1]Royal National Hospital for Rheumatic Diseases, Bath, United Kingdom, [2]University Hospitals Coventry and Warwickshire, Coventry, United Kingdom, [3]Royal Free Hospital, London, United Kingdom, [4]Royal Free and University College Medical School, London, England, [5]UCL Medical School, London, United Kingdom, [6]Kings College Hosptial, London, United Kingdom, [7]National Jewish Health, Denver, [8]Royal Brompton Hospital, United Kingdom

Background/Purpose: Autoantibodies occur in 75–95% of Systemic Sclerosis (SSc) patients. Studies have shown that the presence of particular SSc-specific autoantibodies (anti-centromere, anti-topoisomerase-1, anti-RNA polymerase III, anti-U3RNP, anti-U11/U12 RNP and anti-To/Th) correlates with distinct clinical subsets of patients. Additionally, SSc-related autoantibodies (PmScl, Ku, Ro60, La and U1RNP) can be found in a variety of other connective tissue diseases including SSc patients with overlap features. However, despite this vast array of SSc associated autoantibodies, there still remains a minority of patients that appear to be autoantibody negative. Here we report a novel SSc-specific autoantibody in 7 SSc patients.

Methods: Serum and clinical data were available from 379 patients with SSc investigated for interstitial lung disease (ILD) at the Royal Brompton Hospital and a separate 169 unselected SSc patients (Bath). Serum was also available from a control population consisting of 171 patients with other forms of connective tissue disease (dermatomyositis, polymyositis, systemic lupus erythematosus and rheumatoid arthritis), 141 patients with idiopathic ILD and 88 healthy normal controls. All sera were tested by routine serological techniques followed by radiolabelled protein immunoprecipitation (IPP) for samples negative for anti-centromere, anti-topoisomerase 1 and anti-RNA polymerase III. Patients' sera immunoprecipiating a novel 30 kDa band were further analyzed by indirect immunofluorescence and IPP using depleted cell extracts, to establish a common reactivity. A combination of non-radiolabelled IPP and mass spectrometry (MS) was used to identify the novel autoantigen and findings were confirmed using a commercial antibody in both immunodepletion and IPP-western blotting assays.

Results: A novel autoantigen at 30 kDa was recognized by sera from 7 sera from patients with SSc and by no controls. None of the 7 positive sera contained other known SSc-specific autoantibodies, although one patient co-immunoprecipiated SSc-associated Ro60 autoantigens. All 7 sera resulted in a cytoplasmic speckled pattern on IIF. Immunodepletion experiments indicated that all 7 serum samples immunoprecipitated the same autoantigen and MS analysis identified the novel autoantigen as EIF2B (Eukaryotic Initiation Factor 2B, subunit β). These findings were confirmed by both IPP and IPP-western blotting using a commercial anti-EIF2B antibody. Clinically, 6 anti-EIF2B positive patients had confirmed ILD, whilst the 7th patient did not have a chest CT, but had a reduced pulmonary gas transfer, demonstrating an association between anti-EIF2B and ILD (p=0.018). Six of the patients had diffuse cutaneous involvement (p=0.008) and four had overlap features with other autoimmune diseases (two polymyositis and two RA).

Conclusion: We report the presence of SSc-specific autoantibodies to anti-EIF2B in approximately 1% of SSc/SSc overlap patients. These autoantibodies are associated with the presence of ILD and diffuse cutaneous disease, and may therefore act as a biomarker, aiding in the clinical diagnosis and treatment of this subset of patients.

Identification of a *Burkholderia* -Like Strain From Temporal Arteries of Subjects with Giant Cell Arteritis. Curry L. Koening[1], Bradley J. Katz[2], Jose Hernandez-Rodriguez[3]. Marc Corbera-Bellalta[4], Maria C. Cid[4], Herbert P. Schweizer[5], Dean Li[2], Jerry Kaplan[2], Gary S. Hoffman[6] and Ivana De Domenico[2], [1]Salt Lake City Veterans Administration, Salt Lake City, UT, [2]University of Utah, Salt Lake City, UT, [3]Hospital Clínic. University of Barcelona. IDIBAPS, Barcelona, Spain, [4]Vasculitis Research Unit. Hospital Clínic. University of Barcelona. IDIBAPS, Barcelona, Spain, [5]Colorado State University, Fort Collins, CO, [6]Cleveland Clinic, Cleveland, OH

Background/Purpose: Giant cell arteritis (GCA) is a granulomatous vasculitis of large- and medium-sized arteries. An infectious organism has been hypothesized to cause GCA. We used 16S rRNA analysis to amplify a bacterial genomic sequence unique to the temporal arteries of GCA subjects. Identification of the bacteria allowed us to detect the organism's lipopolysaccharide (LPS) in the serum of these subjects and isolate the bacteria from temporal arteries of GCA patients.

Methods: Frozen and paraffin-embedded temporal arteries from biopsy-proven GCA subjects and controls were used for analysis.GCA subjects fulfilled the 1990 ACR criteria for GCA.DNA and RNA were isolated from frozen temporal arteries. 16S rRNA analysis was performed using primers to the conserved regions of bacterial 16S rRNA. Multilocus sequence typing (MLST), a PCR-based method of bacterial identification, was performed to type the organism.A *Burkholderia* anti-LPS monoclonal antibody was used to perform immunofluorescence (IF) and ELISA.*Burkholderia* was cultured from a temporal artery and the isolate was injected into C3H/HeSnJ mice. Infected mice were sacrificed and organs were analyzed by light microscopy for vasculitis.Student's t-test was used to compare mean values.

Results: 16S rRNA analysis identified a genomic sequence within an affected artery that was 100% homologous to the genus *Burkholderia*. Primers specific for the bacteria identified the organism in 9/10 GCA arteries but in none of the controls (0/11).MLST analysis identified the organism as *B. pseudomallei-like* (BpGCA).RT-PCR confirmed the absence of type III secretion factors, a genetic profile that confers an attenuated phenotype for many species of *Burkholderia*. IF of paraffin-embedded temporal arteries identified BpGCA-LPS in GCA arteries but not controls.ELISA detected BpGCA-LPS at high levels in the serum of GCA subjects (n=61, mean 437.8 pg/ml, SEM 36.7) but not healthy controls (n=102, mean 28.1 pg/ml, SEM 3.8, p<0.0001).BpGCA was cultured from the temporal artery of a subject with GCA and the isolate was used to infect C3H/HeSnJ mice. Mice injected with the organism developed inflammation of pulmonary blood vessels.

Conclusion: An attenuated newly identified species of *Burkholderia* has been isolated from temporal arteries of GCA subjects.LPS of the organism is detectable in the serum of GCA subjects. Mice infected with the organism develop vasculitis. BpGCA appears to be a critical factor in the pathogenesis of GCA.

Am80, a Retinoic Acid Receptor Agonist, Ameliorates Murine Vasculitisthrough the Suppression of Neutrophil Migration and Activation. Chie Miyabe[1], Yoshishige Miyabe[1], Noriko Miura[2], Kei Takahashi[3], Yuya Terashima[4], Etsuko Toda[4], Fumiko Honda[1], Tomohiro Morio[1], Naohito Ohno[2], Jun-ichi Suzuki[4], Mitsuaki Isobe[1], Kouji Matsushima[4], Ryoji Tsuboi[5], Nobuyuki Miyasaka[1] and Toshihiro Nanki[1]. [1]Tokyo Medical and Dental University, Tokyo, Japan, [2]School of Pharmacy, Tokyo University of Pharmacy and Life Science, Tokyo, Japan, [3]Toho University Ohashi Medical Center, Tokyo, Japan, [4]The University of Tokyo, Tokyo, Japan, [5]Tokyo Medical University, Tokyo, Japan

Background/Purpose: Vasculitis is characterized by leukocyte infiltration in the vessel walls with destructive damage to mural structures. Retinoids are compounds that bind to retinoic acid receptors (RARs)and have biological activities of vitamin A, including modulatory effects on cell proliferation and differentiation. Synthetic retinoid, Am80, is a specific ligand for RAR-α/β but not RAR-$\gamma$and is characterized by higher stability, fewer potential adverse effects, and superior bioavailability compared with all-*trans* retinoic acid. Previously we showed that Am80 ameliorated murine collagen-induced arthritis and experimental autoimmune*myositis*. In this study, we examined the therapeutic effects of Am80 on a murine model of vasculitis induced by *Candida albicans* water-soluble fraction (CAWS).

Methods: Vasculitis was induced in BALB/c mice by intraperitoneal injection of CAWS from day 1 for 5 days. Neutrophils were depleted by injection of anti-neutrophil serum. Am80 was administrated orally once dailyfrom day 1 for 5 weeks or from day 8 for 4 weeks. Vasculitis was histologically evaluated. Number of migrated cells of labeled-adaptively transfer cells was counted. Chemotaxis was analyzed using cell mobility analysis device. Production of reactive oxygen species (ROS) and phosphorylation of mitogen-activated protein kinases was measured by flow cytometry. Concentrations of elastase, CCL2 and IL-6 were measured by enzyme-linked immunosorbent assays.

Results: Administration of CAWS induced vasculitis in the coronary arteries and aortic root with abundant neutrophil infiltration. Depletion of neutrophils reduced CAWS-induced vasculitis. Treatment with Am80 from day 1 significantly attenuated the experimental vasculitis. In addition, administration of Am80 from day 8, after the onset of vasculitis, also ameliorated the vasculitis. Am80 inhibited migration of transferred neutrophils into the site of vasculitis. *In vitro*, Am80 suppressed N-formyl-methionyl-leucyl-phenylalanine (fMLP)-induced chemotaxis of human peripheral blood neutrophils. Am80 reduced ROS production by phorbol 12-myristate 13-acetate, Pam3CSK4 or lipopolysaccharide (LPS)-stimulated peripheral blood neutrophils. Elastase release by fMLP and cytochalasin B-stimulated neutrophils was inhibited by incubation with Am80. Am80 also inhibited phosphorylation of extracellular signal-regulated kinase 1/2 and p38 in neutrophils-stimulated with fMLP and LPS. Moreover, Am80 reduced CCL2 and IL-6 production from human umbilical vein endothelial cells-stimulated with TNF-α or IL-1β.

Conclusion: Am80 significantly suppressed CAWS-induced vasculitis presumably through inhibition of neutrophil migration and activation.

Impairment of the Inhibitory PD-1-PD-L1 Axis in Giant Cell Arteritis (GCA). Mazen Nasrallah[1], Augusto Vaglio[2], Shalini Mohan[1], Bjorn Hartmann[1], Joyce Liao[3], Kenneth J. Warrington[4], Jorg J. Goronzy[5] and Cornelia M. Weyand[6]. [1]Stanford University, Stanford, CA, [2]University of Parma, Parma, Italy, [3]Stanford University, Palo Alto, CA, [4]Mayo Clinic, Rochester, MN, [5]Stanford Univ School of Medicine, Stanford, CA, [6]Stanford University School of Medicine, Stanford, CA

Background/Purpose: Giant cell arteritis (GCA) is an autoimmune syndrome characterized by granuloma formation in the media of medium and large arteries. In a healthy immune system, excessive immune stimulation is counteracted by negative costimulatory signals which oppose T cell activation and protect tissue tolerance. An important inhibitory molecule within the B7/CD28 family is the programmed death-1 receptor (PD-1), with its ligand PD-L1. We have screened T cells from GCA patients for molecular elements that regulate inhibitory pathways and have tested the functional role of co-inhibitory molecules in in vitro and in vivo models of vasculitis.

Methods: Peripheral blood T cells from 45 patients with biopsy-proven GCA and 54 age-matched controls were profiled for the expression of positive and negative costimulatory receptors which critically adjust T cell-responsiveness. Transmural migration of activated T cells was studied in 3-dimensional cellulose fiber-based scaffolds populated with endothelial cells or vascular smooth muscle cells and assembled into walls mimicking human medium arteries. Disease-relevant functions of patient-derived CD4 T cells were studied in vivo in humanized chimera mice engrafted with human arteries.

Results: GCA patients have significantly increased frequencies of PD-1$^+$ CD4 T cells when compared to controls (30.3 % vs. 19.7 %; p=0.02). The PD-1 ligand PD-L1, normally strongly expressed on endothelial cells of the vasa vasorum was barely detectable in GCA-affected temporal arteries. PD-1-PD-L1 interactions were critically involved in regulating transfer of T cells across the endothelial barrier in the 3D-custom made arterial walls. Antibody-mediated blockade of PD-1 doubled the number of CD4 T cells crossing the endothelial layer (n=7 distinct T cell donors; p=0.04) and enhanced pooling of intrawall T cells. To explore the significance of negative signaling in arteritis, human artery-SCID chimeras were treated with the PD-1 blocking PD-L1 fusion protein. Disrupting PD-1 signaling effectively accelerated vessel wall inflammation; by enhancing T cell pooling and DC activation and boosting the production of innate and adaptive cytokines.

Conclusion: The PD-1-PD-L1 pathway protects the vessel wall from inflammatory attack. Several steps of the immune activation cascade relevant for GCA underlie regulation by this negative signaling pathway. T cells from GCA patients receive insufficient inhibitory signals due to a lack of PD-L1 expression. Reestablishing negative signaling may be necessary to prevent detrimental immune responses in GCA and to restore the immune privilege of the arterial wall.

Dense Genotyping, Imputation, and Regression Analysis Identifies Multiple Independent Genetic Susceptibility Loci within the HLA Region in Behcet's Disease. [1]University of Michigan, Ann Arbor, MI, [2]Oklahoma Medical Research Foundation, Oklahoma City, OK, [3]Istanbul University, Istanbul Faculty of Medicine, Department of Physiology, Istanbul, Turkey, [4]Ege University, Izmir, Turkey, [5]Ankara University, Ankara, Turkey, [6]Kocaeli University, Kocaeli, Turkey, [7]Okmeydaný Research and Education Hospital, Istanbul, Turkey, [8]Akdeniz University, Antalya, Turkey, [9]Arcispedale S Maria Nuova. IRCCS, Reggio Emilia, Italy, [10]Molecular Biology Laboratory, Arcispedale S. Maria Nuova, Reggio Emilia, Italy, [11]University Hospital, Tuebingen, Germany, [12]University Medical Hospital Groningen, University of Groningen, Groningen, Netherlands, [13]Marmara University, School of Medicine, Istanbul, Turkey, [14]Istanbul University, Istanbul Faculty of Medicine, Istanbul, Turkey

Background/Purpose: The genetic association between *HLA-B51* and Behcet's disease is well established. However, localizing this genetic effect and exploring additional susceptibility loci within the HLA has been limited by the complexity and the strong linkage disequilibrium in this region. Herein, we provide evidence for multiple independent genetic effects within the HLA region in Behcet's disease, using two independent and ethnically divergent cohorts.

Methods: A total of 503 Turkish patients and 504 controls, and 144 Italian patients and 1270 controls were genotyped across 8,572 SNPs in the HLA extended region (Chr6: 28,889kb-33,000kb, HG19) using a custom platform (Immunochip). After applying quality control and tests for autosomal heterozygosity, identity by descent, and population stratification by principal component analysis, 467 Turkish patients and 472 controls, and 127 Italian patients and 1266 controls were included in the final analysis. Additional variants from the 1000 Genomes Project were imputed in both cohorts using Impute 2 with a combined reference panel of 1,092 individuals. Meta-analysis was then performed among 24,834 markers conserved between the two cohorts and genetic analysis performed. Next, logistic regression and pairwise conditional analysis was performed to identify independent effects among the associations detected.

Results: Three independent genetic association effects were detected between the HLA region and Behcet's disease ($r^2<0.30$).The most significant association was with rs116799036 (meta-analysis: OR= 3.88, P= 9.42×10^{-50}; Turkish: OR= 3.74, P= 5.75×10^{-33}; Italian: OR= 4.14, P= 4.93×10^{-23}) which is located approximately 24kb upstream of *HLA-B* and 18kb upstream of *MICA*. A second independent genetic association tagged by rs12525170 located within *PSORS1C1* (meta-analysis: OR= 3.01, P= 3.01×10^{-26}; Turkish: OR= 2.90, P= 1.35×10^{-17}; Italian: OR= 3.22, P= 4.51×10^{-12}), and a third tagged by rs114854070 located 1.4kb upstream of *HLA-F-AS1* (meta-analysis: OR= 1.95, P= 7.84×10^{-14}; Turkish: OR= 1.97, P= 2.34×10^{-9}; Italian: OR= 1.91, P= 3.74×10^{-6}) were also detected. Each of these three genetic associations in the HLA region maintained significance after controlling for the effects of the other two using regression analysis, in both cohorts independently and in the meta-analysis. This was confirmed using pairwise conditional analysis.

Conclusion: Multiple independent genetic associations are observed in the HLA region for Behcet's disease. While the most significant association resides upstream of *HLA-B* and *MICA* genes, two genetic associations in *PSORS1C1* and in *HLA-F-AS1* appear to be independent.

Endothelin-1 (ET-1) Induces Extracellular Matrix Protein Production by Human Temporal Artery Derived Myointimal Cells. A Mechanism Potentially Leading to Intimal Hyperplasia and Vascular Occlusion in Giant-Cell Arteritis. Ester Planas-Rigol[1], Marc Corbera-Bellalta[2], Marco A. Alba[2], Itziar Tabera-Bahillo[2], Sergio Prieto-Gonzalez[2], Georgina espigol-Frigole[2], Jose Hernandez-Rodriguez[3]. Ester Lozano[4] and Maria C. Cid[1], [1]Vasculitis Research Unit. Hospital Clínic. University of Barcelona. IDI-BAPS, Barcelona, Spain, [2]Hospital Clinic University Barcelona, Barcelona, Spain, [3]Hospital Clínic. University of Barcelona. IDIBAPS, Barcelona, Spain, [4]Hospital Clinic University Barcelona

Background/Purpose: Endothelin-1 (ET-1) is the main isoform of the Endothelin family. It is also the most powerful vasoconstrictor identified. ET-1 is constitutively produced in blood vessels by endothelial cells and vascular smooth muscle cells (VSMC). VSMC express two endothelin receptors: Endothelin receptor A and B (ETAR and ETBR) but the main effect of vasoconstriction may be the result of the interaction between ET-1 and ETAR. Transforming Growth Factor β1 is a fibrogenic cytokine and recent studies suggest that ET-1 contributes to the fibrogenic effect of TGFβ by fibroblasts.

To investigate whether ET-1 and TGFβ may contribute to vascular occlusion by inducing pro-fibrotic responses in cultured vascular myointimal cells.

Methods: VSMC were obtained from cultured human temporal artery sections obtained for diagnostic purposes as described (Ann Rheum Dis. 2008 Nov; 67(11):1581–8). ET-1, TGFb, collagen type I (COL1) and type III (COL3) expression was assessed by quantitative real-time PCR (Taqman[R] Gene Expression Assay) from Applied Biosystems. COL1 and COL3 protein production was determined by ELISA (Takara and USNC Biological) kits respectively.

Results: ET-1 and TGFb up regulated COL1, COL3 expression by VSMC at the mRNA and protein level. This increase was inhibited by ETAR receptor antagonist BQ123 and partially abrogated by ALK5 inhibitor SB525334.

ET-1 induced indeed a remarkable early expression of TGFβ and TGFb induced, in turn, a later induction of ET-1. A double blockade of these cytokines enhanced the inhibition of COL1 and COL3 expression suggesting that collagen production by VSMC may be dependent of both ET-1 and TGFβ.

Phenotypic changes in ET-1-treated-VSMC were also observed. These cells became adherent earlier than untreated ones. Treatment with BQ123 reverted this phenotype suggesting that ET-1 may have an important role in the regulation of VSMC adhesion and migration

Conclusion: ET-1 may contribute to intimal hyperplasia directly by inducing collagen type I and III by human medium-size artery derived myointimal cells. Since ET-1 and TGFb are expressed in GCA lesions these preliminary results suggest that ETAR and ALK5 receptor antagonists may prevent intimal hyperplasia and vascular occlusion in GCA.

Interleukin-21, B Cell Activating Factor and Unmethylated CpG Oligodeoxynucleotides Synergize in Promoting Anti-Proteinase 3 Autoantibody Production *in Vitro*. Nikola Lepse[1], Judith Land[1]. Abraham Rutgers[1], Cees G.M. Kallenberg[1], Coen A. Stegeman[1], Peter Heeringa[2] and Wayel H. Abdulahad[1], [1]University Medical Center Groningen, Groningen, Netherlands, [2]University Medical Center Groningen, Netherlands

Background/Purpose: Anti-neutrophil cytoplasmic autoantibody (ANCA)-associated vasculitides (AAV) are characterized by the presence of circulating autoantibodies that are often directed against proteinase 3 (PR3). Although the mechanisms that lead to ANCA production in AAV are not clear, bacterial infections have been linked to disease development. We have reported that unmethylated CpG oligodeoxynucleotides (CpG-ODN), which resemble bacterial DNA, in combination with IL-2 enhance ANCA production *in vitro*. Recent studies have highlighted the role of IL-21 in plasma cell formation and antibody production by synergizing with B cell activating factor (BAFF). This study aimed to assess the involvement of CpG-ODN, IL-21, and BAFF in the mechanisms that contribute to ANCA production in AAV patients.

Methods: Twenty two patients with PR3-AAV (18 in clinical remission, 4 with active disease) and 8 healthy controls (HC) were included in the study. Peripheral blood mononuclear cells (PBMC) were isolated and cultured *in vitro* for 12 days in the presence of BAFF and IL-21, with or without CpG-ODN. IgG production was measured in culture supernatants by ELISA and PR3-ANCA production was quantified by Phadia EliA and expressed in response units (RU). The percentage of circulating IL-21 producing CD4+ T cells was analyzed by flow cytometry in blood samples stimulated *ex vivo* with phorbol-myristate-acetate and calcium ionophore in the presence of brefeldin A. CFSE Cell Proliferation Kit was used to assess the effect of BAFF, IL-21, and CpG-ODN on B cell proliferation.

Results: PBMC stimulation with CpG-ODN and IL-2 significantly increased *in vitro* production of IgG in both HC and patients (P=0,0004) whereas PR3-ANCA production was detected in patient samples only (RU median 0,85 (range 0,00–36,72), compared to 0,10 (0,00-0,14) in HC). Stimulation with BAFF and IL-21 also significantly increased IgG production in HC and patients (P=0,0001) and ANCA production in patient samples (median 0,90 (range 0,00–58,80) versus 0,11 (0,00-0,12) in HC), which could be further augmented by addition of CpG-ODN (median 1,06 (range 0,00–140,00) versus 0,17 (0,10–0,26) in HC). Compared to HC, the proportion of IL-21 producing CD4+ T cells was significantly increased in the circulation of AAV patients. Preliminary data indicate that stimulation with BAFF, IL-21 or the combination of BAFF/IL-21 does not induce B cell proliferation. In contrast, stimulation with CpG-ODN alone induced proliferation in 11,6% of B cells, whereas the combined treatment with BAFF, IL-21 and CpG-ODN induced proliferation in 57,8% of B cells.

Conclusion: IL-21, BAFF and CpG ODN synergize in promoting IgG and PR3-ANCA production from PBMCs of AAV patients *in vitro*. This effect was associated with substantial B cell proliferation. The increased percentage of IL-21 producing CD4+ T cells in AAV patients suggests the involvement of IL-21 in ANCA production *in vivo*. Overall, these data indicate that the interplay between endogenous B cell stimuli and bacterial products may contribute to PR3-ANCA reactivation in AAV via B cell activation and proliferation.

A Family Based Pedometer Walking Program in an Adolescent Population with Juvenile Idiopathic Arthritis. Sara M. Stern, Jill R. Blitz, Amber Richards and Katherine AB Marzan. Children's Hospital Los Angeles, Los Angeles, CA

Background/Purpose: Walking programs are effective in adult arthritis but have not been studied in adolescents with arthritis.The study's objective was to evaluate the impact of a family based pedometer (PED) walking program and an educational program on the exercise tolerance of adolescent juvenile idiopathic arthritis (JIA) patients (Pts) with lower extremity involvement.

Methods: 27 Pts with lower extremity JIA were prospectively studied in a 2 phase exercise program.In the 1st 6 week (wk) phase Pts were given typical guidance from a rheumatologist and physical therapist to increase their activity with daily walking.Data was obtained at baseline, and after the 1st and 2nd 6 wk phases.In the 2nd 6wk phase all Pts and family members received a PED to record their daily steps and were randomized into 2 groups.One group attended a 30 min Arthritis Foundation *Walk with Ease* (WWE EP) educational program specifically adapted for adolescents and the other did not.The 6 minute walk test (MWT) was the primary outcome measure to assess program effectiveness.Secondary outcome measures included body mass index (BMI), Childhood Health Assessment Questionnaire (CHAQ), and visual analogue scale (VAS) for pain.

Results: 27 Pts (23 F: 4M) 11–19 yrs old (mean 16 yrs) participated.19 were Latino (Lat) reflecting the population of the center.13 completed the study.All but 1 of the 14 Pts (12 Lat, p = 0.1) that discontinued the study did so between the 1st and 2nd visit prior to receiving a PED primarily due to 2nd thoughts about participating in an exercise program.While no statistically

significant differences were noted between Pts that discontinued and completed the study, those that discontinued had a trend towards higher BMI, shorter 6MWT, smaller HR change and higher VAS scores possibly reflecting a less motivated group.

13 pts (7 Lat) with mean age of 16 ± 2 yrs completed the study (12F: 1M).They generally had mild disease with a mean CHAQ of 0.65 ± 0.79 and mean VAS of 2.5 ± 3.6 cm.5 Pts had active JIA at the initial visit and 3 other Pts had active JIA over the course of the study.There was a significant increase in 6 MWT distance from baseline (458.0 ± 70.8 m) to the end (501.4 ± 59.8 m) of the 6wk initial phase (p = 0.029).During the interventional 2nd phase, Pts maintained their improved exercise tolerance with a modest trend toward increased 6 MWT from 501.4 ± 59.8 mto 504.7 ± 60.6 m (p = 0.76).There were no differences in the 6 MWT between the Pts that received the education program (n=9) to those that did not (n=4) possibly due to small sample size (p = 0.93).However, the WWE EP group at baseline visit appeared to have an overall higher exercise tolerance (6 MWT 478.1 ± 78.5 m vs 417.8 ± 27.2 m) and had a healthier initial BMI (23±5 vs 26±3).In addition, Pts in the WWP EP group overall walked more steps per day while using their PED (2978 ± 3002 steps vs 1968 ± 1472 steps), although this was not statistically significant.

Conclusion: In motivated adolescents with JIA, an exercise program with consistent support from a physical therapist and rheumatologist significantly increased exercise tolerance.The addition of a PED and modified WWE EP to a walking program helped Pts maintain or increase exercise tolerance.

What Is the Impact of a Transition Program On Adolescents with Juvenile Idiopathic Arthritis and Their Parents ? Deborah Hilderson[1], Rene Westhovens[2], Rik Joos[3], Carine H. Wouters[2] and Philip Moons[4]. [1]University Hospital Leuven, KU Leuven, Leuven, Belgium, [2]University Hospital KU Leuven, Leuven, Belgium, [3]University Hospital Gent, Ghent, Belgium, [4]KU Leuven, Leuven, Belgium

Background/Purpose: To date, there is no structured or systematic approach in Belgium for transferring adolescents with juvenile idiopathic arthritis from pediatric rheumatology to an adult rheumatology setting. We explored the impact of a transition program for adolescents with JIA on patient- and parent-related outcomes.

Methods: Using a one-group pretest-posttest design with a non-equivalent posttest only comparison group, we included literate, Dutch-speaking adolescents (14–16 years of age) with JIA, treated and followed-up at the department of pediatric rheumatology of the University Hospitals of Leuven in the experimental group. The intervention consisted of five key components: introduction of the transition coordinator (TC), focus upon health behavior, adolescent-information day, transfer plan and transfer to adult rheumatology care under the guidance of the TC. The comparison group comprised adolescents aged 17–23 years, who have recently been transferred to the adult rheumatology program without a specific transition program. Outcomes were operationalized in terms of medication adherence (VAS, SHCS-AQ), illness related knowledge (modified PKQ), functional status (CHAQ), health status (PedsQL), global quality of life (LAS), fatigue (MVI-20), and patients' knowledge (modified PKQ). In parents, we measured promotion of independence (PI Scale), support of autonomy (Autonomy Support Scale), psychological control (Psychological Control Scale), health status (PedsQL for parents) and functional status of their child (CHAQ). A total of 33 patients in the intervention group and 45 patients in the comparison group participated. Overall, 23 patients could be matched with controls on gender, JIA subtype, clinical remission, medication prescription and disease activity with comparison patients. Effect sizes in outcomes of the experimental group were measured at baseline and after transfer to the adult program (longitudinal study). Effect sizes in outcomes between the experimental group and the matched comparison group of patients transferred to the adult program without a specific self-management/transition program were measured (comparative study).

Results: *Longitudinal study*: A large positive effect was calculated for the improved psychosocial health. A medium positive effect was found in the improvement of quality of life of patients. Medium negative effects were found in improved health status rheumatology, perceived by parents. *Comparative study:* For patients in the experimental group, a large positive effect was found in reduction of parental expectations. Medium positive effects were found in improved psychosocial health and reduction in behavioral control. Medium negative effects were found in reduction of psychological control.

Conclusion: Implementation of a transition program can improve the psychosocial health and quality of life of adolescents with JIA during the transition process. It is important to involve the parents into the transition process in order to promote self-management of the adolescent with JIA.

Employment of a Needs Assessment Survey to Shape a Novel Web-Based Pediatric Rheumatology Curriculum for Primary Care Providers. Amy L. Woodward and Z. Leah Harris. Vanderbilt University School of Medicine, Nashville, TN

Background/Purpose: Pediatric rheumatology faces many challenges due to the shortage of board certified physicians in the field and the imbalance in their geographic distribution.This shortage has required primary care physicians and adult rheumatologists to assume the care of children with rheumatologic diseases, though these physicians report significant discomfort doing so. We are addressing this issue through the development of a novel web-based curriculum aimed at primary care physicians, employing a needs assessment survey to help guide the curriculum.

Methods: Tenants of adult learning theory stress activating the learners' prior knowledge and engaging the learner in determining personal educational goals. We therefore distributed a needs assessment survey to Vanderbilt Pediatric residency graduates (1981–2010) working in primary care who kept an address on file with the Vanderbilt Medical Alumni Association. Our goals were to understand perceptions of what the needs are and what educational interventions would be most effective.

Results: Of 152 surveys sent successfully via Survey Monkey, we received 28 responses (18.4%). When asked the question "On completion of your residency training were you comfortable recognizing the following diseases in children?", the self-reported ability to recognize chronic arthritis on completing residency was high (71.4%), while confidence in recognizing other chronic autoimmune diseases was low, with only 64.3% comfortable recognizing lupus, the majority uncomfortable recognizing juvenile dermatomyositis (53.6%), localized scleroderma (75%), systemic sclerosis (82.1%), Behcet's Disease (75%) and sarcoidosis (82.1). (Figure 1) We also found primary care physicians to have interest in practical, problem oriented educational resources, including action plans for common rheumatologic complaints (71.4%) and emergencies by specific disease (67.9%) (Figure 2).

Specific autoimmune disease	Yes	No
Chronic arthritis	71.4% (20)	28.6% (8)
Systemic lupus erythematosus	64.3% (18)	35.7% (10)
Juvenile dermatomyositis	46.4% (13)	53.6% (15)
Henoch-Schonlein purpura	100% (28)	00.0% (0)
Kawasaki Disease	92.9% (26)	7.1% (2)
Localized Scleroderma	25.0% (7)	75.0% (21)
Systemic sclerosis (systemic scleroderma)	17.9% (5)	82.1% (23)
Behcet's Disease	25.0% (7)	75.0% (21)
Sarcoidosis	17.9% (5)	82.1% (23)

Possible Intervention

Intervention	% favorable response
Additional education in Pediatric Rheumatology	78.6%
Proactive plan of approach for common rheum problems	71.4%
Action plan for emergencies by specific disease	67.9%
Action plan for emergencies for specific patients	60.7%
Improved access to peds rheumatologist for questions	57.1%
Improved access to peds rheumatologist for urgent visits	39.3%

Conclusion: Our needs assessment survey of primary care physicians found a high self-reported ability to recognize chronic arthritis when leaving

residency training, though low confidence in recognizing rarer but potentially more serious or life-threatening autoimmune diseases. Our results also indicate that primary care physicians have interest in practical, problem oriented educational resources to assist them in caring for children with rheumatologic diseases. We will utilize our survey results to develop a learner centered web-based curriculum in pediatric rheumatology, with the ultimate goal of improving care for children with autoimmune diseases.

Will I Waste Your Time? Delays in Help-Seeking for RA Flares. Caroline A. Flurey[1], Marianne Morris[1], Jon Pollock[1], Rodney A. Hughes[2], Pamela Richards[3] and Sarah Hewlett[1]. [1]University of the West of England, Bristol, United Kingdom, [2]St. Peters Hospital, Chertsey Surrey, United Kingdom, [3]University of Bristol, Bristol, United Kingdom

Background/Purpose: Anecdotal evidence suggests that patients vary in how long they wait before seeking medical help for an RA flare. The aim of this research is to explore why, and their tipping points for seeking help.

Methods: Q-Methodology: 29 RA patients sorted 23 statements (generated in previous qualitative interviews) about their help seeking behaviours when in a flare, across a forced distribution in ranked order of agreement. Data were analysed using centroid factor analysis with varimax rotation (i.e. the participants and not the items are the variables). Demographic and clinical data were collected and patients completed comments booklets about their rationale for sorting the statements.

Results: Consensus was reached on 9 statements and two factors were produced, which explained 51% of the study variance and accounted for 22 of the 29 participants. None of the Q-sorts were confounded (loading on more than one factor). A participant loading of 0.54 reached significance at p<.01.

Consensus: "When I just don't know what to do anymore": The top 3 of the 9 consensus statements are 'when the pain becomes too intense', 'when the Flare has gone on longer than expected' and 'when the symptoms become uncontrollable', suggesting these are the tipping points for seeking help.

Factor A: Definite Decision: "It won't go away, so I won't wait": Sixteen participants: mean disease duration 15.2yrs (SD 10.3), age 54.8yrs (SD 9.6), HAQ score 1.360 (SD 0.8), 69% female, 69% on biologic therapies.

These patients will seek help quickly when they are in a flare, they know that their medical team can help and that their flare won't go away on its own. They don't worry about wasting their own or the Rheumatologist's time and will not wait until their next scheduled appointment for help. Tipping points for seeking help for these patients are worries about long term damage to their joints, knowing their flare needs to be controlled by new medication and their quality of life being affected.

Factor B: Cautious Indecision: "Lying down and not moving until it goes": Six participants: mean disease duration 18.7yrs (SD 13.9), age 50.5yrs (SD 15.4), HAQ score 1.23 (SD 0.9) 67% female, 0% on biologic therapies.

These patients wait to contact the medical team when they are in a flare. They are reluctant to seek help as they hope the flare will go away on its own and do not believe it will last until they seek medical help. They don't like asking for help and worry about wasting the Rheumatologist's time. They may wait until their next scheduled appointment before seeking help and will try to manage their symptoms themselves. These patients need to be prompted by a friend or family member to seek help.

Conclusion: Whilst consensus indicates pain is a tipping point, for some patients a complex interaction of beliefs hinders their help-seeking behaviour. Health care professionals should be aware that some patients delay help-seeking due to fears of time wasting, thus potentially risking further damage.

Disclosure: **C. A. Flurey**, None; **M. Morris**, None; **J. Pollock**, None; **R. A. Hughes**, None; **P. Richards**, None; **S. Hewlett**, None.

A Methodology for Estimating Disease State Transitions: Repeated Measures Markov Models with Covariate Dependence. George W. Reed[1], Andrew S. Koenig[2]. Katherine C. Saunders[3], David H. Collier[4], Joel M. Kremer[5] and Sameer Kotak[6], [1]University of Massachusetts Medical School, Worcester, MA, [2]Pfizer Inc., Collegeville, PA, [3]CORRONA, Inc., Southborough, MA, [4]Amgen Inc., Thousand Oaks, CA, [5]Albany Medical College and The Center for Rheumatology, Albany, NY, [6]Pfizer Inc., New York, NY

Background/Purpose: Many RA patients have variable disease activity over time due to disease flare, reduction in efficacy of current medications and other disease mediating changes. Understanding these transitions and the factors associated with these transitions are important in the treatment of RA. Appropriate analytic models for estimating these transitions are needed.

Methods: Modeling methods were explored for estimating transitions from various disease states defined by low, moderate and severe using CDAI. The framework needed to provide intuitive estimates of the probability of transitioning between states, stability using variable time intervals, allow repeated measures within patients, and a method of estimating associations of patient and treatment characteristics with transition probabilities. A Markov modeling framework was examined. To test the models we used RA patient disease activity data from the CORRONA RA registry and examined multiple visits per patient. There were over 160,000 visits from over 24,000 RA patients available for analysis.

Results: Starting with a simple transition model (Figure 1a), a first order Markov process was assumed and a logistic regression model that incorporates a single prior state produced stable estimates for variable time between visits. Transition probabilities differed by 0.07 for large differences in visit intervals, 3 mos vs 1 yr. A single logit equation can estimate the impact of the prior state ($Y_{i,\,j-1}$), covariates (x_{ij}) associated with the transitions and test if different covariate associations are dependent on prior state:

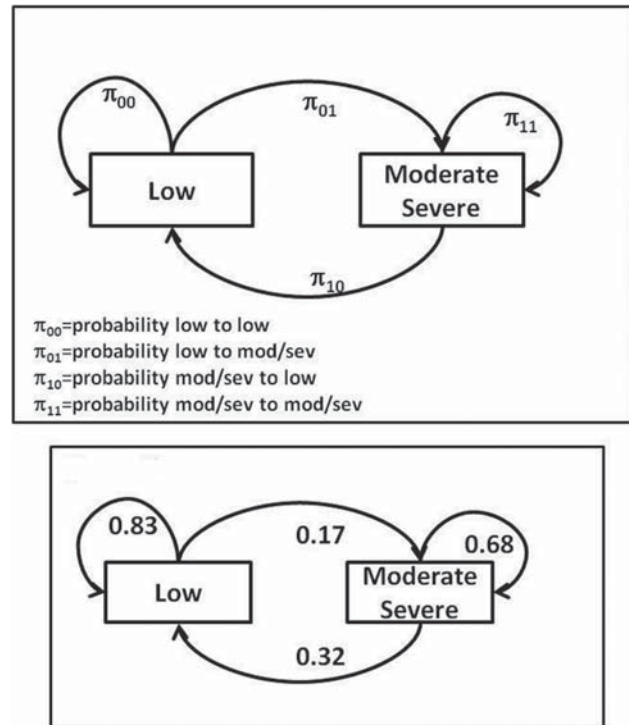
$$\text{logit Pr}(Y_{ij} = |Y_{ij} = y_{ij}) = \beta_0 x_{ij} + y_{ij-1}\alpha_{ij},$$

where

$$\pi_{j-1,1} = \text{Pr}(Y_{ij} = 1 | Y_{ij-1} = y_{ij-1}).$$

Figure 1b illustrates estimated transition probabilities.

The modeling framework is able to accommodate additional complexities. A multinomial logistic model provides estimates for more than two states. The models allow the use of higher order Markov processes to estimate the influence of disease state at earlier visits.

π_{00}=probability low to low
π_{01}=probability low to mod/sev
π_{10}=probability mod/sev to low
π_{11}=probability mod/sev to mod/sev


Conclusion: Markov models and logistic or multinomial models of the transition probabilities provides a framework for analyzing patient disease states, the population transition probabilities and covariates associated with those transitions.

Pain Is Associated with Telomere Shortening in Women with Fibromyalgia. Afton L. Hassett[1], Daniel J. Clauw[1], Richard E. Harris[1], Steven E. Harte[1], Anson E. Kairys[1], Steven Buyske[2] and David A. Williams[1]. [1]University of Michigan, Ann Arbor, MI, [2]Rutgers University, Piscataway, NJ

Background/Purpose: Telomere length is considered a marker of cellular aging and has been linked to an increased risk for morbidity and mortality. Psychosocial factors associated with shortened telomeres (e.g., obesity, depression, anxiety, trauma) are also common in chronic pain; yet, little is known about telomere length in pain populations. Thus, a preliminary investigation was conducted in fibromyalgia.

Methods: Leukocyte telomere length was evaluated in 66 women with fibromyalgia and 22 healthy female controls. Participants were from a convenience sample of individuals who underwent a blood draw and completed questionnaires including the Brief Pain Inventory (BPI) and Center for Epidemiologic Studies Depression Scale (CESD). A subgroup of fibromyalgia patients underwent quantitative sensory testing (QST; n=12) and neuroimaging (voxel-based morphometry; n=12). Telomere length was measured using the quantitative polymerase chain reaction method.

Results: Although patients had shorter telomere length than controls, the difference was not statistically significant. However, higher levels of pain within fibromyalgia were associated with shorter telomere length ($r_{partial} = -.267$, $p = 0.039$). In a comparison of patients categorized as having higher levels of pain (BPI $\geq 5/10$; n = 30) and lower levels of pain (BPI $< 5/10$; n = 31), those with higher levels of pain were more likely to have shorter telomere length than those with low levels of pain despite chronological age ($F = 5.39$, $p = 0.024$). In a similar comparison of telomere length between those with likely depression (CESD scores $\geq$ 19; n = 24) and those likely without depression (CESD scores $<$ 19; n = 42), no significant group differences were detected ($p = 0.175$). However, when pain and depression were combined, patients categorized as high-pain/high-depression had an age-adjusted telomere length 265 base pairs shorter than those with low-pain/low-depression ($p = 0.043$); a difference consistent with over six years of chronological aging. In the subset tested, telomere length was also related to experimentally-induced pain threshold ($r_{partial} = .728$, $p = 0.017$), mild pain ($r_{partial} = .642$, $p = 0.045$) and slightly intense pressure pain ($r_{partial} = .706$, $p = 0.023$), as well as gray matter volume (e.g., primary somatosensory cortex: $r = .725$, $p < 0.05$ corrected), such that patients with shorter telomeres tended to be more sensitive to evoked pressure pain and have less gray matter volume in pain processing regions of the brain.

Conclusion: Our data suggest that pain in fibromyalgia is associated with shortened telomere length. These effects are largely independent of other factors commonly associated with telomere shortening.Interestingly, short telomere length was directly related to evoked pain sensitivity and altered brain structure. Although these findings are preliminary, they suggest that pain may accelerate cellular aging.

867

Events That Triggerthe Onset of the Fibromyalgia Syndrome (FMS). Robert S. Katz[1], Sharon M. Ferbert[2], Alexandra Small[3] and Susan Shott[1]. [1]Rush University Medical Center, Chicago, IL, [2]Advocates for Funding Fibromyalgia Treatment, Education and Research(AFFTER), Libertyville, IL, [3]University of Illinois Medical School

Background/Purpose: Triggering events – those that are followed by the onset or rapid increase in FMS symptoms – have a significant impact in some cases.In order to learn more about the nature and impact of triggering events, we asked FMS patients about traumatic experiences in their lives, and whether these events affected the onset of their FMS symptoms.

Methods: As a part of an Internet survey administered by the volunteer community fibromyalgia organization, AFFTER, 763 female self-identified FMS patients and 115 female controls without FMS responded to questions about emotionally stressful or life-changing events and whether any of these events suddenly triggered FMS, as well as follow-up questions on the pace of onset of FMS symptoms before and after triggering events. Only women's responses were analyzed to eliminate confounding by gender.

To validate the Internet Survey, an identical rheumatology office questionnaire was administered to 115 FMS patients and 63 control patients with other rheumatic diseases.The chi-square test of association and Fisher's exact test were used to compare percentages, and the Mann-Whitney test was done to compare FMS and control patients with respect to age. A 0.05 significance level was used and all tests were two-sided.

Results: In the Internet survey the mean respondent age was 49.8 ± 11.4 years. 78.0% of FMS respondents reported that they had experienced a significant life-changing event or emotional stressor, vs. 35.7% of controls ($p < 0.001$). Specific traumatic events experienced by FMS patients vs. controls included major surgery (70.4% vs. 43.5%, $p < 0.001$), major or long lasting illness (44.7% vs. 18.3%, $p < 0.001$), and accidents 26.9% vs. 12.2, $p = 0.001$).

Post-traumatic symptoms included startling easily (32.2%), intrusive memories of the trauma (18.1%), nightmares (17.7%), reluctance to speak or think about the trauma (14.5%), and symptoms of hypervigilance and post-traumatic stress disorder.30.2% indicated that their FMS began suddenly after one of these events. These post-traumatic episodes generally began as either back pain (50.4%), neck pain (50.0%) or both.

In the rheumatology office practice questionnaire 81.7% of FMS patients and 61.9% of control patients were women ($p = 0.004$). The mean age was 48.1 ± 12.3 years for FMS patients and 50.7 ± 13.6 for control patients ($p = 0.092$). 88.7% of FMS patients and 76.2% of control patients reported that they had experienced at least one very stressful or life-changing event ($p = 0.028$). Some of the FMS patients who reported a traumatic FMS trigger also reported other post-trauma symptoms: startling easily (15.4%), intrusive memories of the trauma (10.3%), reluctance to speak or think about the trauma (10.3%), and nightmares (7.7%).

Conclusion: Surgery, severe illness, and accidents precipitated the onset of fibromyalgia in some patients. In the Internet survey, 30.2% of fibromyalgia patients experienced FMS onset after a traumatic event.Fibromyalgia symptoms usually began with neck or back pain. Some of the FMS patients experienced symptoms consistent with hypervigilance and post-traumatic stress disorder.

868

Illness Perceptions Among Patients with Different Forms of Vasculitis. Peter C. Grayson[1], Naomi Amudala[1], Carol McAlear[2], Renée Leduc[3], Denise Shereff[3], Rachel Richesson[3], Liana Fraenkel[4] and Peter A. Merkel[5]. [1]Boston University Medical Center, Boston, MA, [2]Vasculitis Clinical Research Consortium, University of Pennsylvania, Philadelphia, [3]University of South Florida, Tampa, FL, [4]Yale University School of Medicine, Veterans Affairs Connecticut Healthcare System, New Haven, CT, [5]University of Pennsylvania, Philadelphia, PA

Background/Purpose: Patient-held beliefs about their illness are central for understanding patient reactions to specific diseases. This study aimed to compare illness perceptions, defined as the organized cognitive beliefs patients hold about disease, among different forms of vasculitis and to identify risk factors for negative illness perceptions.

Methods: Participants were recruited from an online registry in vasculitis to complete the revised Illness Perception Questionnaire (IPQ-R) which measures dimensions of illness perception. High scores on the *identity, timeline, cyclical, consequences,* and *emotional representations* dimensions represent strongly held beliefs about the number of symptoms attributed to illness, the chronicity and cyclical nature of the condition, the negative consequences of illness, and the negative emotional impact of disease. High scores on the *personal control, treatment control* and *illness coherence* dimensions represent positive beliefs about the controllability of the illness and personal understanding of the condition. Mean scores in IPQ-R dimensions were compared across types of vasculitis where n>30 and to literature-reported IPQ-R scores in diabetes mellitus, hypertension, and osteoarthritis using ANOVA with post-hoc Scheffe tests. Cluster analysis of IPQ-R scores was used to identify a group with negative illness perceptions, and stepwise regression was used to identify clinical variables (age, sex, race, ethnicity, place of birth, education, income, depression) and disease characteristics (activity status, severity, duration, overall health) associated with negative illness perception.

Results: 692 participants with 9 forms of vasculitis completed the IPQ-R. For 6 dimensions, there were no significant differences in mean IPQ-R scores between the different vasculitides.Scores in *identity* and *cyclical* dimensions

were significantly higher in Behçet's disease compared to other types of vasculitis (13.5 vs 10.7; 4.0 vs 3.2, p<0.05). Compared to other chronic diseases, patients with vasculitis perceived greater negative disease impact on function and emotional well-being (**Table**). Younger age (OR=1.04; 95%CI 1.02–1.06), depression (OR=4.94; 95%CI 2.90–8.41), active disease status (OR=2.05; 95%CI 1.27–3.29), and poor overall health (OR=3.92; 95%CI 0.88–17.56) were significantly associated with negative illness perception.

Table 1. Mean IPQ-R Dimension Scores in Vasculitis and Other Chronic Diseases

	Vasculitis* n = 692	Diabetes[a] n = 164	Hypertension[b] n = 514	Osteoarthritis[c] n = 241
*Identity***	10.7 (±5.1)	NC	NC	NC
Timeline	4.1 (±0.8)	3.9 (±0.8)	3.6 (±0.4)	4.2 (±0.8)
Cyclical	3.2 (±1.0)	2.8 (±0.7)	3.2 (±0.8)	3.6 (±0.8)
*Consequences****	3.8 (±0.8)	2.9 (±0.6)	2.6 (±0.6)	2.8 (±0.8)
*Emotional repr.****	3.1 (±1.0)	2.0 (±0.6)	2.6 (±0.7)	2.4 (±0.8)
Personal control	3.3 (±0.8)	3.9 (±0.6)	3.5 (±0.7)	3.1 (±0.6)
Treatment control	3.3 (±0.7)	4.6 (±0.9)	3.5 (±0.6)	2.8 (±0.6)
Illness coherence	3.4 (±1.0)	3.5 (±0.9)	NR	3.6 (±0.8)

* Vasculitis types include Behçet's disease (n=48), central nervous system vasculitis (n=12), Churg-Strauss syndrome (n=121), giant cell arteritis (n=32), Henoch-Schönlein purpura (n=12), microscopic polyangiitis (n=42), polyarteritis nodosa (n=36), Takayasu's arteritis (n=57), and granulomatosis with polyangiitis (n=332). ** Identity was scored on scale from 0–22. All other dimensions were scored on a scale from 1–5. *** Difference between vasculits and all other diseases (p<0.05). NC = not comparable across diseases due to disease-specific modifications to IPQ-R. NR = not reported. [a] = Searle, *J of Psych Res*, 2007; [b] = Ross, *J of Hum Hypertension*, 2004; [c] = Bijsterbosch, *A&R*, 2009.

Conclusion: Patients with vasculitis have a unique set of illness perceptions. Clinicians should be aware that younger age, a history of depression, active disease status, and poor overall health are risk factors for negative illness perceptions in systemic vasculitis. Given the similarities in illness perceptions across the vasculitides, ongoing efforts to derive patient-reported outcome measures in vasculitis should focus on measures that are universally applied to different types of vasculitis.

Concepts Which Determine Health in a Positive Way Are Important to People with Rheumatoid Arthritis and Are Covered by Some Patient-Reported Outcome Instruments. Mona Dür[1], Michaela Coenen[2], Josef S. Smolen[3] and Tanja A. Stamm[1]. [1]Medical University of Vienna, Vienna, Austria, [2]Ludwig-Maximilians-University, Munich, Germany, [3]Medical University of Vienna and Hietzing Hospital, Vienna, Austria

Background/Purpose: Rheumatoid arthritis is a chronic autoimmune disease that has a major impact on functioning, health and well-being. Concepts which determine health in a positive way are often not addressed in a busy clinical setting. The aim of this study is to explore which concepts determine health in a positive way and are meaningful to patients with RA. Furthermore we wanted to analyse whether they are covered by patient-reported outcome (PRO) instruments, and which of them could be recommended for clinical use and/or research.

Methods: We conducted a qualitative narrative biographic study consisting of three steps (see figure): people with RA were asked to tell their life stories which were analysed with the biographical narrative interpretative method afterwards. Hereinafter, we linked concepts which determine health in positive way derived from a systematic literature search to the perspective of patients. Finally, we explored whether these concepts were covered by PROs identified in another systematic literature search. The evaluation of the PROs' coverage was based on the model of the WHO International Classification of Functioning, Disability and Health (ICF).

Results: 15 people with RA with a median age of 52,5 years (IQR 35.75 – 62,5) and median disease duration of 24.50 months (IQR 10 – 59,25) participated in the qualitative study. Occupational balance, social support, participation and coping were the most frequently mentioned meaningful concepts (see table). While coping was mentioned by a higher number of men (83% of all men), optimism and vocational gratification were only important for women (78 resp. 67%). The concept of work-life balance did not appear in the qualitative data. Secondary gain from illness was found in only in 2 participants (13%). 28 PROs were derived from the systematic literature search. The concepts coping, self-efficacy, participation, optimism and social

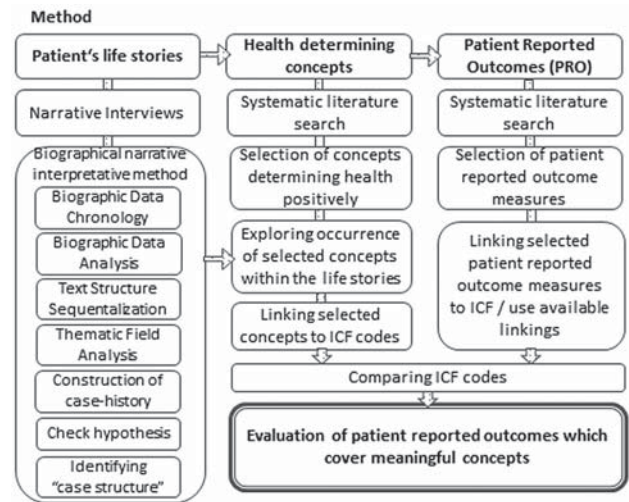
support were covered particularly.


Table 1. Frequency of concepts in a ranked der per sex

Concepts	RA %	Women %	Men %
Occupational Balance	80	89	67
Social support	67	67	67
Participation	63	22	50
Coping	60	44	83
Optimism	47	78	0
Self-efficacy	47	67	17
Vocational gratification	40	67	0
Sense of Coherence	40	44	33
Job satisfaction	33	56	0
Resilience	27	22	33
Social acceptance	27	33	17
Secondary illness gain	13	22	0
Work-Life Balance	0	0	0
n per group	15	9	6

Conclusion: Several concepts which determine health in a positive way show a gender difference. Social support and coping should get more attention in clinical routine and research of people with RA. Therefore the use of MOS social support survey (Sherbourne & Stewart 1991) and the arthritis self-efficacy scale (Lorig et al. 1989) is recommended.

870

To Love and to Hold: Men Describe Parenting in the Presence of Inflammatory Arthritis. Catherine L. Backman[1] and Alana Longson[2]. [1]University of British Columbia, Vancouver, BC, [2]Arthritis Research Centre of Canada, Vancouver, BC

Background/Purpose: Inflammatory arthritis (IA) may limit participation in life roles such as parenting. Surprisingly little research has investigated the impact of IA on parenting tasks and experiences of fathers. This descriptive pilot study adapted a mail survey used in a cross-sectional study of mothers to an online format to (a) examine feasibility of the tool and items for use with men, and (b) assess self-reported performance of parenting tasks, parenting satisfaction, and parenting efficacy in fathers with rheumatoid arthritis (RA), psoriatic arthritis (PsA), or ankylosing spondylitis (AS).

Methods: Men with IA were recruited through rheumatologists' offices, arthritis consumer newsletters and web sites, and public education forums on arthritis. Eligibility criteria included a diagnosis of IA confirmed by a rheumatologist and at least one child ≤18 yrs living with them. Volunteers were sent a web link and password to access the survey. The Parenting Disability Index (PDI) and Parenting Sense of Competency Scale (PSOC) were used to measure parenting outcomes. Surveys also inquired about employment, household work, social support, family quality of life, health status, demographics, and survey feasibility questions. Descriptive statistics

were used to assess numeric responses and thematic content analysis used to examine text responses.

Results: Twelve men volunteered and 10 submitted complete surveys, and reported taking 15 to 60 minutes to do so. They ranged in age from 38 to 59 years, and had 1 to 5 children ranging in age from 4 months to late 20s. Eight were married, 2 were separated/divorced. Four had RA, 4 had AS, and 2 had PsA, from 1 to 32 years in duration (mean = 17.5). Seven were employed. Health Assessment Questionnaire II scores ranged from 0 to 1.5 (mean =.53, median =.40); the common functional limitation was lifting and moving heavy objects. They reported few limitations in parenting tasks, with PDI scores ranging from.20 to 1.26 (0 to 3 scale), mostly related to having energy to be patient with their child, getting up during the night or early morning, and playing (on the floor or outdoors). PSOC total scores ranged from 2.0 to 2.82 (0 to 6 scale; mean = 2.28, SD =.29), while parenting sense of efficacy subscale ranged from 1.67 to 3.56 (mean = 2.32, SD =.60) and parenting satisfaction subscale ranged from 1.50 to 2.75 (mean = 2.22, SD =.38). Men reported many joys in parenting ("to love and to hold" their children), and several challenges ("communicating the fact I'm in pain in a way that doesn't make my 7 year old worried or overly protective; I also don't want to downplay it"). A key motivator for participating in the survey was "most seminars and clinics are directed at or attended by women, so a men's questionnaire is a must!"

Conclusion: The online parenting survey was relevant to the participating men. Although this sample is too small to generalize, findings suggest men with IA experience specific limitations in parenting, but experience great satisfaction with this role. Assessment of parenting task performance may be important to assess in both practice and research settings when selecting outcomes that are meaningful to people living with arthritis.

871

Depression Predicts Mortality in RA. Christina Bode[1], Chris Tonner[2], Laura Trupin[3] and Patricia P. Katz[4]. [1]University of Twente, Enschede, Netherlands, [2]UCSF, San Francisco, CA, [3]UC San Francisco, San Francisco, CA, [4]Univercity of California San Francisco, San Francisco, CA

Background/Purpose: Depression rates are elevated among individuals with rheumatoid arthritis (RA).Studies in cardiovascular disease and among elderly populations have found that depression is a risk factor for mortality, but the risk of mortality from depression in RA has received little attention.

Methods: Data were derived from a longitudinal cohort study of individuals with RA recruited from community rheumatology practices and interviewed annually by telephone.To be eligible for the current analysis, participants had to have an interview in either 2002 or 2003 and have at least one follow-up interview (n=530).Subjects were followed until 2009. Cox regression models estimated the association of depression with the risk of all-cause mortality.Depression was defined as a score ≥5 on the 15-item Geriatric Depression Scale (GDS). Using a time-dependent value, depression was

defined as GDS≥5 in the last interview prior to death or censorship. In separate analyses we also examined the risk of a 2-point increase in GDS score from the penultimate to the last interview prior to death or censorship. Analyses controlled for age, gender, disease duration, and presence of any cardiovascular disease risk factors.Separate analyses also examined the conjoint effects of gender and depression.

Results: Mean age (±SD) was 60 (±13), mean disease duration was 19 (±12) years, 84% were female, and 46% reported at least one cardiovascular risk factor. Subjects were followed for a mean of 4.9 (±1.6) years until death or censorship.63 (12%) participants died during the follow-up period. In bivariate analyses, depression was associated with an increased risk of death (HR=3.5 [95% CI 2.1, 5.8]).Worsening of GDS score by ≥2 points was also associated with an increased mortality risk (HR=2.5 [1.5, 4.2]).Controlling for covariates, both depression and an increase in GDS remained significant predictors of mortality (see Table). Interaction models showed men with depression had 5 times the risk of death compared to women with no depression.Men without depression also had a greater mortality risk than women with no depression after controlling for covariates.

Table 1. Depression and increase of depression proximal to death as a risk factor for death among individual with RA

		Hazard Ratio (95% CI)
Model 1	Baseline GDS< 5	(referent)
	Baseline GDS≥5	2.3 (1.4, 3.9)
Model 2	GDS increase < 2 points	(referent)
	GDS increase ≥ 2 points	1.9 (1.1, 3.3)
Model 3	Baseline GDS <5 Women (ref)	(referent)
	Baseline GDS ≥ 5 Women	2.5 (1.4, 4.6)
	Baseline GDS < 5 Men	3.1 (1.4, 6.5)
	Baseline GDS ≥5 Men	5.9 (2.7,13.1)
Model 4	GDS increase < 2 points Women (ref)	(referent)
	GDS increase ≥ 2 points Women	2.1 (1.1, 3.9)
	GDS increase < 2 points Men	3.0 (1.5, 6.0)
	GDS increase ≥ 2 points Men	5.1 (2.2,11.8)

All models controlled for age, disease duration, cardiovascular disease risk factors. Models 1 and 2 also controlled for gender.

Conclusion: Depression and increase in depressive symptoms are significant risk factors for all-cause mortality in RA.Men with either of these characteristics are particularly at risk. These findings provide additional evidence of the importance of identifying and treating depression among persons with RA.Strategies to motivate men for treatment of depression are especially needed.

Disclosure: C. Bode, None; **C. Tonner**, None; **L. Trupin**, None; **P. P. Katz**, None.

affection and indicate that CC chemokines should be further studied to clarify a role as biomarkers or novel therapeutic targets in JDM.

872

Monocyte Chemoattractant Protein-1 and Eotaxin Are Associated with Parameters of Cardiac Dysfunction in Juvenile Dermatomyositis. Thomas Schwartz[1], Ivar Sjaastad[2], Berit Flatø[1], Maria Vistnes[1], Geir Christensen[1] and Helga Sanner[1]. [1]Institute for Clinical Medicine, University of Oslo, Oslo, Norway, [2]Institute for Experimental Medical Research, Oslo University Hospital, Oslo, Norway

Background/Purpose: Juvenile dermatomyositis (JDM) is a vasculopathic disease affecting not only skeletal muscle and skin, but other organs as well. Previously we have shown that JDM patients can have cardiac dysfunction (measured by E/e'). Considering the systemic nature of the disease, it is reasonable to believe that inflammation of the myocardium can occur, similar to what is seen in skeletal muscle. Increased abundance of pro-inflammatory cytokines has been shown in cardiac and rheumatic diseases. We examined associations between cytokine levels and cardiac parameters in patients with JDM and matched controls.

Methods: 54 JDM patients (estimated to represent the vast majority of known cases in Norway diagnosed from 1970–2006) were clinically examined, follow-up time median 16.8 years (range 2–38 years) after disease onset, and compared with 54 age- and sex-matched controls. Disease activity score (DAS) and myositis damage index (MDI) were assessed at follow-up by clinical examination and at 1 year post-diagnosis by chart review (DAS and MDI 1 year). Cytokines were analyzed by Luminex technology. Echocardiography with tissue Doppler was performed and analyzed blinded to patient information.

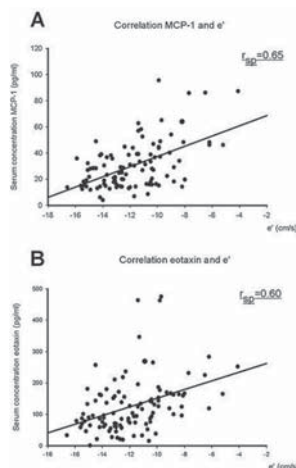
Results: Early diastolic tissue velocity (e') that reflects diastolic cardiac function, was lower in JDM patients than in controls (11.2 vs.12.6 cm/s, p=0.004), suggesting diastolic dysfunction in JDM. E' correlated with MDI 1 year, MDI at follow-up and DAS 1 year (rsp=0.46, rsp=0.59 and rsp=0.60, all p<0.001). Also, DAS 1 year predicted a low e' (diastolic dysfunction), at follow up after correcting for gender and age in a linear regression model (standardized β=0.38, p<0.001). In patients, the serum level of the two CC chemokines, monocyte chemoattractant protein-1 (MCP-1) and eotaxin, correlated with e' (rsp=0.65 and rsp=0.59, both p<0.001) (Figure). For MCP-1, association with e' was also present after adjusting for disease duration and gender in a linear regression model (standardized β=0.36, p=0.001). No correlations were seen between the two CC chemokines and systolic parameters. MCP-1 and eotaxin also correlated with diastolic blood pressure (rsp=0.46 and rsp=0.50 both p<0.001). In controls, the CC chemokines did not correlate with any echocardiographic or clinical parameters.


Figure.

Conclusion: Patients with JDM had subclinical diastolic dysfunction (measured by e') compared to controls, and those with sustained early disease activity seemed to be at risk later in life to develop diastolic dysfunction. Considering the correlation with e', MCP-1 and eotaxin might be involved in an inflammatory response in JDM, leading to myocardial fibrosis and subsequently diastolic dysfunction. The findings give new insight in the mechanism of myocardial

873

Imbalance Between Histone Acetyl Transferase and Histone Deacteylase Activities and Modulation of HDAC Activity and Tnfa Production by HDAC Inhibitors in Patients with Ankylosing Spondylitis or Rheumatoid Arthritis. Eric Toussirot[1], Wasim Abbas[2], Kashif Aziz Khan[3], Marion Tissot[2], Alicia Jeudy[2], Lucile Baud[2], Ewa Bertolini[4], Daniel Wendling[5], Georges Herbein[6] and CIC Biotherapy[7]. [1]CIC Biotherapy 506 and Rheumatology and EA 4266 Pathogens and Inflammation, Besançon, France, [2]EA 4266 Pathogens and Inflammation, Besançon, France, [3]EA Pathogens and Inflammation, Besançon, France, [4]Rheumatology, Besançon, France, [5]Minjoz University Hospital, Besancon, France, [6]Virology and EA 4266 Pathogens and Inflamamtion, Besançon, France, [7]University Hospital, Besançon, France

Background/Purpose: TNFa is a major cytokine involved in conditions such as ankylosing spondylitis (AS) and rheumatoid arthritis (RA). Epigenetic regulation corresponds to different processes including modifications in histone proteins. These mechanisms regulate the transcription of genes coding for inflammatory cytokines such as TNFa. The acetylation of histone proteins (dependent on histone acetyl transferase-HAT-) promotes gene transcription while deacetylation (controlled by histone deacetylase) prevents this reaction. Limited data are available on HAT and HDAC activities in AS or RA. HDAC inhibitors (HDACi) are currently in development and may be of interest in modulating TNFa production in RA or AS.

Objectives: To determine the levels of HAT and HDAC activities in patients with AS or RA compared to healthy controls (HC) and to evaluate the *ex vivo* effects of HDACi (trichostatin A-TSA- and sirtinol -Sirt-) on HAT and HDAC activities and TNFa production by PBMC.

Methods: 21 patients with AS (New York criteria, 18 M, mean age ±SEM 44.3 ± 3.2 years, disease duration 14.1 ± 2.2 years), 52 patients with RA (ACR 1987 criteria, 16 M, mean age 56.9 ± 1.6, disease duration 11.3 ± 1.2) and 38 healthy controls (HC) (12 M, mean age: 34.6 ± 1.8) were evaluated.No patient received biologics. HAT and HDAC activities were assessed on nuclear extracts of PBMC isolated by Ficoll hypaque using a colorimetric assay (EpiQuick HAT Activity/inhibition Assay kit, and EpiQuick HDAC Activity/inhibition Assay kit, Epigentek). These activities were measured prior and after *ex vivo* treatment of PBMC by HDAC inhibitors. TNFa was evaluated in PBMC culture supernatants after 1 and 3 days (TNFalpha Quantikine ELISA kit, R&D Systems).

Results: HAT activity was decreased in patients with AS compared to HC (68.2 ± 8.1 *vs* 111.3 ± 15.5 ng/h/mg) (p= 0.05) while RA patients had increased HAT activity (126.8 ± 16.4 *vs* 111.3 ± 15.5 ng/h/mg; NS). Compared to HC, HDAC activity was decreased in both AS (p=0.01) andRA (NS) (HC vs AS *vs* RA: 4778.9 ± 752 *vs* 1984. 6 ± 249 *vs* 3915.9 ± 790 pmol/min/mg). No correlation was observed between clinical disease assessment in RA or AS and HAT or HDAC activity. *Ex vivo* addition of TSA or Sirt to PBMC reduced HDAC activity by 51.1% in HC and by 37.7% in RA but had no effect in AS.HAT activity was not modulated by HDACi. TNFa production by PBMC was down regulated by the addition of TSA or Sirt to cell culture in HC and RA but this regulation was only obtained with Sirt in PBMC culture from patients with AS.

Conclusion: HAT and HDAC activities are dysregulated in AS and RA with a balance between HDAC and HAT favoring HAT activity and promoting gene transcription. *Ex vivo* treatment of PBMC by HDAC inhibitors may regulate HDAC activity and TNFa production especially in HC and RA but seems less effective in AS.

874

TNFα Induces Sustained Signaling and a Prolonged and Unremitting Inflammatory Response in Synovial Fibroblasts. Angela Lee, Galina Grigoriev, Janice Chen, Lionel B. Ivashkiv and George D. Kalliolias. Hospital for Special Surgery, New York, NY

Background/Purpose: The non resolving character of synovial inflammation in rheumatoid arthritis (RA) is a conundrum. To identify the

contribution of fibroblast-like synoviocytes (FLS) to the perpetuation of synovitis, we investigated the molecular mechanisms that govern the TNFa-driven inflammatory program in human FLS.

Methods: FLS obtained from synovial tissues of patients with RA or osteoarthritis were stimulated with TNFa and assayed for gene expression and cytokine production by qPCR and ELISA. NF-kB signaling and chromatin accessibility were evaluated using Western blotting and restriction enzyme accessibility (REA) assays.

Results: In FLS, TNFa induced prolonged transcription of *IL-6* and progressive accumulation of IL-6 protein over four days (Figure 1A). Similarly, induction of IL-8, CCL5, MMP1 and MMP3 mRNA, after TNFa stimulation, was sustained for several days (data not shown). This contrasted with the macrophage response to TNFa, which characteristically involved a transient increase in the expression of pro-inflammatory genes (Figure 1B). In FLS, TNFa induced prolonged activation of NF-kB signaling (Figure 2A) and a sustained increase in chromatin accessibility at the *IL-6* promoter (Figure 2B).Furthermore, FLS expressed low levels of the feedback inhibitors ABIN3, IRAK-M, ATF3 and SOCS3 that terminate inflammatory responses in macrophages (Figure 3).
Conclusion: TNFa signaling is not effectively terminated in FLS, leading to an uncontrolled inflammatory response. The results suggest that prolonged and sustained inflammatory responses by FLS, in response to synovial TNFa, contribute to the persistence of synovial inflammation in RA.

875

Discovery of Pharmacologic MIF Antagonists by Structure-Based Molecular Design. William L. Jorgensen[1], Alissa A. Hare[1], Zoe Cournia[1], Sunilkumar Gandavadi[1]. Xin Du[1], Lin Leng[1] and Richard J. Bucala[2], [1]Yale University, New Haven, CT, [2]Yale University School of Med, New Haven, CT

Background/Purpose: Cytokine inhibition is becoming a mainstay for the therapy of autoimmunity but current antibody-based approaches remain limited by high cost, parenteral administration, and anti-idiotype responses. Orally available, small molecules offer considerable advantages, yet the discovery of molecules that effectively disrupt the molecular interactions between cytokines and their receptors remains to be achieved. Macrophage migration inhibitory factor (MIF) is an attractive drug target because of its genetic association with autoimmunity and its role in counter-regulating glucocorticoid immunosuppression. The discovery of the MIF receptor (CD74) together with X-ray crystallography of MIF has enabled structure-based design using ligand docking, moleculegrowing computational methodologies, and receptor binding assessment. By this approach, we are pursuing the discovery of potent and selective MIF antagonists with auspicious pharmacologic properties.

Methods: Utilizing a high resolution MIF crystal structure, virtual screening was performed by docking 2.1 million compounds into the MIF tautomerization site, which was judged to interface with the MIF receptor. Validation by in vitro functional analyses revealed novel compounds with μM inhibitory activity in several molecular series. Structure optimization was pursued by synthesis of substituted benzoxazol-2-ones and MIF receptor binding, MIF ligand selectivity, and MIF-dependent signal transduction evaluated in vitro.

Results: Binding analysis of MIF interaction with the MIF receptor ectodomain revealed 11 novel compounds with IC50s in the μM range. Beginning with a 1 μM candidate, substituted benzoxazol-2-ones were discovered with IC50 values as low as 80 nM for MIF receptor antagonism. One such molecule: 3-(3-hydroxybenzyl)-5-methylbenzo[**d**]oxazol-2(3**H**)-one (Debio 1036) was evaluated more closely and functional inhibition established in synovial fibroblasts for MIF-dependent ERK1/2 phosphorylation (IC50=5 nM) and invasive phenotype. Debio 1036 also was 1000-fold more selective for MIF than for its close structural homolog, DDT (MIF-2).

Conclusion: Several highly potent, small molecule MIF receptor antagonists have been identified by a combination of structure-based molecular design and functional analysis. Compounds with oral bioavailability and auspicious pharmacologic properties are anticipated to provide promising candidates for the treatment of human autoimmunity.

876

Xanthine Oxidase-Derived ROS Direct Context-Dependent Action of NFAT5 Toward Inflammatory Response in Macrophages. Nam Hoon Kim. Catholic university of Korea, Seoul of Korea, Seoul, South Korea

Background/Purpose: NFAT5, a well known osmo-protective factor, can be activated by isotonic stimuli, such as Toll-like receptor (TLR) triggering. Here, we identified a novel signal pathway activated in macrophages upon TLR ligation.

Methods: We demonstrated that high salt and TLR ligation activate distinct sets of downstream target genes in a NFAT5-dependent manner. While ROS are essential for this, their source differs depending on the context; mitochondria for high salt and xanthine oxidase for TLR. The two pathways are mutually suppressive. Moreover, the xanthine oxidase-NFAT5 pathway is required for TLR-mediated inflammatory arthritis, inducing the proinflammatory cytokine production.

Results: we identified a novel xanthine oxidase- reactive oxygen species (ROS)-p38-NFAT5 pathway activated in macrophages upon TLR ligation.

Conclusion: Together, xanthine oxidase-derived ROS function as molecular sensors to discriminate TLR ligation from osmotic stimulus in macrophages, directing NFAT5 action toward innate immunity.

877

Aberrant Expression of BAFF Receptor (BR3) in Peripheral Monocytes of Patients with Primary Sjögren's Syndrome Impacts Abnormal Activation of BAFF Signaling Through IKK-Alphaand IKK-Beta. Keiko Yoshimoto[1], Maiko Tanaka[1], Masako Kojima[1], Hideko Ogata[1], Hideto Kameda[1], Katsuya Suzuki[1], Tohru Abe[2] and Tsutomu Takeuchi[1]. [1]Keio University School of Medicine, Tokyo, Japan, [2]Saitama Medical School, Kawagoe-shi Saitama, Japan

Background/Purpose: B cell activating factor belonging to the TNF superfamily (BAFF) regulates proliferation, differentiation and survival of B cells and plays a pivotal role in the pathogenesis of autoimmune diseases such as primary Sjögren's syndrome (pSS). BAFF is a ligand for three TNF-receptor family members; i.e., BAFF receptor (BR3), TACI and BCMA. Several lines of evidence demonstrate that BR3 is the receptor that mediates BAFF-dependent B cell biology and that BAFF activates alternative NF-kB signaling in B cells. However, the regulatory mechanisms of BAFF signaling in other immune cells, such as monocytes, are not well understood. In our previous study, we revealed that BAFF induced robust increase in the production of IL-6 by pSS monocytes. We also found that the expression levels of BR3 and several transcription factors such as NF-IL-6 and NF-kB2 were enhanced in pSS monocytes compared to normal monocytes. These data suggest that BAFF signaling is abnormal in pSS monocytes. The purpose of the present study is to elucidate these possible abnormalities.

Methods: Whole blood was prepared from pSS patients and age-matched normal individuals, and the expression level of BR3 on monocytes was analyzed by FACS. Peripheral monocytes were stimulated in vitro with soluble BAFF (sBAFF), and the production of IL-6 by the cells was measured by ELISA. The expression levels of IKK-alpha and IKK-beta, which are involved in NF-kB pathways, were analyzed by western blotting analysis.

Results: In accordance with our previous findings with quantitative PCR, FACS analysis showed that the expression level of BR3 was significantly elevated in pSS monocytes compared to normal monocytes.Interestingly, the expression level of BR3 on monocytes was positively correlated with the amount of IL-6 produced by pSS monocytes triggered by sBAFF. When the monocytes were cultured with sBAFF in the presence of NF-kB activation inhibitor, the production of IL-6 by the cells was strongly suppressed in a dose-dependent manner. In addition, phosphorylation level of IKK-alpha was elevated in pSS monocytes compared to normal monocytes without stimulation, whereas that of IKK-beta was not significantly different between pSS and normal monocytes. Moreover, phosphorylation levels of IKK-alpha and IKK-beta in the monocytes were enhanced upon stimulation with sBAFF.

Conclusion: BAFF acts through BR3 to activate the expression of the IL-6, and that IKK-alpha and IKK-beta are involved in the signal transduction pathway triggered by sBAFF.

878

Differential Regulation of Cytokines by Extracellular-Signal Regulated Kinase and c-Jun N-Terminal Kinase in Map Kinase Kinase-3 and -6 Deficiency. Deepa Hammaker, Katharyn Topolewski, Monica Guma, David L. Boyle and Gary S. Firestein. UCSD School of Medicine, La Jolla, CA

Background/Purpose: p38 inhibitors have limited efficacy in rheumatoid arthritis (RA), possibly because p38 blockade suppresses IL-10 production and increases JNK and ERK phosphorylation in macrophages. This positive feedback mechanism elevates IL-6 levels and decreases IL-10 production. In contrast, bone marrow derived macrophages (BMDM) deficient in upstream p38 regulators (MKK3 or MKK6) have normal ERK and JNK responses and near normal IL-10 gene expression. The goals of this study were (1) to determine if dual ERK and JNK inhibition avoids reflex increases in pro-inflammatory cytokine expression and (2) to dissect the mechanisms of IL-10 regulation in MKK-deficient and p38 inhibitor treated BMDM.

Methods: Bone marrow derived macrophages from wild type (WT), MKK3−/− and MKK6−/− mice were pre-treated with p38 inhibitor SB203580 (SB), JNK inhibitor SP600125 (SP) and/or ERK inhibitor PD98059 (PD) and stimulated with LPS. Supernatant IL-6 and IL-10 levels were measured by immunoassay. IL-10 mRNA half-life was measured using LPS-stimulated BMDM treated with actinomycin D and qPCR. IL-10 promoter activity was determined in BMDM transfected with a mouse IL-10 promoter luciferase construct and normalized to a Renilla construct.

Results: We evaluated the role of JNK and ERK in BMDM IL-6 and IL-10 production. SB increased IL-6 production induced by LPS while SP and PD significantly reduced IL-6 levels in WT, MKK3−/−, and MKK6−/− cells (Figure 1, SP % inhibition: WT (91±1%), MKK6−/− (81±8%), and MKK3−/− (84±4%, n=3/group, p<0.008) (PD % inhibition: WT (85±3%), MKK6−/− (65±3%), and MKK3−/− (65±1%, n=3, p<0.02). SP or PD alone or in combination with SB reduced IL-6production, indicating that blocking JNK and/or ERK overcame thepro-inflammatory effect of p38 inhibition.IL-10 levels were significantly reduced by SB in WTBMDM (62±9%), MKK6−/− (62±6%), and MKK3−/− (57±4%) (n=3/group, p<0.034). SP also inhibited IL-10 levels while PD had no effect. Surprisingly, the combination of SB and SP prevented the p38-mediated reduction in IL-10 production suggesting that JNK and p38 pathways have opposing effects on this cytokine. We then looked at the effect of SB and MKK-deficiency on IL-10 promoter activity in BMDM treated with LPS. IL-10 promoter activity in WT cells was reduced by 43±6% by SB (n=3/group, p=0.02). However, MKK3- and MKK6-deficient cells had normal promoter activity, indicating that IL-10 transcription is not impaired in MKK-deficient cells. IL-10 mRNA half-life was unaffected by MKK-deficiency or SB-treatment in LPS-stimulated BMDM.
Conclusion: Increased JNK and ERK activation, along with suppressed IL-10 production contribute to the pro-inflammatory effects of p38 inhibition in BMDM. Combining a p38 inhibitor with a JNK inhibitor might be more effective than a selective p38 inhibitor by preserving anti-inflammatory responses and blocking the reflex pro-inflammatory response.

879

Fucosyltransferase 1 (fut1) Is Overexpressed in Rheumatoid Arthritis Synovial Tissue and Modifies Cytokine Production. Takeo Isozaki[1], Jeffrey H. Ruth[1], M. Asif Amin[1], Phillip L. Campbell[1], Steven E. Domino[1], G. Kenneth Haines III[2] and Alisa E. Koch[3]. [1]University of Michigan, Ann Arbor, MI, [2]Yale University, New Haven, CT, [3]University of Michigan Medical School, Ann Arbor, MI

Background/Purpose: Rheumatoid arthritis (RA) is a systemic auto-immune disease characterized by inflammation and joint destruction. Angiogenesis and cytokine production are involved in the pathogenesis of RA. We have shown that soluble H and Lewis[y] antigens are mediators of angiogenesis and are upregulated in the RA joints compared to normal (NL) or osteoar-thritis (OA) joints. Fucosyltranseferase 1 (fut1) is an $\alpha(1,2)$-fucosyltransferase responsible for synthesis of the H blood group and Lewis[y] antigens. However, a direct role for fut1 in RA has not been demonstrated. In this study, we examined the expression of fut1 in RA synovial tissue (ST) and deter-minedthe functional consequences of fut1 expression.

Methods: Fut1 expression was determined in RA, OA and NL ST samples by immunohistological staining. To determine whether fut1 was expressed by the human microvascular endothelial cell line (HMEC-1) and human dermal microvascular endothelial cells (HMVECs), real time poly-merase chain reaction (RT-PCR) was performed. To block the expression of fut1, HMEC-1s and HMVECs were transfected with fut1 sense or antisense oligonucleotides (ODNs). After treatment, cells were stimulated with interleukin-1β (IL-1β), IL-17 or phorbol 12-myristate 13-acetate (PMA) to stimulate cytokine expression. We examined monocyte chemotactic protein (MCP)-1/CCL2 expression as this chemokine has been shown to be decreased in mouse KRN arthritis induced fut1 knockout joints. We also examined angiogenic vascular endothelial growth factor (VEGF) and regulated upon activation and normal T-cell expressed, and secreted (RANTES)/CCL5 expression, as these cytokines have been shown to be important in RA pathogenesis. In addition, we isolated endothelial cells (ECs) from wild type (wt) and fut1 knockout mice. To confirm the role of fut1 in angiogenesis, we

performed EC chemotaxis using wt and fut1 knockout ECs in modified Boyden chambers.

Results: RA STs contained a greater percentage of fut1 ECs than did OA or NL STs [mean ± SEM; RA ST (n=18) 34 ± 8%; OA ST (n=18) 14 ± 6% and NL ST (n=18) 11 ± 4%, p<0.05 between RA ST and OA ST; RA ST and NL ST]. To determine if fut1 expression was inducible by inflammatory cytokines, we stimulated ECs with IL-1β and found that fut1 messenger RNA (mRNA) was IL-1β inducible in HMEC-1s and HMVECs.Fut1 antisense ODN transfected HMEC-1s and HMVECs had significantly decreased expression of MCP-1/CCL2 and RANTES/CCL5 compared to fut1 sense ODN transfected cells stimulated withIL-1β, IL-17 or PMA at the mRNA and protein levels (p<0.05). Fut1 knockout mouse ECs stimulated with IL-1β expressed less VEGF mRNA than wt ECs (p<0.05). These results indicate that fut1 regulates EC expression of cytokines important in RA pathogenesis. Finally, fut1 knockout mouse ECs had decreased migration to VEGF compared with wt mouse ECs (10 ± 1 vs. 16 ± 1 cells migrated, n=6 experiments, p<0.05).

Conclusion: These data show that fut1 is overexpressed in RA ST, and that by blocking fut1 expression, we can modify the production of many proinflammatory cytokines. In addition, we show that fut1 regulates EC migration, a facet of angiogenesis in response to VEGF. Hence, fut1 may be an important new target for RA therapy.

Interferon Regulatory Factor 8 Regulates BAFF Production in Murine Macrophages and Is a Nexus for Cross Talk Between IFN-γ and TGF-β.
Weijia Yuan, Sanjay Gupta, Jane E. Salmon and Alessandra B. Pernis. Hospital for Special Surgery, Weill Cornell Medical College, New York, NY

Background/Purpose: Lupus is a systemic autoimmune disease that can lead to severe end-organ damage characterized by unabated inflammation and aberrant tissue repair. Macrophage dysregulation plays a key role in mediating this tissue damage. Interferon regulatory factor 8 (IRF8) is a crucial controller of macrophage function and has been identified as a susceptibility locus for lupus. The cellular pathways regulated by IRF8 may be important in tissue damage in lupus. IRF8 is known to mediate macrophage activation in response to IFN-γ.Infiltrating macrophages stimulated by IFN-γ produce B-cell activating factor (BAFF) which may perpetuate local immune responses. TGF-β, a cytokine linked to tissue repair via Rho-kinase (ROCK), can augment BAFF production. Here we use the regulation of BAFF as a model to dissect the cross talk between IFN-γ and TGF-β and identify a novel and crucial role for IRF8 in this process.

Methods: Bone marrow derived macrophages (BMDM) were stimulated with IFN-γ and/or TGF-β. In selected experiments a ROCK inhibitor, Y-27632, was added. Cytokine production was evaluated by ELISA and/or by qPCR. ROCK activity was assessed by in vitro kinase assay. Chromatin immunoprecipitation (ChIP) assays were performed to determine the binding of IRF8 to the BAFF promoter.

Results: TGF-β augmented IFN-γ-induced BAFF production in BMDM (untreated: 24 ± 5 pg/ml, IFN-γ: 508 ± 181, TGF-β: 57 ± 13, IFN-γ + TGF-β: 990 ± 291, n=5, $p<0.01$). This amplification was specific for BAFF and was not seen when TNF-α or CTGF was examined. IFN-γ increased the expression of IRF8, which was not further increased by the addition of TGF-β. In the absence of IRF8, BAFF production by macrophages was markedly diminished (C57/B6 IFN-γ: 505 ± 207 pg/ml, IRF8 KO IFN-γ: 17 ± 10, n=4, $p<0.02$; C57/B6 IFN-γ + TGF-β: 867 ± 336, IRF8 KO IFN-γ + TGF-β: 14 ± 6, n=4,$p<0.02$). IRF8 KO BMDM exhibited normal differentiation and maintained the capacity to upregulate CTGF in response to TGF-β. In line with these results, we found that IRF8 directly binds to the BAFF promoter upon IFN-γ stimulation. Interestingly, the binding of IRF8 to the BAFF promoter was augmented by the concomitant addition of TGF-β. Given that TGF-β did not change the expression of IRF8, we explored the possibility that TGF-β could modulate IRF8 function by post-translational mechanisms. TGF-β, but not IFN-γ, activated the serine-threonine kinases ROCK1 and ROCK2 in BMDM. ROCK inhibitor Y-27632 decreased BAFF production by BMDM stimulated with IFN-γ and TGF-β and diminished the binding of IRF8 to the BAFF promoter.

Conclusion: We have shown that IRF8 is a critical regulator of BAFF production in BMDM. Our data indicate that while IFN-γ increases IRF8 expression, TGF-β may modulate its function via ROCK activation. We speculate that activated ROCK phosphorylates IRF8 and that increased binding of phosphorylated IRF8 to the BAFF promoter leads to the enhanced

BAFF production when macrophages are simultaneously exposed to IFN-γ and TGF-β. The pathways that mediate the cross talk between IFN-γ and TGF-β uncovered by this study identify novel processes that could lead to aberrant macrophage function in chronic inflammatory state and define new targets to ameliorate tissue damage in SLE.

Microrna-155 Regulates Chemokines and Chemokine Receptors in Rheumatoid Arthritis Monocyte.
Aziza Elmesmari, Derek S. Gilchrist, Alasdair R. Fraser, Diane Vaughan, Ross McQueenie, Gerard J. Graham, James Brewer, Iain B. McInnes and Mariola Kurowska-Stolarska. Institute of Infection,Immunity and Inflammation, College of Medical, Veterinary and Life Sciences, University of Glasgow, Glasgow, United Kingdom

Background/Purpose: Rheumatoid arthritis (RA) is characterized by synovial tissue inflammation leading to joint destruction. Monocytes/macrophages are major effector cells in RA synovitis, principally by releasing TNF-α, IL-6 and other inflammatory cytokines and chemokines. MicroRNAs are a recently discovered class of post-transcriptional regulators –in particular miR-155 is upregulated in RA synovial macrophages where it regulates cytokine expression. We hypothesized that miR-155 regulates migration of monocytes by modulating the chemokine and chemokine receptor system.

Methods: Peripheral blood (PB) was obtained from healthy controls and RA patients who met the 2010 ACR/EULAR diagnostic criteria. Purified CD14+ PB monocytes obtained by magnetic bead isolation were transfected with miR-155 mimic or scrambled mimic using an N-TER nanoparticle system. Taqman Low Density Array and Luminex multiplex assay was used to evaluate chemokine receptor gene expression and chemokine production, respectively. Absolute copy numbers of miR-155 transcripts in PB and SF monocytes of RA and healthy controls were assessed by QPCR. The role of mir155 was investigated further using bone marrow monocytes (BMM) from miR-155$^{-/-}$and WT mice.

Results: RA PB and SF macrophages showed higher copy number of miR-155 compared with healthy controls. Overexpression of miR-155 induced the production of chemokines CCL4, CCL5, CCL8 and CCL22 in RA monocytes and CCL3 in both RA and healthy controls. However, overexpression of miR-155 in healthy control and RA monocytes did not affect the production of CCL2, CCL7, CCL21, CXCL5, CXCL8, CXCL7, CXCL10 and CX$_3$CL1. Analysis of chemokine receptors in BMM of miR-155$^{-/-}$ and WT mice revealed significantly higher levels of CCR1, CCR2, CCR5 and CXCR4 in miR-155 deficient cells suggesting that miR-155 can act as a negative regulator of these receptors in homeostatic state. TLR-4 ligand significantly suppressed expression of these receptors in both WT and miR-155$^{-/-}$cells. Analysis of 3'UTRs of chemokine and chemokine receptor (TargetScan) suggests that miR-155 likely interferes with signaling pathways implicated in chemokine and chemokine receptor system expression.

Conclusion: Deregulation of miR-155 in RA monocytes can contribute to the production of pro-inflammatory chemokines by these cells and to their accumulation at sites of inflammation.

Anti-Inflammatory Effects of Phosphodiesterase 4 Inhibition Are Mediated by Mitogen-Activated Protein Kinase Phosphatase-1.
Riku Korhonen, Tuija Hömmö, Mirka Laavola, Tiina Keränen, Mari Hämäläinen and Eeva Moilanen. University of Tampere School of Medicine and Tampere University Hospital, Tampere, Finland

Background/Purpose: MAP kinase phosphatase-1 (MKP-1) is a nuclear tyrosine/threonine phosphatase that limits p38 MAP kinase activity. MKP-1 KO mice display excessive inflammatory response, and exhibit increased disease severity and more extensive bone destruction in experimental arthritis models. Anti-inflammatory effects of glucocorticoids are partly mediated by increased MKP-1 expression. Phosphodiesterase (PDE) 4 is expressed in several inflammatory and immune cells, and it hydrolyzes cAMP to 5'AMP down-regulating cAMP signalling in cells. PDE4 inhibitors are under investigation for treatment of arthritis, and they have already entered the clinics in the treatment of COPD as an anti-inflammatory remedy. In the present study,

we found that a PDE4 inhibitor rolipram enhanced MKP-1 expression which was involved in the anti-inflammatory effects of rolipram.

Methods: The effect of MKP-1 and a PDE4 inhibitor rolipram on inflammatory gene expression was investigated in mouse J774 and human THP-1 macrophage cell lines, and in primary mouse peritoneal macrophages (PM) from wild-type (WT) and MKP-1(–/–) mice. In cell lines, MKP-1 expression was silenced by siRNA. We also investigated the effect of rolipram on carrageenan-induced paw inflammation in WT and MKP-1(–/–) mice.

Results: TNF and IL-6 production was increased in macrophages with impaired MKP-1 (that is in cells transfected with MKP-1 siRNA or macrophages from MKP-1 KO mice), and it was related to increased p38 MAP kinase phosphorylation. p38 MAP kinase phosphorylation was inhibited by rolipram and by a cAMP analog 8-Br-cAMP. LPS-induced MKP-1 expression was enhanced by rolipram, by a non-selective PDE inhibitor IBMX and by 8-Br-cAMP in J774 and THP-1 cells and in PMs. Rolipram, IBMX and 8-Br-cAMP also inhibited TNF production in J774 and THP-1 cells. p38 MAP kinase inhibitor BIRB 796 inhibited TNF production in macrophages, as expected. Rolipram inhibited TNF production in PMs from WT mice (63% inhibition) but, interestingly, the inhibition of TNF production by rolipram was greatly attenuated (27% inhibition) in PMs from MKP-1(–/–) mice. Furthermore, rolipram attenuated carrageenan-induced paw inflammation in WT but not in MKP-1(–/–) mice.

Conclusion: The results showed that a PDE4 inhibitor rolipram suppressed p38 MAP kinase pathway, and inhibited TNF production and carrageenan-induced inflammation, and these effects were mediated by MKP-1. The results suggest that the anti-inflammatory effects of PDE4 inhibitors are, at least partly, mediated by MKP-1. The findings emphasize MKP-1 as a potential mediator of anti-inflammatory drug effects. Compounds that enhance MKP-1 expression and/or MKP-1 activity hold potential as novel anti-inflammatory drugs.

Role of Phospholipase D1 (PLD1) in the Expression of Proinflammatory Genes in Rheumatoid Arthritis Synovial Fibroblasts (RASF). Sean C. Friday[1] and David A. Fox[2]. [1]The University of Michigan, Ann Arbor, MI, [2]Univ of Michigan Med Ctr, Ann Arbor, MI

Background/Purpose: Interleukin-17 (IL-17) and Tumor Necrosis Factor alpha ((TNFa), when co-applied to RASF, induce synergistic expression of proinflammatory genes such as IL-6 and IL-8.Work from our laboratory using co-cultures of cytokine-activated T cells and RASF has demonstrated that this synergy is largely contact-dependent (Tran et al., 2007).Recently, Hot et al (2011) showed that PLD1 mRNA was similarly upregulated by IL-17A and the less potent IL-17F in RASF.Another recent report (Sethu et al., 2010), used a mouse model of peritonitis to show that blocking PLD1 mitigates TNFa-driven inflammation *in vivo*. In light of these observations, we sought to examine the potential role of PLD1 in pro-inflammatory gene expression by RASF stimulated with IL-17A and/or TNFa.

Methods: We used quantitative real-time PCR to characterize the cytokine-mediated effects on mRNA levels for a cluster of genes encoding cytokines, chemokines, and tissue remodeling enzymes important in the pathogenesis of RA.Also, secretion of IL-6, IL-8, and CCL20 was measured by ELISA.To investigate the relevance of PLD1 activity, we added various concentrations of the PLD1 inhibitor 1-butanol, knocked down PLD1 expression with siRNA, and used the two approaches together.

Results: PLD1 mRNA was weakly induced by IL-17 and/or TNFa (<2-fold increase).1-butanol had complex effects on cytokine-induced target gene mRNA expression, in a manner that was dose-dependent and biphasic for all targets except ICAM1, IL-8, and MMP-14.Compared with the 10 other targets studied, including PLD1 itself, ICAM1 mRNA expression showed the least sensitivity to treatment with 1-butanol.When RASF were transfected with PLD1-specific siRNA, there was an effect on induction of mRNA and secreted protein, particularly for induction of IL-6, IL-8, and CCL20 when IL-17 was co-applied with TNFa.Effects on mRNA and secreted protein were not always positively correlated.For example, interference with PLD1 activity resulted in increased CCL20 mRNA, but inhibited CCL20 secretion. Effects of PLD1 knockdown were in part distinct from effects of 1-butanol.

Conclusion: PLD1 might be an important modulatory target for reducing cytokine-evoked expression of proinflammatory genes by RASF, because it exhibits gene-specific effects on mRNA levels and effects on efficacy of regulated secretion/exocytosis.Stability of mRNAs and modulation of tran-

scription efficiency are likely mechanisms by which PLD1 affects cytokine-induced expression of proinflammatory genes.The effects of 1-butanol may reflect inhibition of not only PLD1 but also PLD2 and possibly other enzymes.

Receptor Activator of Nuclear Factor ÊB Ligand-Mediated Osteoclastogenesis Is Augmented by Interleukin-1â Via up-Regulation of Endoplasmic Reticulum Stress Signals. Myong-Joo Hong[1], Myung-Soon Sung[1], Eun-Gyeong Lee[1], Yoon Kyung Hong[1], Chang-Hoon Lee[2], Myeung Su Lee[3] and Wan-Hee Yoo[1]. [1]Department of Internal Medicine, Chonbuk National University Medical School and Research Institute of Clinical Medicine, Jeonju, South Korea, [2]Department of Internal Medicine, School of medicine, Wonkwang university, Iksan, Chonbuk, South Korea, [3]Reumatology, Iksan, Chonbuk, South Korea

Background/Purpose: Interleukin-1β (IL-1β) and thapsigargin (TG)-augmented endoplasmic reticulum (ER) stress modulate the receptor activator of nuclear factor kappa-B ligand (RANKL)-mediated osteoclastogenesis. However, the mechanism by which IL-1β and TG affect osteoclastogenesis remains elusive. Thus, we investigated the relationships between RANKL-mediated osteoclast specific pathways and ER stress relevant signals in osteoclast differentiation of bone marrow-derived cells.

Methods: Bone marrow cells (BMCs) were obtained from 5-week-old male ICR mice. The cells were cultured to be differentiated into osteoclasts with macrophage-colony stimulating factor (M-CSF) and RANKL in the presence or absence of IL-1β, thapsigargin (TG, ER stress inducer), or 4-phenylbutyric acid (PBA, ER stress inhibitor). The formation of osteoclasts was evaluated by tartrate-resistant acid phosphatase (TRAP) staining and resorption pit assay with dentine slice. The molecular mechanisms of IL-1β and ER stress in osteoclastogenesis of BMCs were investigated using reverse transcription-polymerase chain reaction (RT-PCR) and immunoblotting. Osteoclast specific and ER stress relevant signaling molecules were analyzed. Transfections of small interfering RNA (siRNA) for glucose-regulated protein 78 (GRP78), protein kinase RNA-like ER kinase (PERK) and inositol-requiring enzyme 1 (IRE1) were performed to knockdown ER stress initiating signals to verify the relationships between osteoclast specific pathways and ER stress signals.

Results: The formation of osteoclasts was increased by IL-1β and TG augmented ER stress. PBA significantly inhibited IL-1β and TG induced osteoclats formation. The expressions of osteoclast specific pathways such as c-Fos and NFATc1, and ER stress associated signals such as PERK, IRE1, GRP78, and eIF2α were significantly increased by IL-1β and TG which was inhibited by PBA. Inhibition of ER stress initiating signals by siRNA inhibited the expression of above mentioned osteoclast specific signals, thus reduced IL-1β and/or TG-induced osteoclastogenesis.

Conclusion: IL-1β and/or TG-augmented ER stress significantly increased osteoclast formation which was inhibited by PBA. The mechanisms were mainly associated with up-regulation of ER stress signals such as GRP78, PERK, p-eIF2α and IRE1. Thus the modulation of ER stress signals affecting osteoclast formation might be a new therapeutic strategy to prevent inflammatory and destructive arthritis diseases such as rheumatoid arthritis (RA) and diverse osteoporotic diseases.

Interferon α and Self-Organized Criticality Theory. Shunichi Shiozawa[1], Yumi Miyazaki[2] and Ken Tsumiyama[1]. [1]Kyushu University Beppu Hospital, Beppu, Japan, [2]Kyushu University Beppu Hospital/ Kobe University Graduate School of Health Sciences, Beppu/ Kobe, Japan

Background/Purpose: One of the biggest obstacle we face in elucidating the pathogenesis of autoimmunity today is the mechanism how autoreactive lymphocyte clones could survive or emerge beyond the firewall called 'forbidden clone' of Burnet. We have proposed that autoreactive clones emerge *via de novo* T cell receptor (TCR) revision from thymus-passed non-autoreactive clones at periphery, and we named this T cell as autoantibody-inducing CD4 (*ai*CD4) T cell (Tsumiyama K *et al*. PLoS ONE 4(12):e8382, 2009). Our novel 'self-organized criticality theory' explains that systemic autoimmunity or systemic lupus erytematosus (SLE) necessarily

takes place when host's immune system is overdriven by repeated exposure to antigen to levels that surpass the immune system's stability-limit, i.e., self-organized criticality. This *ai*CD4 T cells not only induced varieties of autoantibodies but also helped final maturation of CD8 T cell into cytotoxic T lymphocyte (CTL) *via* antigen cross-presentation to induce tissue injuries identical to SLE. We here examine the role of interferon α (IFNα) in relation to the *ai*CD4 T cell.

Methods: BALB/c mice were repeatedly immunized with ovalbumin (OVA), keyhole limpet hemocyanin (KLH) or staphylococcal enterotoxin B (SEB), and sera and tissues were examined using ELISA, immunohistopathogy, PCR, southern blotting and flow cytometry. Because IFNα transgenic (Tg) mice are basically infertile, we adopted a Tet-off expression system. Mouse IFNa1 (mIFNα)cDNA integrated under TetOp promoter (TetOp-mIFNα) was microinjected into fertilized eggs of C57BL/6 to obtain TetOp-mIFNα Tg mice. They were mated with EμSR-tTA Tg mice under the control of IgH chain enhancer/SRα promoter (EμSR-tTA) to obtain double Tg TetOp-mIFNα/EμSR-tTA mice. IFNα was inducible 12 weeks after doxycycline cessation.

Results: Repeated immunization with antigen caused lesions identical to SLE including anti-dsDNA and anti-Sm autoantibodies in the mice otherwise not prone to spontaneous autoimmune diseases. Overstimulation of CD4 T cells led to the development of *ai*CD4 T cell which had undergone TCR revision and was capable of inducing autoantibodies and overdriving CD8 T cell to become CTL *via* antigen cross-presentation leading to tissue injuries identical to SLE. However, in the IFNα Tg mice, the lesions identical to SLE just except for anti-Sm antibody were induced by solely increasing IFNα. Pathological lesions included IC-deposited glomerulonephritis, alopecia, epidermal liquefaction and positive skin lupus-band test and splenic onion-skin lesion. The IFNγ^+ activated CD4 and CD8 T cells with effector phenotype (CTL) and activated CD3$^+$CD4$^-$CD8$^-$ double negative (DN) T cell pathognomonic for SLE were increased. This DN T cell not only infiltrated to glomeruli, but also induced *de novo* glomerulonephritis and alopecia upon transfer to naïve mice.

Conclusion: IFNα causes SLE. However, IFNα does not represent the whole picture of SLE and thus, antigen induced mechanism, i.e., 'self-organized criticality theory', was discussed in relation to *ai*CD4 T cell and a classical DN T cell.

886

Association Between Neutrophil Gene Signature and Disease Characteristics in Systemic Lupus Erythematosus Patients. Michelle Petri[1], Hong Fang[1], Jadwiga Bienkowska[2], Norm Allaire[2], Jeff Browning[2] and Susan Kalled[2]. [1]Johns Hopkins University School of Medicine, Baltimore, MD, [2]Biogen Idec Inc., Cambridge, MA

Background/Purpose: Neutrophils and neutrophil death ("netosis") are now understood to play a role in the pathogenesis of SLE. A neutrophil gene signature exists in SLE, although its association with the clinical phenotype is unknown.

Methods: A total of 292 SLE patients were included in the analysis. Among these patients, 91.1% were female; 58.9% were Caucasian, 33.9% were African-American, and 7.2% were other ethnicities. Mean age (standard deviation) at baseline was 46.0 ($\pm$11.9) years. Neutrophil gene expression was high (>6) in 31.9% (N=93), medium (5–6) in 31.5% (N=92), and low (<5) in 36.6% (N=107) of patients.

Results: The neutrophil gene signature was more common in Caucasians (p=0.045). The neutrophil gene signature is strongly associated with same day disease activity, serologies (anti-dsDNA and low complements), and need for prednisone. It is also strongly associated with poor outcomes (myocardial infarction, deep venous thrombosis, diabetes, malignancy).

Table 1. Association between Same-day Visit Disease Activity and Neutrophil Gene Signature

Variable	Low Neutrophil (<5) (%, N=107)	Med Neutrophil (5–6) (%, N=92)	High Neutrophil (>6) (%, N=93)	Adjusted P-value for Ethnicity
Ethnicity African-American	36.5	42.4	22.6	0.045*
Caucasian	57.9	52.2	66.7	
Other	5.6	5.4	10.8	
Physician's global assessment >1	11.2	16.3	30.1	0.003
SELENA SLEDAI ≥2	47.7	60.9	65.6	0.012
Age at visit (years) ≤30	13.1	9.8	12.9	0.75
>30	86.9	90.2	87.1	

	Low Neutrophil (<5)	Med Neutrophil (5–6)	High Neutrophil (>6)	Adjusted P-value for Ethnicity
Use of Prednisone	25.2	32.6	49.5	0.0007
Use of Plaquenil	77.6	88.0	71.0	0.016
Use of Aspirin	30.8	41.3	51.6	0.011
Anti-dsDNA ≥10	10.3	26.1	31.2	0.0005
Lupus Anticoagulant	10.3	12.0	23.7	0.023
C3 <79 mg/dl	8.4	8.7	20.4	0.031
C4 <12 mg/dl	5.6	9.8	18.3	0.034
ESR >20	40.2	53.4	61.5	0.0018

* Unadjusted p-value.

Table 2. Association between SLICC/ACR Damage Index and Neutrophil Gene Expression in SLE

Variable	Low Neutrophil (<5) (%, N=107)	Med Neutrophil (5–6) (%, N=92)	High Neutrophil (>6) (%, N=93)	Adjusted P-value for Ethnicity
Myocardial Infarction	0.0	6.5	5.4	0.0056
Deep Venous Thrombosis	1.9	0.0	6.5	0.016
Diabetes	4.7	6.5	14.1	0.024
Malignancy	2.8	12.1	15.2	0.0043

Conclusion: This is the first gene signature to be associated with myocardial infarction, deep venous thrombosis and malignancy. Targeting the neutrophil gene signature appears to be promising for disease activity. Given that atherosclerosis disease is the major cause of death in late SLE, this gene signature may be the "missing link" in understanding how SLE accelerates atherosclerosis. A limitation of the technique is that the neutrophil gene signature will go up when there is lymphopenia.

887

Microrna-155 Protects Against Pulmonary Fibrosis by Targeting the Transcription Regulator LXR Alpha. Mariola Kurowska-Stolarska[1], Manhl Hasoo[1], Derek G. Gilchrist[2], Eva Ruzicska[2], Darren Asquith[2], David Welsh[3], Lynn Crawford[2], Nik Hirani[4], Iain B. McInnes[2] and Charles McSharry[2], [1]Institute of Infection,Immunity and Inflammation, College of Medical, Veterinary and Life Sciences University of Glasgow, Glasgow, United Kingdom, [2]University of Glasgow, Glasgow, United Kingdom, [3]Western Infirmary, Glasgow, United Kingdom, [4]University of Edinburgh, Edinburgh, United Kingdom

Background/Purpose: MicroRNAs (miRs) are a novel class of post-transcriptional regulators. A single miR can have profound effects on cell activation due to its ability to modulate multiple pathways at once. We have previously shown that miR-155 is upregulated in rheumatoid arthritis (RA) synovial macrophages and promotes the development of autoimmunity and joint inflammation. Pre-clinical arthritis may be associated with lung changes e.g. bronchial wall thickening, thus the aim of this study was to investigate the contribution of miR-155 regulated pathways to lung homeostasis.

Methods: Normal human lung tissue was tested by *in situ* hybridisation with miR-155 and control probes. To model the fibrotic response, WT and miR-155$^{-/-}$ mice were given bleomycin (0.06 unit/mouse) intranasally. Intervention included intraperitoneal injections of the Liver X Receptor (LXR) agonist (GW3965 daily; 40 mg/kg). End-points included bronchial lavage (BAL) cytology, lung tissue histology, evaluation of the expression of inflammatory and fibrotic genes by qPCR and concentrations of soluble mediators in serum and BAL fluid by multiplex assays. The validation of miR-155 binding to LXR, and the LXR response element in collagen gene promoters were performed with reporter assays.

Results: *In situ* hybridisation showed an abundant expression of miR-155 in the normal human lung suggesting that this miR may contribute to normal lung homeostasis. miR-155$^{-/-}$ mice developed more severe bleomycin-induced lung fibrosis compared to WT mice, as seen by increased collagen 1a/3a mRNA expression and protein deposition in the lungs, as well as accumulation of macrophages and lymphocytes in BAL. Gene expression analysis of lung extracts revealed an increase in the M2 pro-fibrotic macrophage markers Arginase 2, IL-13R and Ym1. In addition, the levels of pro-fibrotic cytokines such as VEGF and bFGF were significantly higher in BAL and serum of miR-155$^{-/-}$ mice. Primary lung fibroblast lines derived from miR-155$^{-/-}$ mice showed higher proliferation rates and motility compared to WT cells in wound healing assays. Computational analysis followed by functional luciferase assays revealed that the transcription activator LXR alpha is a direct target of miR-155 in the lungs. Expression of

LXR alpha was significantly upregulated in the lungs of naïve miR-155$^{-/-}$ mice and was further increased in mice given bleomycin compared to similarly treated WT controls. Injection of the LXR agonist to WT mice increased LXR expression and mirrored the same phenotypic response to bleomycin as the miR-155 deficient mice; shown by increased collagen deposition and M2 macrophage and fibroblast activation. Promoter analysis revealed that LXRs could directly induce collagen production by binding to *col1a* and *col3a* promoters.

Conclusion: miR-155 appears important for lung homeostasis, likely by fine tuning levels of LXRα thereby protecting from excessive remodelling. Given this and the emerging contribution of miR-155 to development of autoimmunity, this miR may act as a master-switch determining the duration of inflammation and the initiation of remodelling, as well as the balance between the immune and auto-immune responses.

Plasma Cells Express the Novel Cytokine Interleukin-36α in Psoriatic and Rheumatoid Arthritis Synovium. Anja Derer[1], Silke Frey[1], Maria-Elena Messbacher[1], Serena Bugatti[2], D. Baeten[3], Carlomaurizio Montecucco[4], Georg A. Schett[1] and Axel J. Hueber[1]. [1]University of Erlangen, Erlangen, Germany, [2]Division of Rheumatology, University of Pavia School of Medicine, IRCCS Policlinico San Matteo Foundation, Pavia, Italy, [3]Academic Medical Center, University of Amsterdam, Amsterdam, Netherlands, [4]University of Pavia School of Medicine, IRCCS Policlinico San Matteo Foundation, Pavia, Italy

Background/Purpose: IL-36α is a recent described IL-1 cytokine family member with proinflammatory and clear pathogenic properties in psoriasis. Aim of this study was to determine IL-36α expression in psoriatic arthritis (PsA) compared to rheumatoid (RA) and osteoarthritis (OA).

Methods: Synovial tissue gathered from arthritis patients were stained for IL-36α, IL-36 receptor (IL-36R) and IL-36R antagonist (IL-36Ra) by immunohistochemistry and immunofluorescence. Lysates were tested for IL-36α by western blot analysis. Synovial fibroblasts (FLS) stimulated with IL-36α were assessed for cytokine expression.

Results: The IL-36R and its ligands IL-36α and IL-36Ra could be detected in inflammatory arthritis in the synovial lining layer as well as cellular infiltrates. IL-36α was significantly higher expressed in PsA and RA synovium compared to OA (p=0.0011 and p<0.0001, respectively). No differences were seen in IL-36R and IL-36Ra. The expression of IL-36α was confirmed by western blot analysis. IL-36α induced expression of IL-6 and IL-8 in FLS. CD138-positive plasma cells were determined as major cellular source for IL-36α.

Conclusion: We described that the novel cytokine IL-36α is upregulated in PsA and RA synovium mainly expressed by plasma cells. This insight needs further studies to determine if the IL-36 family can function as a potential target for arthritis therapy.

Modeling Environmental and Genetic Determinants to Identify the Association of Risk Genes in Anti-Ro60-Mediated Injury: Relaxin Receptor I and Tumor Necrosis Factor. Joanne H. Reed[1], Paula S. Ramos[2], Jiri Zavadil[1], Jill P. Buyon[1] and Robert M. Clancy[1]. [1]New York University School of Medicine, New York, NY, [2]Medical University of South Carolina, Charleston, SC

Background/Purpose: Fetuses exposed to maternal anti-Ro60 antibodies can develop cardiac conduction abnormalities and life threatening cardiomyopathy; manifestations of neonatal lupus (NL). Recent data support an injury model in which immune complexes (IC) comprised of Ro60, ssRNA, and anti-Ro60 engage Toll-like receptors (TLR) and promote secretion of proinflammatory and profibrotic factors.To identify risk genes related to TLR-dependent fibrosis, a novel strategy was designed based on: 1) gene expression of macrophages stimulated by Ro60-related hY3 ssRNA as a proxy of the in utero environmental contribution and 2) the association of genetic variation with cardiac NL. This is the first approach to employ environmental

and genetic determinants to identify the association of risk genes in anti-Ro60-mediated injury.

Methods: Human macrophages obtained from PBMCs were transfected with hY3 or cultured with IC containing Ro60, anti-Ro60,and hY3 to ligate TLR7 with or without IRS661, a specific TLR7 inhibitor. Affymetrix HG-U133A 2.0 microarray analysis using RNA isolated from the test conditions (n=6) was employed.Selection was prioritized to expression of genes common to both hY3 and IC stimulation in which the copy number increased by 50%. Ingenuity Pathway Analysis was used to generate a list of genes with fibrotic functions.Variants from our previously published genome-wide association study (GWAS) were used to test for an enrichment of association in these genes. This list was then compared to the overexpressed transcripts, and shared genes were ranked using a weighted composite score with a focus on the TLR7 pathway (ratio of transcript copy number for IC/IC+IRS661, high to low, and by the P-value of the variant, most significant to least).

Results: In hY3 and IC stimulated conditions 1184 shared genes were upregulated of which 1110 and 891 were reduced by 50% with IRS661 co-treatment, respectively. Among these, there was an enrichment of genes known to be related to inflammation and fibrosis.Based on our previously published GWAS, 327 fibrotic genes showed a significant enrichment of associations with cardiac NL (P=2.27 $\times$ 10^{-9}).Of these genes, 20 were overexpressed in the macrophage array in a TLR7-dependent manner.To select candidates with a potential functional role in mediating cardiac injury, the candidate list was narrowed to three genes based on a ranking of a composite score. The risk gene with the highest score was the relaxin receptor 1 (*RXFP1*) (transcript copy number (IC/(IC+IRS661)) ratio=21.2 and rs10517692 P=0.035), a G-protein coupled receptor that binds relaxin and plays a role in collagen and connective tissue remodeling. Key inflammatory mediators included *C5* (ratio=6.4, rs2269066 P=0.008) and *TNF* (ratio=4.1, rs2844482 P=0.004). The latter was previously reported to have both genetic variation and biologic relevance associated with cardiac NL.

Conclusion: These data support the applicability of a novel model in which causal alleles can be identified by combining expression and association datasets to delineate the molecular mechanisms by which anti-Ro60 antibody mediates cardiac injury. The identification of *RXFP1* and the further confirmation of *TNF* provide important targets for consideration.

The Role of Adipocytokines in Osteophyte Formation in Osteoarthritis. Susann Junker[1], Grit Krumbholz[1], Klaus Frommer[1], Angela Lehr[2], Stefan Rehart[2], Jürgen Steinmeyer[3], Markus Rickert[4], Georg A. Schett[5], Ulf Müller-Ladner[1] and Elena Neumann[6]. [1]Justus-Liebig-University of Giessen, Kerckhoff-Klinik, Bad Nauheim, Germany, [2]Markus-Hospital, Frankfurt, Germany, [3]University Hospital Gießen and Marburg, Gießen, Germany, [4]University Hospital Giessen and Marburg, Giessen, Germany, [5]Department of Internal Medicine III and Institute for Clinical Immunology, University of Erlangen-Nuremberg, Erlangen, Germany, [6]Justus-Liebig-University of Gießen, Kerckhoff-Klinik, Bad Nauheim, Germany

Background/Purpose: Obesity is an established risk factor in osteoarthritis (OA), but there is not much known about the interaction between bone formation and the so-called adipo(cyto)kines. Adipokines, such as adiponectin (Ad), visfatin (Vis) or resistin (Res), are adipose tissue-derived factors, which are associated with the pathogenesis of rheumatoid arthritis (RA) and OA. Adipokines can be produced by other cell types, *e.g.* fibroblasts, osteoblasts, osteoclasts and chondrocytes. However, in contrast to their joint-destructive effects in RA, their role in joint remodeling in OA, specifically in osteophyte formation, is still unclear. Therefore, the expression of adipokines in osteophyte development and cells of bone formation and their effect on these cells were analyzed.

Methods: Osteophytes, cartilage and osteoblasts were obtained from OA patients during joint replacement surgery. Serial sections of bone tissue were stained (Masson trichrome, TRAP) and scored from grade one (no ossification, mainly connective tissue and cartilage) to five (ossified, mineralized osteophyte, <10% connective tissue). For analysis of adipokine localization, immunohistochemistry was performed to detect alkaline phosphatase, collagen-type II, Ad, Vis, and Res. Immunoassays for Vis were performed on cartilage and isolated primary chondrocyte lysates. Osteoblast cultures were stimulated with Ad or Res and measurements of IL-6, IL-8, and MCP-1 were performed in cell culture supernatants.

Results: Ad, Res and Vis were detectable in all osteophyte grades. In osteophytes without ossification (grade 1), especially Ad and, to a lower extent, Res and Vis were localized in connective tissue fibroblasts. In ossified osteophytes (grade 2–5), Res and Vis protein expression was co-localized with osteoclasts and osteoblasts. Vis was detectable additionally in chondrocytes in osteophytes of all grades (50 % stained chondrocytes). Vis expression in human cartilage and cultured chondrocytes was confirmed on protein and mRNA level. Ad was detectable in co-localization with osteoblasts as well as around blood vessels.

Vis expression in osteoblasts was confirmed on mRNA level. Immunocytochemistry on cultured osteoblasts confirmed the expression of Ad, Res and Vis. Stimulation of osteoblasts with Ad and Res led to an increased IL-6, IL-8 and MCP-1 release when compared to unstimulated controls (Ad: 5,7-fold, 9,5-fold, 3,6-fold, respectively/Res: 1,7-fold, 1,6-fold, 1,3-fold, respectively). The immunomodulatory effect of Ad on osteoblasts was stronger than the effect of Res.

Conclusion: The expression of Ad and Vis in osteophyte connective tissue and cartilage suggests an involvement in early osteophyte formation. Res and Vis expression by osteoblasts and osteoclasts in ossified osteophytes suggests a role in bone remodeling of osteophytes at later stages. Osteoblasts respond to the stimulation with Ad and Res with an increased secretion of inflammatory mediators. Therefore, adipokines are most likely involved in osteophyte formation at different stages of OA and affect different cell types of cartilage and bone formation.

Fatty Acids Promote Secretion of Proinflammatory and Prodestructive Factors by Synovial Fibroblasts. Klaus W. Frommer[1], Andreas Schäffler[2]. Stefan Rehart[3], Angela Lehr[3], Ulf Müller-Ladner[1] and Elena Neumann[1], [1]Justus-Liebig-University of Gießen, Bad Nauheim, Germany, [2]University of Regensburg, Regensburg, Germany, [3]Markus-Hospital, Frankfurt, Germany

Background/Purpose: Due to their role in inflammatory metabolic diseases, we hypothesized that free fatty acids (FFA) are also involved in primary inflammatory joint diseases including rheumatoid arthritis (RA) and psoriasis arthritis (PsA) as well as in degenerative joint diseases with secondary inflammatory properties, specifically osteoarthritis (OA). To test this hypothesis, we analyzed the effect of FFA on synovial fibroblasts (SF), a key cell type in the pathophysiology of arthritis. We also investigated whether FFA need to be internalized to have an effect and if the innate immune system is involved in the modulation of this effect.

Methods: RASF, OASF and PsASF were stimulated *in vitro* with different saturated and unsaturated FFA within their physiological range of concentrations. Immunoassays were used to quantify FFA-induced protein secretion. Sulfosuccinimidyl oleate sodium (SSO) was used to inhibit the fatty acid translocase (FAT), which is responsible for transporting long-chain fatty acids into the cell. In addition, TLR4 signaling, which can contribute to driving arthritis, was inhibited intracellularly and extracellularly.

Results: In RASF, FFA dose-dependently enhanced the secretion of the proinflammatory cytokine IL-6, the chemokines IL-8 and MCP-1, as well as the matrix-degrading enzymes MMP-1 and MMP-3. Cell population, cell source (RA, OA, or PsA) and the respective molecular parameters were factors that influenced the changes of protein secretion (e.g. for lauric acid [100 μM] with RASF/IL-6: 9.1-fold increase; IL-8: 14.9-fold increase; MCP-1: 2.4-fold increase; pro-MMP1: 5.1-fold increase; MMP-3: 83.6-fold increase). At equal concentrations, both saturated and unsaturated fatty acids showed similar effects, while responses to FFA were generally stronger for OASF and PsASF than for RASF (e.g. for palmitic acid [10 μM] with RASF/IL-6: 2.8-fold increase; with OASF: 15.2-fold increase; with PsA-SF: 39.3-fold increase). Pre-incubation of RASF with SSO almost completely abrogated the effect of palmitic acid on IL-8 secretion. However, both intracellular and extracellular TLR4 signaling inhibition blocked the palmitic acid-induced IL-6 secretion of RASF.

Conclusion: The data show that FFA are not only metabolic substrates but also directly contribute to articular inflammation and degradation in various joint diseases. Moreover, the data support the hypothesis that FFA-induced joint destruction is mediated through the innate immune system.

The Epigenetically Repressed Long Noncoding RNA Hotair Influences the Expression of Matrix Metalloproteases in Synovial Fibroblasts. Michelle Trenkmann[1], Matthias Brock[2], Renate E. Gay[1], Beat A. Michel[3], Lars C. Huber[2] and Steffen Gay[1]. [1]Center of Experimental Rheumatology, University Hospital Zurich, Zurich, Switzerland, [2]Department of Internal Medicine, University Hospital Zurich, Zurich, Switzerland, [3]Department of Rheumatology, University Hospital Zurich, Zurich, Switzerland

Background/Purpose: Long noncoding RNAs (lncRNA, >200nt) have recently emerged as regulators of gene expression functioning as signals, decoys, guides or scaffolds for transcription factors and/or the epigenetic machinery of the cell. The repressive epigenetic mark trimethylated histone 3 lysine 27 (H3K27me3) is transferred by the histone methyltransferase EZH2 which is up regulated in rheumatoid arthritis (RA) synovial fibroblasts (SF) and inducible by tumor necrosis factor (TNF)-α (Trenkmann M *et al.*, ARD, 2011). The lncRNA HOX transcript antisense RNA (HOTAIR) has been associated with cancer and metastasis; it was shown to interact with EZH2 and proposed to guide H3K27 trimethylation of target genes (Wang KC and Chang HY, Mol Cell, 2011). Here, we studied expression, regulation and function of HOTAIR in SF.

Methods: Gene expression in SF was measured by SYBR Green or TaqMan real-time PCR with normalization to GAPDH. SF were stimulated with TNFα (10ng/ml; n=11) and interleukin (IL)-1β (1ng/ml; n=5). Osteoarthritis (OA)SF were transfected with a vector encoding EZH2 (n=4) or siRNA targeting HOTAIR (n=11). Chromatin from SF was precipitated with antibodies for histone 3 (H3), H3 methylation H3K4me3 and H3K27me3, and H3 acetylation (Ac), and the HOTAIR promoter was analyzed for epigenetic regulation.

Results: The expression of HOTAIR was strongly decreased (12.7-fold) in RASF (n=9) compared to OASF (n=13) (ΔCt 14.3$\pm$3.3 vs. 10.6$\pm$1.7, p=0.005). EZH2 over expression in OASF reduced the expression of HOTAIR by 30$\pm$17% (p<0.05) suggesting that EZH2-mediated methylation of H3K27 may regulate HOTAIR expression. Indeed, HOTAIR levels in RASF and OASF inversely correlated with the repressive H3K27me3 epigenetic mark in the promoter of HOTAIR (Spearman R=$-$0.8725, p<0.0001). In detail, the H3K27me3 to H3 ratio in RASF was 0.51$\pm$0.35 whereas the HOTAIR promoter in OASF showed much less H3K27 trimethylation (ratio to H3 0.25$\pm$0.23; p=0.0309). Interestingly, neither in RASF nor in OASF H3K4me3 or H3-Ac could be detected at the HOTAIR promoter. Stimulation of OASF with TNFα for 24h and 48h decreased HOTAIR levels by 63$\pm$16% and 56$\pm$26% (p<0.0001). IL-1β-stimulation reduced HOTAIR expression by 54$\pm$10% and 63$\pm$6%, respectively (p<0.0005). To identify a functional role for HOTAIR repression in RASF, we silenced HOTAIR in OASF using RNA interference. The silencing of HOTAIR significantly increased mRNA levels of the matrix metalloproteases (MMP) 3, 13 and 14 (MMP3 by 1.8$\pm$0.7-fold, MMP13 by 4.3$\pm$3.1-fold and MMP14 by 2.1$\pm$0.7-fold, p<0.05); in contrast, results for MMP1 were inconsistent. The TNFα-induced expression of MMP3 (51.6$\pm$21.2-fold) and MMP13 (6.9$\pm$2.6-fold) was further increased by silencing of HOTAIR (71.5$\pm$28-fold and 18.8$\pm$8.6-fold, p<0.05) whereas the IL-1β-stimulated expression was not significantly changed (n=5 each).

Conclusion: This is the first report of a differential expression of a lncRNA in RA. The expression of HOTAIR is strongly reduced in RASF via the repressive epigenetic mark H3K27me3. We demonstrate that HOTAIR silencing may account for the up regulation of matrix-degrading enzymes indicating a potential role for HOTAIR repression in the activated, matrix-destructive phenotype of RASF.

Nuclear Factor-κB Activation by Type II Collagen Peptide in Osteoarthritic Chondrocytes: Its Inhibition by Hyaluronan Via CD44. Tadashi Yasuda. Tenri University, Tenri, Japan

Background/Purpose: Some proteolytic products of cartilage matrix may contribute to cartilage destruction through their catabolic activities. Recently, we have found that a 24-mer synthetic peptide of type II collagen named CB12-II stimulates type II collagen cleavage with induction of matrix metalloproteinase (MMP)-13 in cartilage explant culture. Although the intracellular signaling that leads to cartilage destruction is mediated by a

cluster of catabolic pathways including nuclear factor-κB (NF-κB), the effect of CB12-II on NF-κB remains unclear.

Hyaluronan (HA) of high molecular weight is widely used in the treatment of osteoarthritis (OA) by intra-articular injection. An increasing body of evidence indicates that HA suppresses catabolic actions by proinflammatory cytokines like interleukin-1 and matrikines such as fibronectin fragments. However, little is known of HA effect on actions of CB12-II through interaction with HA receptor such as CD44.

This study was aimed to examine activation of NF-κB in association with MMP-13 production by CB12-II and its inhibition by HA in chondrocytes.

Methods: Cartilage explants harvested from OA knee joints or isolated chondrocytes in monolayer were incubated with CB12-II or its scramble peptide with or without pretreatment with 2700 kDa HA. In another set of experiments, following preincubation with anti-CD44 antibody or non-specific IgG, cartilage explants were incubated with or without HA, followed by coincubation with CB12-II or the scramble peptide.

Enzyme-linked immunosorbent assays for phosphorylated p65 NF-κB and MMP13 were performed using total cell lysates and culture supernatants, respectively.

Results: When cartilage explants or chondrocytes in monolayer were incubated with CB12-II, the type II collagen peptide activated NF-κB in association with enhanced MMP-13 production. Inhibition studies with the specific inhibitor indicated the requirement of NF-κB for CB12-II-induced MMP-13 production. Pretreatment with HA resulted in significant suppression of CB12-II-stimulated MMP-13 production in cartilage as well as in chondrocyte monolayer cultures. HA suppressed NF-κB activation by CB12-II, leading to a decrease in MMP-13 production. Anti-CD44 antibody reversed HA effect on CB12-II action.

Conclusion: The present study clearly demonstrated that HA suppressed CB12-II-activated NF-κB via CD44 in OA articular chondrocytes, leading to decreased MMP-13 production. HA could down-regulate the catabolic action of type II collagen fragments in osteoarthritic joints through the mechanism demonstrated in this study.

Genetic Variants in the *IL-4* and *IL-4* Receptor Genes in Association with the Severity of Joint Damage in Rheumatoid Arthritis: A Study in Seven Cohorts.
A. Krabben[1], A. G. Wilson[2], R. Knevel[1], A. Zhernakova[3], E. Brouwer[3], E. Lindqvist[4], T. Saxne[4], G. Stoeken-Rijsbergen[1], J. A. B. van Nies[1], D. P. C. de Rooy[1], T.W.J. Huizinga[1], B. P. C. Koeleman[5], R. E. M. Toes[1], P. K. Gregersen[6] and A. H. M. van der Helm-van Mil[1]. [1]Leiden University Medical Center, Leiden, Netherlands, [2]University of Sheffield, Sheffield, United Kingdom, [3]University of Groningen, University Medical Center, Groningen, Netherlands, [4]Lund University, Lund, Sweden, [5]University Medical Center Utrecht, Utrecht, Netherlands, [6]Feinstein Institute Medical Research and North Shore-Long Island Jewish Health System, Manhasset, NY

Background/Purpose: The severity of RA is reflected by the severity of radiological joint destruction. It is highly variable between patients and up to 58% of this variance is explained by genetic factors. In order to increase the understanding of the processes underlying joint damage progression, it is relevant to identify individual risk factors. In vitro studies and mice studies showed that *IL-4* has a role in suppressing arthritis severity. The effect of *IL-4* is mediated by a heterodimeric receptor composed of the IL-4R alpha chain. Several genetic variants in *IL-4* and *IL-4R* have been described to associate with RA severity, though these findings have not been replicated. Together these data prompted us to investigate the association between *IL-4* and *IL-4R* tagging SNPs and progression rate of joint damage in a multi-cohort candidate gene study.

Methods: *IL-4* and *IL-4R* tagging SNPs (8 and 39, respectively) were genotyped in 600 RA patients of whom 2,846 sets of hands and feet X-rays were collected during 7 years follow-up. Subsequently, significantly associated SNPs were genotyped and studied in relation to 3,523 X-rays of 2,064 RA patients of several European and North-American cohorts. These concerned data-sets from Lund (Sw) (781 X-rays in 147 patients), Sheffield (UK) (391 X-rays in 391 patients), Groningen (NL) (872 X-rays in 280 patients), NARAC (USA) (385 X-rays in 385 patients), Wichita (USA) (337 X-rays in 101 patients) and NDB (USA) (757 X-rays in 757 patients). Three SNPs of phase-2 were not available for the latter two cohorts. In all cohorts X-rays were scored with high reproducibility. The relative increase in progression rate per year in the presence of a genotype was determined, as this outcome measure is comparable between cohorts. Subsequently, since the individual replication cohorts had less number of X-rays than the discovery cohort, an inverse variance weighting meta-analysis was done on the cohorts that together formed the replication phase.

Results: In the discovery phase none of the *IL-4* SNPs and seven of the *IL-4R* SNPs were significantly associated with joint damage progression rate. In the replication phase, two SNPs in *IL-4R* gene were significantly associated with joint damage progression rate (rs1805011, p=0.017 and rs1119132, p=0.001). After Bonferroni correction for testing seven SNPs in phase-2 rs1119132 remained significantly associated with joint progression rate ($p_{corrected}$=0.007). Leiden RA-patients carrying both minor alleles of rs1119132 had a 1.09 fold rate of joint destruction compared to other patients, which corresponds to 81% higher rate of joint destruction over a period of 7 years.

Conclusion: rs1119132 in *IL-4R* was identified as well as independently replicated to associate with progression rate of joint damage in RA.

Transcriptomics of Synovial Tissue of Early Human (CHECK) and Experimental OA Identify Pathways Associated with Cartilage Damage.
Arjen B. Blom[1], Peter L.E.M. van Lent[1], Martijn H. van den Bosch[1], Hans Cats[2], Peter M. van der Kraan[1] and Wim B. van den Berg[3]. [1]Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands, [2]Sint Maartenskliniek, Nijmegen, Netherlands, [3]Rheumatology Research and Advanced Therapeutics, Department of Rheumatology, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands

Background/Purpose: Many osteoarthritis (OA) patients show synovial inflammation, even relatively early during the disease. Mechanisms through which synovial activation contributes to the joint pathology that characterizes OA, are not known. The objective of this study is to identify common pathways in the synovium that determine cartilage damage during OA.

Methods: From patients that entered the CHECK Cohort study (Cohort Hip and Cohort Knee) and from controls (n=7) synovial biopsies were collected. CHECK is a prospective 10-year follow-up study on participants with early osteoarthritis-related complaints. Kellgrenn&Lawrence score (KL) was determined at inclusion (n=18). In addition, biopsies of 7 control synovia were collected. A longitudinal expression analysis was performed on murine synovial tissue at day 7, 21 and 42 after induction of collagenase induced OA (CIOA). CIOA was induced by intra-articular injection of collagenase and contra lateral knee joints served as controls. Microarray experiments were performed on all synovial tissues. Functional annotation clustering (FAC) and pathway analysis was done using DAVID.

Results: Gene expression profiles of control synovia were compared to CHECK synovia. Enrichment analysis revealed several annatations, including regulation of macrophage differentiation, innate immune responses, cell migration, TGFβ-, BMP- and wnt-signaling. This signifies clear activation of the synovium in CHECK patients compared to controls. Next we compared synovial tissue of patients with radiological damage (KL$\geq$1) with patients without damage (KL=0). Genes that showed the strongest association with cartilage damage were MMP-1, MMP-3, S100A8 and cartilage glycoprotein-39 (18, 10, 6 and 6-fold), all of which have been associated with cartilage damage. Response to wounding, chemotaxis, innate immune response and metalloproteases were strongly and significantly enriched and thus associated with joint damage. Pathway analysis demonstrated that in the synovium of patients with joint damage the complement-activation pathway, TGFβ- and BMP-signaling and TLR-activation were significantly upregulated. These results were underlined by analysis of synovium from CIOA. Among the genes that were strongly upregulated on all time points after induction were MMP-3, MMP-13, MMP-14 and COMP (6, 16, 6 an 13-fold). Again, wound healing, innate immune response and metalloproteases were significantly enriched, as were the complement pathway, the TLR-, TGFβ, BMP and wnt-signaling pathways. A recent publication demonstrated complement to be essential in experimental OA. We therefore determined expression of complement binding proteins, and found a strong upregulation of COMP, lumican, osteomodulin, biglycan, decorin and fibromodulin.

Conclusion: These data suggest an active role for the synovium in OA pathology, and identify pathways that are likely to be involved. In particular the association of cartilage damage with the complement pathway was strong.

In addition, TGFβ-, BMP- and wnt-signaling in the synovium, may contribute to further joint damage. The enhanced expression of cartilage damaging MMP-1, MMP-3 and MMP-13 suggests an active role of the synovium in OA pathology.

Tyro3, Axl, MerTK-Receptor Activation by Gas6 or Pros1 Gene Delivery, ameliorates Collagen-induced arthritis. Fons A.J. van de Loo[1], Ben T. van Den Brand[1]. Shahla Abdollahi-Roodsaz[1], Eline A. Vermeij[2], Miranda B. Bennink[2], Onno J. Arntz[2] and Wim B. van den Berg[1], [1]Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands, [2]Nijmegen, Netherlands

Background/Purpose: Insufficient controlled activation of innate immunity by cytokines and pattern recognition receptors could develop into auto-immune diseases. Stimulation ofdendritic cells via the Axl receptor in conjunction with IFNAR leads to upregulation of suppressor of cytokine signaling (SOCS) proteins 1 and 3 and broadly inhibit both Toll-like Receptor (TLR) signaling and TLR-induced cytokine-receptor cascades (Rothlin et al. Cell 2007). This study evaluated whether Tyro3 Axl MerTK (TAM)- receptor stimulation by Growth arrest specific 6 (Gas6) and Protein S (Pros1) as natural negative feedback for Toll-Like Receptor and cytokine signaling can be used to treat collagen-induced arthritis.

Methods: Adenoviruses ($1 \times 10E7$ FFU) overexpressing Gas6 and Pros1 were injected intravenously (i.v.) or $3 \times 10E8$ FFU intra-articularly (i.a.) into mice before onset of collagen-induced arthritis. Splenic T-helper subsets of intravenously injected were studied by flow cytometry and knee joints of mice injected i.v. and i.a. were assessed histologically. Messenger RNA expression was analyzed in synovium of i.a. injected mice. Ciruclating cytokines were measured on a Luminex-100 System (Luminex corp.) using a magnetic bead-based multiplex immunoassay (Milliplex, Merck Millipore). Joint inflammation was imaged using the ProSense probe with the IVIS Lumina (Caliper Life Sciences), using the Cy5.5 filter.

Results: Gas6 or Pros1 did not affect arthritis incidence in either IV or IA injected animals. However, Pros1 did significantly reduce ankle joint swelling, and circulating levels of KC and IL-6. Histological analysis of knee joints revealed a moderate reduction of joint pathology and a significant reduction of splenic T-helper 1 cells when Pros1 was overexpressed systemically. Local overexpression of Gas6 decreased joint inflammation (as assessd histologically or imaged by ProSense) and joint pathology. Pros1 treatment showed a similar trend of protection. Consistently, Gas6 and Pros1 markedly reduced cytokine (IL-1β, IL-6, and TNFα) production in synovium. Moreover, IL-12 and IL-23 mRNA levels were reduced by Gas6 and Pros1, corresponding to a decrease in IFNγ and IL-17 production in synovium.

Conclusion: We provide the first evidence that TAM receptor stimulation by Gas6 and Pros1 can be used to ameliorate arthritis when applied systemically or locally. TAM receptor stimulation limits proinflammatory signaling and the adaptive immunity. This pathway provides a novel strategy to combat rheumatoid arthritis.

IL-33 Promotes Mast Cell Survival Via Inhibition of Apoptosis Associated with Enhanced Expression of Bcl-X$_L$. Shinjiro Kaieda[1], Jun-Xia Wang[1] and Peter A. Nigrovic[2]. [1]Brigham and Women's Hospital, Harvard Medical School, Boston, MA, [2]Brigham and Women's Hospital, Boston, MA

Background/Purpose: Mast cells (MCs) are potent innate immune cells that frequently accumulate in chronically inflamed tissues, including the arthritic synovium. The factors that regulate MC persistence and survival in such tissues are unknown. Recent studies have found that the mesenchymal-derived cytokine IL-33 exerts potent effects on MC phenotype and function. Knowing that IL-33 can inhibit apoptosis in cardiac myocytes and hepatocytes, we tested the hypothesis that IL-33 might also regulate MC proliferation and survival, including the development of synovial mastocytosis in the context of inflammatory arthritis.

Methods: Murine bone marrow derived MCs (mBMMCs) were generated from wild-type (WT) mice and animals lacking the IL-33 receptor IL1RL1. Cell viability, proliferation and apoptosis were examined after exposure to IL-33, and compared with exposure to IL-3, a known survival factor for MCs.Expression of the anti-apoptotic molecules Bcl-2 and Bcl-X$_L$ were determined both as mRNA and as protein. To examine the role of IL-33 in vivo, fluorescently-labeled mixed WT and IL1RL1$^{-/-}$ mBMMCs were transferred into the peritoneum of IL1RL1$^{-/-}$ mice. Following 6 days of treatment with IL-33 (100ng/d/mouse, i.p.), peritoneal MCs were harvested and analyzed using flow cytometry.WT and IL1RL1$^{-/-}$ mBMMCs were sorted and the levels of Bcl-2 and Bcl-X$_L$ mRNA were examined by qRT-PCR. Synovial tissue MCs were enumerated in WT and IL1RL1$^{-/-}$ animals at baseline and after induction of K/BxN serum transfer arthritis.

Results: While the viability of WT and IL1RL1$^{-/-}$ mBMMCs was similar in IL-3-supported culture, exogenous IL-33 was able to support the survival of WT but not IL1RL1$^{-/-}$ mBMMCs after IL-3 withdrawal. CFSE dilution studies confirmed that this effect did not reflect enhanced proliferation, but rather arose via inhibited apoptosis as evident by a reduction in the number of Annexin V positive cells. Exploring the mechanism of this effect, we found that IL-33 increased expression of Bcl-X$_L$ but not Bcl-2, unlike IL-3 which supported mBMMC survival via enhanced Bcl-2 but not Bcl-X$_L$. Correspondingly, WT mBMMC persisted better than IL1RL1$^{-/-}$ BMMC in IL-33-treated recipients, an effect again mediated not by proliferation but by impaired apoptosis and Bcl-X$_L$ expression. While WT and IL1RL1$^{-/-}$ demonstrated no difference in the number of synovial MC at baseline, after K/BxN serum transfer the number of MC in ankle synovium was significantly reduced in IL1RL1$^{-/-}$ compared with WT mice. However, since IL-1RL1$^{-/-}$ mice also exhibited less inflammation, the density of MC was similar in both strains, suggesting the IL-33 is not uniquely required for maintaining these cell populations in vivo.

Conclusion: These findings identify a novel role for IL-33 as a promoter of murine MC viability, an effect likely mediated by enhanced expression of the anti-apoptotic protein Bcl-X$_L$. This effect could represent a new mechanism by which IL-33-producing cells, such as fibroblasts, support the maintenance of tissue mastocytosis.However, at least in the short term K/BxN arthritis model, other pathways appear sufficient to enable and maintain tissue MCs even when this mechanism is interrupted by genetic deletion of the IL-33 receptor IL1RL1.

Nuclear Receptor Related 1 Induces Synovial Hyperplasia Via Transcriptional Regulation of Novel Target Genes. Kimberlee S. Mix. Loyola University New Orleans, New Orleans, LA

Background/Purpose: Nuclear receptor related 1 (NURR1/NR4A2) is an orphan member of the nuclear receptor super-family that functions as a constitutively active transcription factor. This receptor has critical functions in the central nervous system, where it is required for the proper development of dopaminergic neurons. Furthermore, recent studies suggest that NURR1 promotes inflammatory diseases such as cancer, multiple sclerosis, and diabetes. We have documented over-expression of NURR1 in inflamed synovial tissues and cartilage from patients with rheumatoid arthritis and osteoarthritis. NURR1 is rapidly and potently induced by inflammatory cytokines, suggesting that this receptor may promote disease progression and tissue destruction.We have recently demonstrated that NURR1 induces a hyperplastic phenotype in fibroblast-like synoviocytes by increasing proliferation, anchorage-independent growth, and invasion. In the current study, we seek to elucidate the molecular mechanisms of NURR1 and identify downstream transcriptional targets of this receptor that may contribute to synovitis and cartilage degradation.

Methods: To achieve elevated levels of NURR1 similar to those observed in inflamed synovial tissues, NURR1 cDNA was transduced into normal human synoviocytes.Transcriptional activity was confirmed by the activation of a consensus NURR1 reporter construct. Quantitative RT-PCR arrays were used to identify genes that were differentially regulated by NURR1.

Results: Paralleling the effects of TNF-alpha, NURR1 regulates a subset of genes involved in angiogenesis, proliferation, and apoptosis. NURR1 potently induces expression of prolactin (300-fold), a peptide hormone that enhances synoviocyte activation and lymphocyte recruitment. Angiopoietin-1, a ligand for endothelium-specific tyrosine kinase receptors involved in synovial angiogenesis was induced by NURR1 (6-fold). Expression of the tyrosine kinase receptor TEK was also induced (30-fold), suggesting activation of an autocrine signaling pathway in synoviocytes.Raf kinase and the downstream mitogenic transcription factor c-Myc were both induced 3-fold by NURR1. Furthermore, the tumor suppressor gene p53 was

synergistically repressed by NURR1 and TNF-alpha, suggesting that NURR1 may block DNA repair mechanisms and prevent apoptosis of synoviocytes.

Conclusion: Taken together, we have identified a novel set of NURR1 target genes that converge on multiple pathways regulating synovial hyperplasia. We hypothesize that antagonizing NURR1 activity with a small molecule inhibitor may provide an innovative strategy to block pannus formation and tissue destruction.

A Role for Soluble Interleukin-6 Receptor As an Antagonist of Interleukin-27 Signaling. Misato Hashizume, Keiko Esaki and Yoshihiro Matsumoto. Chugai Pharmaceutical Co., Ltd., Gotemba, Japan

Background/Purpose: Recently, it has been reported that interleukin (IL)-27 treatment reduces inflammation and ameliorates arthritis in collagen-induced arthritis mice. IL-27 is a heterodimeric cytokine composed of IL-27p28, which is similar to IL-6, and EBI3, which is similar to soluble IL-6 receptor (sIL-6R). Notably, each subunit is produced independently, allowing IL-27 to associate with other proteins. sIL-6R is highly concentrated in serum from patients with rheumatoid arthritis (RA). We elucidated the role of sIL-6R in regulating IL-27 signaling.

Methods: Surface Plasmon Resonance analysis was used to examine the binding of IL-27 to sIL-6R. Competitive ELISA was performed to evaluate the binding to IL-27p28 and the dissociation of EBI3 from IL-27p28 in the presence of sIL-6R. $CD14^+$ cells were isolated from peripheral blood mononuclear cells of healthy subjects. $CD14^+$ cells were incubated with IL-27 and sIL-6R for 20 minutes, and phosphorylation of STAT3 was measured by FACS. $CD14^+$ cells were incubated with M-CSF, TNF-α, IL-27 and sIL-6R for 48 hours, and MCP-1 production from $CD14^+$ cells was measured by ELISA. $CD14^+$ cells were cultured with RANKL and M-CSF in the presence of IL-27 and sIL-6R for 4 days, and the number of osteoclasts was counted after tartrate-resistant acid phosphatise (TRAP) staining. Concentrations of IL-27p28/sIL-6R complex and IL-27p28/EBI3 complex in serum from healthy subjects and those with RA were determined by ELISA.

Results: Surface Plasmon Resonance analysis showed that binding curves were generated from experiments in which IL-27 was exposed to a high-density of sIL-6R coated on a sensor chip. sIL-6R promoted the dissociation of EBI3 from IL-27p28 and the formation of IL-27p28/sIL-6R complex in a dose-dependent manner. Anti-IL-6 receptor antibody (tocilizumab) inhibited the formation of IL-27p28/sIL-6R complex. To examine the effect of sIL-6R on IL-27 signaling, we measured phosphorylation of STAT3, which is increased by IL-27, after stimulating sIL-6R and IL-27, and found that sIL-6R decreased phosphorylation of STAT3. Next, we examined whether sIL-6R inhibited the IL-27-mediated anti-arthritic effect. Whereas IL-27 reduced TNF-α-induced MCP-1 production from $CD14^+$ cells, IL-27 did not decrease TNF-α-induced MCP-1 production in the presence of sIL-6R. Similarly, RANKL-mediated osteoclast formation was inhibited by IL-27 but was not inhibited by IL-27 in the presence of sIL-6R. Finally, we examined whether IL-27p28/sIL-6R complex was formed in serum from healthy subjects and from those with RA. Surprisingly, IL-27p28/sIL-6R complex in RA serum was significantly higher than that in healthy serum.

Conclusion: We elucidated that sIL-6R binds to IL-27p28, antagonizes IL-27 signaling, and blocks IL-27-mediated anti-arthritic effect. In addition, we showed that IL-27p28/sIL-6R complex was more abundant in serum from RA patients than in that from healthy subjects. These data suggest that sIL-6R may be involved in regulating the IL-27 function in RA.

Deletion of RBP-J in a Murine Model of Inflammatory Arthritis Reveals Differential Pro-Inflammatory Cytokine and FoxP3 Gene Expression. Soumya D. Chakravarty, Karmen Au, Xiaoyu Hu and Lionel B. Ivashkiv. Hospital for Special Surgery, New York, NY

Background/Purpose: The DNA-binding protein RBP-J serves as the central transcriptional regulator of the Notch signaling pathway. Prior work done using a knockdown approach of RBP-J in human macrophages and conditional deletion of RBP-J in mouse macrophages has demonstrated diminished LPS-induced expression of TNFa, IL-6 and IL-12p40, with IL-1 induction preserved. Elsewhere, it has been observed that host regulatory T cells in RBP-J deficient mice have an attenuated ability to suppress effector

T cell responses *in vitro*, with augmented proliferation and function of effector T cells noted *in vivo*, raising the possibility that dysregulation in the frequency or function of regulatory T cells may contribute to RBP-J's selective modulation of pro-inflammatory mediators. Here, we evaluated the *in vivo* effects of RBP-J's conditional deletion in the myeloid cell compartment on pro-inflammatory cytokine expression, as well as lymphoid tissue immunocyte composition, using a K/BxN serum transfer model of inflammatory arthritis.

Methods: RBP-J$^{flox/flox}$ LysM-Cre knock-out (KO) mice with littermate RBP-J$^{+/+}$LysM-Cre controls (n=5 for each group) were used. After treatment with K/BxN serum, the clinical course of arthritis was followed by measuring total joint thickness up to 14 days, at which point the mice were sacrificed. Total joint RNA from each mouse was obtained for gene expression analyses by qPCR. Splenic tissue was harvested from each mouse for gene expression analyses by qPCR, as well as pooled collectively for each group for immunophenotyping through flow cytometry. The latter was also done for superficial inguinal and draining popliteal lymph node (LN) tissue. Statistical analysis was done using the unpaired student's t-test with p < 0.05 considered significant.

Results: Preliminary findings showed no significant difference in clinical phenotype of K/BxN serum-induced arthritis between KO and control mice. Gene expression profiling of whole joint tissue showed decreases in TNFa, IL-6, IFN-g expression, as well as selective Notch target gene expression, while maintaining comparable IL-1, CXCL10, and IL-12p40 levels. Surprisingly, expression levels of FoxP3 in KO mice vs. controls were significantly decreased in both joint and splenic tissue (p=0.0244 and p=0.0286, respectively). Immunophenotyping of splenic and LN tissue showed increased proportions of total CD4+ T cells in KO mice vs. controls, but a markedly lower proportion of the CD4+CD25+FoxP3+ subset. Lower proportions of F4/80+ and Ly6G+ cell populations in splenic and draining LN tissue of KO mice vs controls, but higher populations of Ly6C+ cells, were also observed.

Conclusion: Deletion of RBP-J in the myeloid compartment does not lead to phenotypic differences in K/BxN serum-induced inflammatory arthritis, though selective modulation of pro-inflammatory cytokine gene expression *in vivo* does occur. Decreased gene expression of FoxP3 and fewer CD4+CD25+FoxP3+ cells in RBP-J deleted mice may contribute to this selective modulation. The functional significance of these findings, coupled with differences in myeloid cell composition and trafficking observed, remain undetermined and will be further studied.

Colony-Stimulating Factor (CSF) Receptor 1 Blockade Overcomes Overlapping Effects of M-CSF and Interleukin-34 On Myeloid Differentiation and Gene Expression to Reduce Inflammation in Human and Murine Models of Rheumatoid Arthritis. Samuel Garcia[1], Linda M. Hartkamp[1], Inge E. van Es[1], Haishan Lin[2], Li Long[2], Emma L. Masteller[2], Brian R. Wong[2], Paul P. Tak[3] and Kris A. Reedquist[1]. [1]Academic Medical Center, University of Amsterdam, Amsterdam, Netherlands, [2]Five Prime Therapeutics, Inc., South San Francisco, CA, [3]Academic Medical Center, University of Amsterdam and GlaxoSmithKline, Amsterdam, Netherlands

Background/Purpose: Disease activity and response to therapy in RA correlates with changes in synovial macrophage numbers and their products. M-CSF or IL-34 stimulation of their receptor CSFR1 promotes macrophage differentiation, activation and osteoclastogenesis. Pharmacological inhibition of CSFR1 is beneficial in animal models of arthritis but the relative contributions of M-CSF, IL-34 and their receptor to inflammation in RA are unknown.

Methods: M-CSF, IL-34, and cellular markers were detected by immunohistochemistry and digital image analysis in synovial tissue from 18 biological-naïve RA patients, 14 PsA patients, and 4 controls without inflammatory disease (2 healthy donors and 2 OA patients). Gene expression in M-CSF and IL-34 –differentiated human macrophages was assessed by FACS analysis and q-PCR arrays. RA synovial explants were incubated with M-CSF, IL-34, control antibody (Ab), or a humanized CSFR1-blocking Ab. Prophylactic effects of control and CSFR1-blocking Ab were examined in murine collagen-induced arthritis (CIA).

Results: Expression of M-CSF and IL-34 was similar in RA and PsA synovial tissue, but lower in controls (p< 0.05). M-CSF expression was restricted to endothelial cells and IL-34 was observed in sublining mononuclear cells and intimal lining layer cells. *CXCL5, CXCL6, FN1, COL1A1, COL6A1–2, COL14A1, COL15A1, MMP7, MMP8* and *MMP9* mRNA

expression was significantly upregulated in macrophages differentiated in M-CSF compared to IL-34, while *CXCL7*, *CXCL9*, *CXCL10*, *CXCL11*, *CXCL12*, *LAMA1*, and *MMP2* were significantly downregulated. M-CSF or IL-34 had no effect on RA synovial explant IL-6 production, but anti-CSFR1 Ab dose-dependently reduced IL-6 production. Treatment with anti-CSFR1 Ab in CIA significantly reduced paw swelling and joint destruction.

Conclusion: M-CSF and IL-34 are expressed in topographically distinct regions of inflamed synovial tissue and differentially effect macrophage capacity to attract inflammatory cells and remodel tissue. Simultaneous inhibition of CSFR1 interactions with both M-CSF and IL-34 suppresses inflammatory activation of RA synovial tissue and pathology in CIA, suggesting a novel therapeutic strategy for the treatment of RA.

902

Activation of NF-Kb Via Poly(I:C)-Induced Monocyte-Derived Microparticles Decreases TRAIL-Induced Apoptosis of Rheumatoid Arthritis Synovial Fibroblasts. Mojca Frank Bertoncelj[1], Blaz Rozman[2], Beat A. Michel[3], Renate E. Gay[1], David S. Pisetsky[4], Oliver Distler[5], Steffen Gay[6] and Astrid Juengel[1]. [1]Center of Experimental Rheumatology, University Hospital Zurich and Zurich Center of Integrative Human Physiology (ZIHP), Zurich, Switzerland, [2]Department of Rheumatology, University Medical Centre Ljubljana, Ljubljana, Slovenia, [3]Department of Rheumatology, University Hospital Zurich, Zurich, Switzerland, [4]Duke University Medical Center, Durham, NC, [5]Department of Rheumatology and Center of Experimental Rheumatology, University Hospital Zurich, Zurich, Switzerland, [6]Center of Experimental Rheumatology, University Hospital Zurich and Zurich Center of Integrative Human Physiology (ZIHP), Zurich, CH-8091, Switzerland

Background/Purpose: Decreased sensitivity of rheumatoid arthritis (RA) synovial fibroblasts (SF) to apoptosis leads to synovial hyperplasia and destruction of joints in RA. Activation of NF-kB was shown to modulate apoptotic pathways in different target cells. Based on our recent finding that microparticles (MP) from monocytes, stimulated with Toll-like receptor 3 ligand Poly(I:C) (PIC), increase the resistance of RASF to TRAIL-induced apoptosis and enhance the production of NF-kB-dependent cytokines IL-6 and IL-8, the aim of the present study was to examine the role of NF-κB signaling in the resistance of RASF to TRAIL-induced apoptosis mediated via MP.

Methods: MP were isolated by differential centrifugation from supernatants of untreated or PIC-stimulated (16h) U937 cells or peripheral blood mononuclear cells (PBMC) and were analysed by nanoparticle tracking analysis, flow cytometry and BCA Protein Assay. RASF were treated with MP±TRAIL for 24h. To investigate direct effects of PIC on the apoptosis, RASF were stimulated with PIC±TRAIL for 24h. Apoptosis of RASF was measured by flow cytometry using Annexin V/propidium iodide staining. SC-514, a selective inhibitor of IκB kinase 2, was used to test the role of NF-kB signaling in MP actions in RASF. NF-κB activity was determined by luciferase reporter gene assay in RASF treated with MP for 6h.

Results: PIC-induced MP, but not MP from untreated U937 cells, significantly decreased TRAIL-induced apoptosis of RASF ($9\pm3\%$ vs TRAIL: $18\pm6\%$, p=0.003, n=8), and similar effects were observed with PIC-induced MP derived from PBMC ($18.\pm27\%$ vs $35\pm27\%$, n=3). In contrast, a direct stimulation with PIC alone significantly increased apoptosis of RASF ($11\pm4\%$ vs $6\pm2\%$ in untreated RASF, p=0.03, n=6), however it did not affect TRAIL-induced apoptosis of RASF. Number (MP from untreated cells: $3.0*10^{10}$/mL vs PIC-induced MP: $3.1*10^{10}$/mL; n=2 each), size (median diameter 207 vs 199nm, n=2 each), surface annexin V binding ($66\pm10\%$ vs $63 \pm 9\%$, n=3 each) and total protein content (330 ± 50 vs 325 ± 83 ng/mL, n=3 each) did not differ significantly between MP from untreated and PIC-stimulated U937 cells. SC-514 significantly increased TRAIL-induced apoptosis of RASF in the presence of PIC-induced MP ($20\pm3\%$ vs $9\pm3\%$ in the absence of SC-514, p=0.002, n=8). PIC-induced MP from U937 cells led to activation of NF-κB signaling in RASF (median x-fold change: 13 vs untreated RASF, n=4).

Conclusion: Most interestingly, we could show that the activation of NF-κB plays a major role in the resistance of RASF to TRAIL-induced apoptosis mediated via PIC-induced MP. This observed effect may reflect a specific composition of PIC-induced MP. Alternatively, the effects of MP could result from small amounts of PIC associated with MP although its activity would differ from that in the free state.

903

NR4A1 Mediates Anti-Inflammatory Effects of Apoptotic Cells. Natacha Ipseiz[1], Stefan Uderhardt[1], Georg A. Schett[2] and Gerhard Kronke[1]. [1]University of Erlangen, Erlangen, Germany, [2]Department of Internal Medicine III and Institute for Clinical Immunology, University of Erlangen-Nuremberg, Erlangen, Germany

Background/Purpose: The nuclear receptor NR4A1 has been implicated as negative feedback regulator of NF kappa B signalling and as key regulator during the differentiation of Ly6C-low resident monocytes. Apoptotic cells are known to exert anti-inflammatory effects on macrophages but the underlying mechanisms are still poorly understood. Here we studied a potential role of NR4A1 as mediator of the macrophage response to apoptotic cells.

Methods: We analysed the effect of apoptotic thymocytes on wild type and NR4A1−/− peritoneal resident macrophages, and determined the consequences on intracellular signalling, gene expression and cytokine profile. Moreover, we examined the consequences of the lack of NR4A1 during maintenance of self tolerance by using the pristine-induced model of murine sytemic lupus erythematosus.

Results: Expresion of NR4A1 was rapidly and highly induced in resident macrophages after incubation with apoptotic thymocytes. NR4A1−/− resident macrophages showed an exacerbated pro-inflammatory profile as well as an increased activity of NF-κB. Moreover, the anti-inflammatory effects of apoptotic cells were reduced in NR4A1−/− macrophages. In the pristine model of murine lupus, NR4A1−/− mice displayed increased levels of autoantibodies such as ds-DNA antibodies.

Conclusion: Our data show for the first time that NR4A1 is an important mediator of the anti-inflammatory effects of apoptotic cells in tissue resident macrophages and thereby contributes to the maintenance of self-tolerance.

Perinatal Characteristics, Maternal Reproductive History and Juvenile Idiopathic Arthritis: A Case-Control Study. Samantha W. Bell[1], Beth A. Mueller[1], J. Lee Nelson[2], Parveen Bhatti[1] and Susan Shenoi[3]. [1]University of Washington, Seattle, WA, [2]Fred Hutchinson Cancer Rsch, Seattle, WA, [3]Seattle Children's Hospital, University of Washington, Seattle, WA

Background/Purpose: Juvenile Idiopathic Arthritis (JIA) is a heterogeneous group of chronic inflammatory arthritis conditions in children with onset before 16 years of age, and is the leading cause of acquired short and long-term disability in childhood. The etiology of JIA is largely unknown, however there is increasing evidence that autoimmune diseases, including JIA, may be associated with maternal reproductive or early childhood exposures.

Methods: We conducted a case-control study of JIA cases identified at a regional children's hospital in the Seattle-Puget Sound area, using linked birth certificate data from 1980 – 2009. Potential cases included all children <20 years with relevant ICD codes who had received inpatient or outpatient care. Their records were linked to Washington State birth records for 1980–2009 to identify those with a Washington State birth certificate (N=1,518). For comparison, control children were randomly selected in a ratio of 4:1 from the remaining birth records, frequency matched on year of birth (N=6,072). Review of medical records further refined case ascertainment based on

specific clinical criteria (N=1,254) and allowed categorization of cases into JIA subtypes. Multivariable logistic regression was used to estimate adjusted odds ratios (OR) and 95% confidence intervals (CI) for the associations of JIA/JIA subtypes with maternal and early life exposures as measured in the birth certificates.

Results: Decreased ORs were observed for JIA in relation to greater maternal parity (2 prior live births, OR 0.70, 95% CI 0.58, 0.85; 4+ prior live births, OR 0.68, 95% CI 0.48, 0.97), a finding also observed for the persistent oligoarticular JIA subtype. Fewer cases (11.4%) than controls (13.3%) had a birth weight >4000 g (OR 0.81, 95% CI 0.67, 0.98). Mothers of cases (5.2%) were slightly more likely than those of controls (4.1%) to have had preeclampsia during their pregnancy (OR 1.29, 95% CI 0.96, 1.73).

Conclusion: To our knowledge, no studies to date in the United States have examined these exposures in relation to JIA. Greater maternal parity, specifically having 2 or more prior live births, was significantly associated with a decreased OR for JIA, a finding consistent with both the hygiene and microchimerism hypotheses.

The Association Between Lower Body Mass Index and Increased Risk of Giant Cell Arteritis Is Not Explained by Differences in Physical Activity.
Karin Jakobsson[1], Lennart T.H. Jacobsson[1], Kenneth J. Warrington[2], Eric L. Matteson[2], Kimberly P. Liang[3], Olle Melander[1] and Carl Turesson[1]. [1]Lund University, Malmö, Sweden, [2]Mayo Clinic, Rochester, MN, [3]University of Pittsburgh, Pittsburgh, PA

Background/Purpose: There is limited data on predictors of giant cell arteritis (GCA). Low body mass index (BMI), a history of smoking and several hormonal factors have been associated with GCA in a retrospective case-control study, and we have confirmed the association with low BMI in a prospective study. Potential explanations for the association between BMI and GCA, include a difference in the level of physical activity. To our knowledge, the impact of physical activity on the risk of GCA has not been studied previously.

Our purpose was to examine potential influence of physical activity as a risk factor of GCA in a nested case-control study based on a prospective health survey.

Methods: Incident cases of GCA among participants in a population based health survey, in which 30447 subject (12121 men and 18326 women) were included between 1991 and 1996, were used for the present study. As part of the health survey, information on medical history and life style factors was obtained using standard physical examinations and self-administered questionnaires. Information on physical activity were obtained by asking participants to estimate the number of minutes per week, for each of the four seasons, they spent performing 17 different physical activities. The answer was multiplied by an intensity factor depending on the activity creating a physical activity score. This method was adapted from the Minnesota physical activity questionnaire, and has been validated against accelerometer-monitoring, an objective measure of physical activity, in a subset of the present health survey population.

Individuals who developed GCA after inclusion was identified by linking the health survey database to the local patient administrative register and the national hospital discharge register. A structured review of the medical records of all identified cases was performed. Four controls for each validated case, matched for sex, year of birth and year of screening, who were alive and free of GCA when the index person was diagnosed with GCA, were selected from the health survey. The impact of BMI and physical activity as predictors of GCA was examined in conditional logistic regression models.

Results: Fifty-five cases [mean age 73.6 years; standard deviation (SD) 5.21), 43 women (78 %), 31 temporal artery biopsy positive] had a confirmed diagnosis of GCA after inclusion. The median time from screening to GCA diagnosis was 9.4 years (range 0.4–16.6). BMI at screening was lower in GCA cases than in matched controls (mean 24.7 vs 26.1 kg/m^2). There was no association found between level of physical activity and development of GCA (mean score in cases and controls: 8349 vs 8134; p=0.95).The association between higher BMI and reduced risk of GCA was similar in bivariate analysis (OR 0.91 per kg/m^2; 95 % CI 0.84–0.99) and in multivariate analysis adjusted for physical activity (OR 0.92 per kg/m^2; 95 % CI 0.84–1.00).

Conclusion: GCA was predicted by a lower BMI, and this could not be explained by the level of physical activity at baseline. Physical activity did not

influence the risk of GCA. Other factors, such as diet, genetics or hormonal factors, may explain the association between low BMI and GCA.

Patient-Rheumatologist Communication Concerning Medication and Disease Risks.
Susan J. Blalock. University of North Carolina at Chapel Hill, Chapel Hill, NC

Background/Purpose: Medications play an important role in the management of rheumatoid arthritis.Principles of informed consent, informed and shared decision-making, and professional ethics highlight the importance of patients' understanding both the risks and benefits of different treatment options. Thus, the work described in this presentation is designed to increase current understanding of patient-rheumatologist communication about the risks associated with medications used to manage rheumatoid arthritis

Methods: We are content analyzing approximately 1000 audiotapes of rheumatoid arthritis patient-rheumatologist office visits that were collected in a previous study.The current study is guided by *fuzzy-trace theory*. This theory suggests that when an individual is exposed to information (e.g., a statement made by one's physician) two representations of the information are encoded in memory, a verbatim representation and a gist representation. Verbatim representations capture the precise information that was provided; whereas, gist representations reflect the essential meaning of the information to the person, including its emotional meaning. A central tenet of *fuzzy-trace theory* is that, when making judgments and decisions, people tend to rely on gist representations that are stored in memory and retrieve verbatim representations only when required by the task at hand. Thus, using *fuzzy-trace theory* as a guiding framework, we have developed a detailed 2-level coding scheme that captures the types of information concerning medication and disease risks that may be exchanged between patients and rheumatologists during office visits.

Results: A total of 3588 medication risks were identified in the transcripts. The most common medication risks were: methotrexate-GI problems (n=219); methotrexate-mouth/nose sores (n=190); methotrexate-need to monitor, but labs not specified (n=167); methotrexate-liver toxicity (n=141); methotrexate-pulmonary problems (n=109); and prednisone-implied risks by desire to minimize exposure to the medication (n=167).An average of 3.87 medication risks were discussed per office visit.Lower patient medication satisfaction was associated with: discussion of more medication risks (p < 0.03), patient and physician expression of medication safety concerns (p's < 0.05 and 0.0001, respectively) and lack of patient and physician endorsement of medication need/efficacy (p's < 0.0001 and.03, respectively).

Conclusion: By examining the manner in which medication and disease risks are discussed in combination, the findings from this study promise to provide a richer understanding of the risk communication that takes place during rheumatology office visits.

Use of Patient Preferences to Inform the Development of Disease Modifying Drugs for Osteoarthritis.
Liana Fraenkel[1], Charles Cunningham[2], Gillian A. Hawker[3] and Lisa G. Suter[4]. [1]Yale University School of Medicine, Veterans Affairs Connecticut Healthcare System, New Haven, CT, [2]McMaster University, Hamilton, ON, [3]Women's College Research Institute, University of Toronto, Toronto, ON, [4]Yale University, New Haven, CT

Background/Purpose: Considerable efforts are currently being directed at developing robust and efficient trial designs to study the efficacy of disease modifying drugs (DMOADs) for osteoarthritis (OA). As part of this effort, an understanding of patients' preferences is needed.

Methods: We administered a conjoint analysis survey to a convenience sample of 304 patients attending outpatient clinics. The survey was composed of 4 attributes each having 3 levels: (1) administration (pill, injection (SC), infusion (IV)), (2) benefit (prevents progression in 40%, 60%, or 80%), (3) risk (mild: < 1 week and reversible, moderate: (1–2 weeks and requires treatment, serious: requires hospitalization), and (4) cost (easy, somewhat, hard to afford). All subjects were provided with a detailed description of each attribute before performing the survey. The survey included 12 choice tasks each with 3 medications and a "None" option (Figure). We performed Latent Class Segmentation analysis and simulations to estimate preferences for 4

options: Best Case (pill, prevents progression in 80%, mild side effects, easy to afford), Worst Case (IV, prevents progression in 40%, serious side effects, hard to afford), SC (SC, prevents progression in 40%, moderate risk, somewhat hard to afford), IV (same as previous except IV).

Results: 304 subjects participated; median (range) age=57 (34–89); 55% female; 69% Caucasian, 45% employed; 37% college graduates; 29% reported knee pain often or very often; 30% reported physician diagnosed knee arthritis. Segmentation analysis revealed 4 distinct groups of patients. The relative importances of the attributes are presented in Table 1. Treatment preferences are described in Table 2. Group 1 (5%) do not want to perform injections and only consider DMOADs under the Best Case scenario; Group 2 (19.4%) are most influenced by risk and fewer prefer DMOADs under more realistic scenarios; Group 3 (16.4%) consistently reject DMOADs, and Group 4 (59.2%) strongly prefer DMOADs regardless of risk or cost.

If these were your only options, which would you choose? Choose by marking one of the buttons below:

Injection given once a week. Prevents progression of arthritis in **80%** of people. Risk of **moderate** side effects. **Easily** affordable. **No** changes in budget needed.

Pill taken once a day. Prevents progression of arthritis in **60%** of people. Risk of **mild** side effects. **Hard** to afford. **Major** changes in budget needed.

Infusion given once a month. Prevents progression of arthritis in **40%** of people. Risk of **serious** side effects. **Somewhat** affordable. **Minor** changes in budget needed.

NONE: I wouldn't choose any of these.

Table 1. Relative Importances of Each Attribute

Attribute	Group 1 (N=15)	Group 2 (N=59)	Group 3 (N=50)	Group 4 (N=180)
1. Administration	58.5	11.5	11.8	2.9
2. Benefit	12.1	22.9	27.5	50.5
3. Risk	14.6	35.7	28.5	24.6
4. Cost	14.8	29.8	32.2	22.1

Table 2. Percent Preferring Each Hypothetical Treatment Option

Scenario	Group 1 (N=15)	Group 2 (N=59)	Group 3 (N=50)	Group 4 (N=180)
Best case	99.4	98.2	18.4	89.8
Worst case	0.7	4.4	7.6	85.4
SC	5.3	67.2	12.4	86.3
IV	20.2	54.9	11.1	86.1

Conclusion: Almost 60% of patients surveyed are willing to accept substantial risk in order to prevent progression of OA. These findings should help inform future drug development.

908

Race, Gender and Total Knee Replacement Consideration: The Role of Social Support.
Ernest R. Vina[1], Yona Cloonan[2], Said Ibrahim[3], Michael J. Hannon[4], Robert M. Boudreau[2] and C. Kent Kwoh[1]. [1]University of Pittsburgh and VA Healthcare System, Pittsburgh, PA, [2]University of Pittsburgh, Pittsburgh, PA, [3]University of Pennsylvania Perelman School of Medicine, Philadelphia, PA, [4]University of Pittsburgh School of Medicine, Pittsburgh, PA

Background/Purpose: There is marked variation in patient preference (i.e. willingness) regarding total knee replacement (TKR), an effective treatment option for end-stage osteoarthritis (OA).Studies have also shown that higher social support is associated with better patient decision-making.No study, though, has ever examined the importance of social support on patient preference.The purpose of this study is to determine whether there are racial differences in social support among patients with knee OA and whether the impact of social support on preference for TKR varies by race and gender.

Methods: Our sample consists of 514 white & 285 African-American (AA) patients with chronic, frequent knee pain and radiographic evidence of knee osteoarthritis (OA).Structured interviews were conducted to determine sociodemographic information, clinical characteristics, and extent of structural (marital status, # of close friends/relatives) and functional (Medical

Outcomes Study-Social Support Scale [MOS-SSS]) social support.A hypothetical, Likert-scaled question was also asked: "Would you be willing to have surgery to replace your knee if your doctor recommended it?". Hierarchical logistic regression models were performed to evaluate the relationship between willingness to undergo TKR and the interaction of patient race and sex, adjusted for recruitment site, age, income, WOMAC total score and measures of social support.

Results: Among AA participants, 22.8% were married, as compared with 53.5% of white participants (p<0.001).The mean numbers of close friends/relatives reported by AA and white patients were 7.52 ± 8.88 and 10.31 ± 13.13, respectively (p<0.001).Half of AA patients reported living alone, as compared with 33.5% of white patients (p<0.001).MOS-SSS scores were lower in AA (13.44 ± 5.26) as compared with white (15.17 ± 4.79) participants (p<0.001).Compared to white patients with knee OA, AA patients with knee OA were less willing to undergo TKR surgery (80.0% vs. 62.4%, p<0.001).

The odds of willingness to undergo TKR surgery was less in white females compared to white males when adjusted for recruitment site, age, income and WOMAC score (OR 0.57, 95% CI 0.34–0.96), but this difference was no longer significant when further adjusted for marital status, number of close friends/relatives and MOS-SSS score (OR 0.60, 95% CI 0.35–1.02).The odds of willingness to undergo TKR surgery was also less in AA females (OR 0.33, 95% CI 0.18–0.60) and AA males (OR 0.26, 95% CI 0.13–0.52) compared to white males when adjusted for sociodemographic and clinical factors.These differences in odds remained significant when further adjusted for all social support measures (OR 0.35, 95% CI 0.19–0.64, in AA females; OR 0.28, 95% CI 0.14–0.54, in AA males).

Conclusion: We found lower preference for TKR surgery in AA compared to white patients with knee OA.AA OA patients also reported less structural and functional social support than white patients.There was a race and gender interaction in patient preferences for TKR surgery.In white patients, social support accounted for the gender difference in willingness to consider TKR.Social support, though, did not seem to mediate the racial difference in patient preferences for TKR.

909

Determinants of Patient Preferences for Total Knee Replacement: A Comparison of Whites and African-Americans.
C. Kent Kwoh[1], Robert M. Boudreau[2], Yona Cloonan[2], Michael J. Hannon[3], Ernest R. Vina[2] and Said Ibrahim[4]. [1]University of Pittsburgh and VA Healthcare System, Pittsburgh, PA, [2]University of Pittsburgh, Pittsburgh, PA, [3]University of Pittsburgh School of Medicine, Pittsburgh, PA, [4]University of Pennsylvania Perelman School of Medicine, Philadelphia, PA

Background/Purpose: TKR is a cost-effective treatment option for end-stage knee osteoarthritis (OA). Although it is one of the fastest growing elective surgeries, there are marked racial disparities in the utilization of TKR. Patient's preferences have been found to be an important consideration in TKR disparities. However, determinants of patients' preference regarding TKR remain unclear. We sought to identify whether determinants of patients' preference for TKR differ by race.

Methods: Our sample consisted of 514 whites (59% female) and 285 AAs (73% female) with chronic, frequent knee pain and radiographic evidence of knee OA. Structured interviews were conducted to collect sociodemographic information, socio-cultural determinants, disease severity (i.e, WOMAC), and treatment preferences. We performed hierarchical logistic regression, stratified by race, to identify determinants of patients' preference for TKR. Clinical and socio-cultural factors were entered simultaneously into race stratified models. Stepwise selection identified factors for inclusion in the final models, using a criterion of p<0.20. All models were adjusted for age, sex, income level, disease severity (WOMAC), and study site.

Results: Compared to whites, AA patients were less willing to undergo TKR (80% vs. 62%, respectively, adjusted OR=0.45, 95%CI 0.29 to 0.70). The results of the multivariate modelare summarized in the table below. Among AA patients, knowledge (p=0.031) and expectations (p=0.084) regarding surgical outcomes, religiosity (p=0.045), and physician trust (p=0.104) were included in the final multivariate model. Among white patients, expectations regarding surgical outcomes (p<0.001), two items related to physician interaction and referral patterns (p=0.039), and trust in the healthcare system (0.068) were included in the final multivariate model.

OR for Willingness to Undergo TKR	AAs OR (95% CI)*	Whites OR (95% CI)*
Knowledge Regarding TKR		
Understands TKR	1.80 (0.97, 3.35)	
Prolonged Length of Stay After TKR	0.81 (0.58, 1.13)	
Residual Pain After TKR	0.73 (0.39, 1.35)	
Residual Difficulty Walking After TKR	0.66 (0.37, 1.16)	
Ever Discuss TKR with a physician		1.96 (1.05, 3.68)
Referred to Surgeon		0.56 (0.32, 0.99)
Expectations Regarding TKR** Second Quartile	1.85 (0.76, 4.51)	1.70 (0.86, 3.33)
Third Quartile	2.82 (1.30, 6.15)	2.73 (1.32, 5.65)
Highest Quartile	2.08 (0.91, 4.79)	5.11 (2.31, 11.30)
Religiosity** Second Quartile	2.52 (0.93, 6.84)	
Third Quartile	1.21 (0.43, 3.42)	
Highest Quartile	0.85 (0.32, 2.26)	
Physician Trust** Second Quartile	2.14 (0.89, 5.15)	
Third Quartile	1.01 (0.46, 2.25)	
Highest Quartile	2.17 (0.90, 5.23)	
Trust in Healthcare System** Second Quartile		2.69 (1.26, 5.76)
Third Quartile		1.94 (0.91, 4.13)
Highest Quartile		1.58 (0.75, 3.31)

* adjusted for sex, age, income level, WOMAC and site; ** Lowest Quartile is reference group.

Conclusion: Although expectations regarding surgical outcomes are associated with preference for TKR in both AA and white patients, they differed with regard to which other clinical and socio-cultural determinants impact the preference to undergo TKR. Interventions to reduce or eliminate racial disparities in the utilization of TKR should consider and target these factors.

910

The Cost-Effectiveness of Total Joint Arthroplasty: A Systematic Review of Published Literature. Meghan E. Daigle, Alexander M. Weinstein. Jeffrey N. Katz and Elena Losina, Brigham and Women's Hospital, Boston, MA

Background/Purpose: Utilization of total hip arthroplasty (THA) and total knee arthroplasty (TKA) has nearly doubled in the last decade. These procedures are increasingly performed in younger, more active individuals. We sought to summarize the state of the literature evaluating the cost-effectiveness of these highly efficacious, costly procedures and identify areas where further work is needed.

Methods: We conducted a systematic review of cost-effectiveness analyses of elective THA and TKA that were published between January 1980 and February 2012. To limit our search to high-quality publications, we selected among papers included in the Cost-Effectiveness Analysis Registry (created by the Center for the Evaluation of Value and Risk in Health); we augmented our search with papers listed in PubMed. Only papers reporting incremental cost-effectiveness ratios (ICERs) as the change in cost over the change in quality-adjusted life expectancy between alternative treatment strategies were included. We abstracted the analysis perspective, time horizon, and ICERs (converted to 2011 USD) from the selected papers.

Results: Seven TKA and six THA studies met the criteria for our review. All economic evaluations of TKA were published between 2006 and 2012, whereas THA studies spanned 1996 to 2008. Out of the 13 included studies, four assumed the societal perspective, eight the payer perspective, and in one study the perspective was unclear. Seven studies spanned the lifetime horizon. Studies of both THA and TKA that have assumed a societal perspective and lifetime horizon have estimated ICERs below $50,000/QALY in cohorts with mean age 69 years or older. Hip resurfacing has been shown to be dominated by THA (more costly, less effective) in a cohort aged 65 years and younger. Unicondylar knee arthroplasty (UKA) has been shown to be cost effective or cost-saving among cohorts of mean age 65–75 years.

Comparison*	Paper		Perspective	ICER ($/QALY; 2011 USD)	Time Horizon
Total Hip Arthroplasty					
THA vs. No Surgery	Chang	1996	Societal	$10,402	Lifetime
Improved Implant (reduced revision rate, increased cost) vs. Standard Implant	Briggs	1998	Payer	$17,671	Lifetime
	Briggs	2004	Payer	cost saving	60 yrs
	Bozic	2006	Not clear	cost saving	Lifetime
THA vs. Hip Resurfacing	McKenzie	2003	Payer	THA dominates	20 yrs
Cementless vs. Cement	Marinelli	2008	Payer	Neither option clearly better	Lifetime
Total Knee Arthroplasty					
Computer Assisted Surgery vs. TKA	Dong	2006	Payer	cost saving	10 yrs
	Novak	2007	Payer	$54,234	15 yrs
UKA vs. TKA	Slover	2006	Payer	cost saving	Lifetime
	Soohoo	2006	Societal	$458	Lifetime
TKA vs. UKA	Xie	2010	Societal	$71,731	2 yrs
TKA vs. No Surgery	Losina	2009	Societal	$11,548	Lifetime
	Dakin	2012	Payer	$12,566	5 yrs

*The first strategy listed is the primary intervention studied, and the second strategy is the reference comparator; that is, ICERs refer to the cost-effectiveness of the first treatment option listed.

Conclusion: THA and TKA have been found to be highly cost-effective in a number of high-quality studies. Further analyses of the cost-effectiveness of alternative surgical options, including knee osteotomy, among young individuals are needed. Future economic evaluations should address the expanding indications of THA and TKA to younger, more physically active individuals.

911

Race- and Sex-Specific Estimates of 10-, 20-, 30-Year, and Lifetime Risk of Diagnosed Symptomatic Knee Osteoarthritis and the Need for TKR in the US. Elena Losina, Meghan E. Daigle, Sara A. Burbine and Jeffrey N. Katz. Brigham and Women's Hospital, Boston, MA

Background/Purpose: A growing body of evidence suggests that females are more likely to be diagnosed with knee osteoarthritis (OA) and that obesity increases the risk of knee OA. Population-based studies suggest that Black and Hispanic females have a greater likelihood of being obese than White females. Sex- and race/ethnicity-specific risks of diagnosed symptomatic knee OA and the need for TKR have not been estimated.

Methods: We combined the OAPol Model – a validated state-transition, computer simulation model – with published data on the incidence of OA, stratified by sex and obesity. Obesity prevalence, stratified by sex and race/ethnicity, was derived from published literature and ranged from 19% for White males to 34% for Black females. The increased risk of symptomatic knee OA conferred by obesity was derived from published studies (RR = 1.7). Rates of progression of knee OA were derived from the Johnston County Osteoarthritis Project and calibrated to published data. The annual incidence of TKR among persons with advanced knee OA (Kellgren-Lawrence grade 3 or 4) was derived using data from two national longitudinal studies of persons with knee OA (Multicenter Osteoarthritis Study and Osteoarthritis Initiative). Input parameters related to mortality, obesity, comorbidities, non-surgical OA treatments, and implant failure were obtained from national survey data and published literature. Using the OAPol Model we estimated the 10-year, 20-year, 30-year and lifetime risks of diagnosed symptomatic knee OA and TKR from age 40, stratified by race and sex.

Results: In persons free of knee OA at age 40, the lifetime risk of diagnosed symptomatic knee OA ranged from 10% among White males to 17% among Black females (Figure). The 20-year risk of diagnosed symptomatic knee OA ranged from about 6% in males (race/ethnicity did not affect the rate meaningfully) to 8% in Black females. By age 65, 11.3%, 10.5%, and 10% of Black, Hispanic, and White females, free of knee OA at age 40, will be diagnosed with symptomatic knee OA (Figure). Lifetime need for TKR ranged from 3.8% for Hispanic males to 6.8% for Black females.

Risk of Diagnosed Symptomatic Knee Osteoarthritis
Conclusion: Lifetime risk of diagnosed symptomatic knee OA varies by age and race/ethnicity. Black females are more likely to be obese, which corresponds with their having the greatest lifetime risk of being diagnosed with knee OA and needing TKR. Race- and sex-tailored weight management programs may reduce the lifetime risk of knee OA.

912

Clinical Features Associated with Progression of Knee Radiographic Osteoarthritis: Data From the Osteoarthritis Initiative. Michelle S. Yau[1], Laura Yerges-Armstrong[1], Braxton D. Mitchell[1] and Marc C. Hochberg[2]. [1]University of Maryland School of Medicine, Baltimore, MD, [2]University of Maryland, Baltimore, MD

Background/Purpose: A better understanding of the factors associated with structural progression of knee osteoarthritis (OA) may help identify individuals not only at risk for more rapid OA progression who can benefit from early intervention, but also help classify high-risk OA patients for inclusion in clinical trials of new treatments. Using the complete 4-year follow-up data from the Osteoarthritis Initiative (OAI), we tested baseline measures from six domains [1) knee examination, 2) anthropometric characteristics, 3) sociodemographic characteristics, 4) medical and family history, 5) physical functioning, and 6) self-reported pain and symptoms] for their association with radiographic knee OA (RKOA) progression.

Methods: Subjects with evidence of RKOA in one or both knees at baseline and with at least 1 follow-up exam over the 4-year period (n = 3,204) were eligible for analysis; knees with end-stage disease were excluded from the analysis. We defined RKOA progression as an increase in Kellgren-Lawrence (KL) grade or osteophyte score or joint space narrowing score. We used Cox regression models to test the association of individual level measures with RKOA progression, adjusting for age, gender, and race. Within each of the six domains, we performed univariate and multivariable stepwise analyses. Significant predictors from all domain-level multivariable models were then included in an overall multivariable analysis with stepwise selection. We also conducted knee-specific analyses with the same approach, but included a robust sandwich estimate of the covariance matrix to account for non-independence of two knees within an individual.

Results: 51% of subjects with baseline RKOA (KL grade 1–3) experienced RKOA progression in one or both knees. Progressors were 58% female, 19% Black, and had mean (SD) age of 61 (9) years and mean body mass index of 29 (5) kg/m[2]. Subjects with no RKOA progression had a similar profile. In the multivariable model for each domain, the following baseline factors were found to be significantly associated with RKOA progression: knee joint effusion, pain on flexion, patellofemoral crepitus, patellar grind, and flexion contracture; number of hand bony enlargements, history of knee injury, and use of analgesics; repeated chair stand pace, 400-meter walk pace, and pain during 400-meter walk; KOOS sports and recreational activities score and KOOS symptoms score. Similar results were obtained with the knee-specific analyses with the additional significant finding of KOOS pain score. Final, overall multivariable models for the individual and knee-specific analyses are presented in Table 1.

Table 1. Hazard Ratios for Associations with RKOA Progression

Domain	Parameter	Hazard Ratio (95% CI)	
		Individual-level	Knee-specific
Knee exam	Knee joint effusion, bulge sign positive	1.34 (1.14–1.58)	1.29 (1.09–1.52)
	Patello-femoral crepitus	1.58 (1.36–1.83)	1.39 (1.22–1.58)
	Knee flexion contracture	1.02 (1.00–1.04)	1.02 (1.00–1.04)
	Knee flexion pain/ tenderness	–	1.26 (1.06–1.49)
Medical and family history	Number of bony enlargements in hands	1.03 (1.00–1.05)	1.04 (1.01–1.06)
	History of knee injury	–	1.27 (1.11–1.46)
Physical functioning	Pain during 400-meter walk	1.33 (1.12–1.59)	–
Self-reported pain/ symptoms	KOOS sports/ recreational activities score	0.99 (0.99–0.99)	0.99 (0.99–1.00)
	KOOS Pain Score	–	0.99 (0.99–1.00)
Adjusted covariates	Black race	1.04 (0.86–1.26)	1.00 (0.84–1.18)
	Asian race	0.74 (0.27–2.00)	0.75 (0.28–2.00)
	Other race	0.63 (0.33–1.22)	0.72 (0.38–1.36)
	Male gender	0.94 (0.81–1.09)	0.93 (0.81–1.07)
	Age	1.00 (0.99–1.01)	1.00 (0.99–1.01)

Conclusion: Out of the six domains investigated, four domains yielded significant measures associated with RKOA progression. These measures may help identify individuals at increased risk of RKOA progression who may benefit from early intervention.

913

Consultation Prevalence of Osteoarthritis in Southern Sweden. Aleksandra Turkiewicz[1], Ingemar F. Petersson[1], Jonas Björk[2], Leif E. Dahlberg[1] and Martin Englund[1], [1]Department of Orthopedics, Clinical Sciences Lund, Lund University, Lund, Sweden, [2]Division of Occupational and Environmental Medicine, Lund University, Lund, Sweden, Lund, Sweden

Background/Purpose: To estimate the prevalence of subjects with osteoarthritis (OA) having led to doctor consultation.

Methods: The Skåne Health Care Register (SHCR) is a legislative, mandatory register based on physicians' International Classification of Diseases (ICD) 10 diagnostic codes. The register covers all in- and outpatient health care in southern Sweden (total population 1.3 million). We identified all adult (20 years of age or older) patients having received the diagnosis of knee OA (ICD-10: M17), hip OA (M16), hand OA (M15.1, M15.2, M18, M19.0D, M19.1D or M19.2D), spine OA (M47) and OA in other locations, i.e., elbow, foot, shoulder, or other joints (M19 different from M19.0D, M19.1D and M19.2D) or polyarthrosis (M15 different from M15.1 and M15.2) during the years 1999 until 2011. We obtained point estimates of consultation prevalence by Dec 31st 2011 by cross referencing with the population register to exclude subjects who had relocated from the county or were deceased. To obtain valid prevalence estimates and confidence intervals in presence of missing data on ICD-10 codes (mainly in private care and in primary care before the year 2004), we used the multiple imputation technique. The variables included in the imputation model were age, sex and clinic and their interactions, year, if consulted physiotherapist, if consulted psychiatrist, residential area, civil status, indicator for in- or outpatient care and the person as a random effect to account for the correlation between visits made by the same patient.

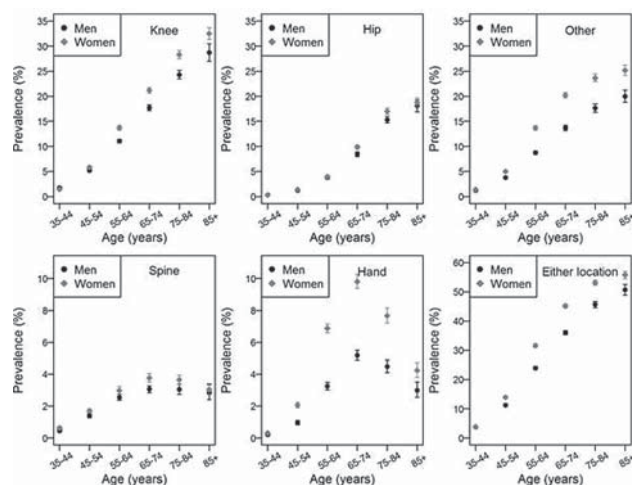
Results: The adult consultation prevalence of OA (any location) was 18.6% (95%CI: 18.4%; 18.7%), 15.8% (95%CI: 15.6%; 16.0%) for men and 21.3% (95%CI: 21.0%; 21.5%) for women. The most common location was knee OA with a prevalence of 9.0%, followed by OA of other joints –7.5%, OA of the hip –4.0%, hand OA – 2.7% and spine OA with the consultation prevalence of 1.6%. The consultation prevalence in population aged 65 or more was 45.5%, 40.5% for men and 49.6% for women. If we considered a diagnosis of joint pain (ICD-10: M25.5) and age 45 or older as OA, the consultation prevalence of OA in extremities increased from 29.6% to 38.5%. The age and sex-specific patterns are displayed in the graph (Figure).


Figure. The prevalence of osteoarthritis by location, sex and age. Vertical bars represent the 95% confidence intervals.

Of subjects who consulted for OA 28% had OA diagnosed in more than one location, knee OA and other OA being the most common combination (12.5%).

Conclusion: The high doctor consultation prevalence of OA in extremities, 18.6% of all adults, 45.5% of all above 65 years of age, shed light on the burden on the health care system and concerns with a steadily ageing and increasingly obese population. It reinforces the need for improved OA patient care and preventive strategies as well as an increased need for join replacement operations.

914

Prognosis for the Year 2030: The Consultation Prevalence of Osteoarthritis in Sweden May Increase by 50%. Aleksandra Turkiewicz[1]. Ingemar F. Petersson[1], Jonas Björk[2], Leif E. Dahlberg[1] and Martin Englund[1], [1]Department of Orthopedics, Clinical Sciences Lund, Lund University, Lund, Sweden, [2]Division of Occupational and Environmental Medicine, Lund University, Lund, Sweden, Lund, Sweden

Background/Purpose: To project the future prevalence of knee and hip osteoarthritis (OA) leading to doctor consultation.

Methods: The Skåne Health Care Register is a legislative, mandatory register in Skåne County, Sweden (total population 1.3 million), based on physicians' International Classification of Diseases (ICD) 10 diagnostic codes. We used observational data on the consultation prevalence of the knee (M17) and hip OA (M16) by the 31st Dec 2011 based on the SHCR data from years 1999–2011. The age-specific (age 20–65 and >65 years) population structure prognosis and its confidence intervals for Skåne were provided by Statistics Sweden. We assumed two scenarios. In scenario 1 (conservative) we assumed that the age-specific prevalence would remain constant. In scenario 2 we assumed that the age-specific prevalence would increase relatively by 2.6% per year in the first 10 years and by 2% per year in the next 10 years for those aged ≤65 and by 1.6% per year in the first 10 years and by 1.2% per year in the next 10 years for the population >65. Initial values for that increase are based on the previously published changes in the prevalence of arthritis between 1994 and 2002 in Canada (Perrucio et al 2006). The reasons for this observed increase are not fully understood but the increase in obesity is the main plausible cause.

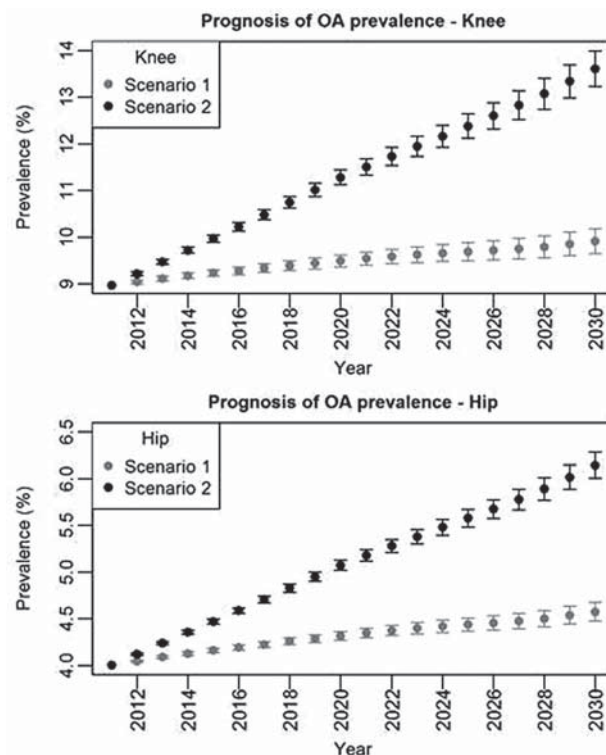
Results: In the conservative scenario which solely depends on changes in age distribution of the population, the consultation prevalence of knee OA in adults (aged 20+) will increase from 9.0% in 2011 to 9.9% in 2030. The hip OA consultation prevalence will increase from 4.0% in 2011 to 4.6% in 2030. Assuming the second scenario, i.e., an increase in age-specific prevalence, the consultation prevalence of knee and hip OA in adults will increase to 13.6% and 6.1% in 2030, respectively.


Figure. The prognosis of knee and hip OA consultation prevalence in Swedish adults (aged 20+). Vertical bars represent the confidence intervals of the prognosis due to uncertainty of the population prognosis.

Conclusion: There is a risk for a 50% increase in OA prevalence in 20 years from now. Results suggest that fighting the negative impact of obesity will be of primary importance to reduce the occurrence of the OA in the future.

915

Incidence of Knee, Hip, and Hand Clinical Osteoarthritis: A Population-Based Cohort Study. Daniel Prieto-Alhambra[1], Aina Pagès-Castellà[2], M. Kassim Javaid[3], Andrew Judge[4]. Cyrus Cooper[5], Nigel K. Arden[3] and Adolfo Díez-Pérez[6], [1]URFOA-IMIM, Parc de Salut Mar; Idiap Jordi Gol; University of Oxford; University of Southampton, Barcelona, Spain, [2]IDIAP Jordi Gol; Institut Català de la Salut, Barcelona, Spain, [3]Oxford NIHR Musculoskeletal Biomedical Research Unit, University of Oxford, Oxford, UK, Oxford, United Kingdom, [4]Oxford University, Oxford, United Kingdom, [5]University of Oxford; Southampton General Hospital, Southampton, United Kingdom, [6]Hospital del Mar-IMIM, Universitat Autònoma de Barcelona, Barcelona; and RETICEF, ISCIII Madrid; Spain, Barcelona, Spain

Background/Purpose: Data on age-specific effects of gender, obesity and previous osteoarthritis (OA) on incident OA at other joints are scarce. We aimed to calculate age and gender-specific incidence of joint-specific clinical OA. Secondly, we studied the age-dependent effect of gender, and the excess risk related to obesity and previous OA on newly diagnosed OA at the knee, hip and hand.

Methods: We screened computerized medical records in the SIDIAP Database (www.sidiap.org) to identify those aged 40 years or older with an incident diagnosis of OA of the knee, hip and hand using ICD-10 codes in the period 2006–2010. SIDIAP contains the anonymised medical records of >3,100 GPs in Catalonia (North-East Spain) with information on an 80% of the total population. Age and gender-specific incidence rates (IR), Female: Male Rate Ratios (RR), and 95%Confidence Intervals (99%CI) were calculated assuming a Poisson distribution. Cox regression was used to compute adjusted (for age, gender, and body mass index(BMI)) hazard ratios (HR) for a new diagnosis of OA according to BMI (WHO categories) and to prevalent joint-specific OA status.

Results: We identified 26,381, 12,567 and 10,092 incident cases of knee, hip and hand OA respectively. Age-specific IRs for knee, hip, and hand OA are shown [Figure]. Female:Male RRs peaked at age 70–75 years for hip and knee, and at the age of 50–55 years for hand OA [Figure]. Adjusted HRs for BMI categories were highest for knee OA (overweight = HR 2.00 (99%CI 1.94–2.06), obesity 1 = HR 3.19 (3.09–2.30), obesity 2 = HR 4.72 (4.56–4.89)), followed by hip OA (HR 1.46 (1.39–1.52); 1.75 (1.66–1.83); 1.93 (1.82–2.05)), and lower for hand OA (HR 1.22 (1.17–1.27), 1.30 (1.25–1.36) and 1.31 (1.24–1.38)).
Figure. Age and gender-specific IR (/1,000 person-years) of knee, hip and hand OA [Top], and unadjusted (solid) and adjusted (dash) Female:Male RR [Below].

Adjusted HR for prevalent knee OA on hip OA was 1.35 (1.28–1.43); HR for previous hip OA on incident knee OA was 1.15 (1.08–1.23). Hand OA predicted both knee and hip OA (HR 1.20 (1.14–1.26) and 1.23 (1.13–1.34) respectively).

Conclusion: Age, gender, BMI and history of OA affecting other joints are related differently to incident knee, hip and hand OA: both the effect of age and gender are greatest in the elderly for knee and hip OA, but around menopause for hand OA. The effect of overweight and obesity is strongest on knee OA, and weakest but significant on hand OA. Finally, a history of knee or hip OA predict incidence of each other, and previous hand OA is related to increased risk of knee and hip OA, all independently of age, gender and BMI.

916

Population Incidence of Soft Tissue Knee Injury: Estimates From a Swedish Health Care Register. Charlotte Bergknut[1], George Peat[2], Richard Frobell[1] and Martin Englund[3]. [1]Lund University, Lund, Sweden, [2]Arthritis Research UK Primary Care Centre, Keele University, United Kingdom, [3]Department of Orthopedics, Clinical Sciences Lund, Lund University, Sweden, Sweden

Background/Purpose: Soft tissue knee injury is a well-established and potent risk factor for development of knee osteoarthritis. However, there is a paucity of epidemiological data from the general population. Our aim was to address this gap using data from a large, regional health care register, i.e., to estimate the annual incidence of clinically diagnosed soft tissue knee-injured subjects in the entire population.

Methods: In Sweden, in- and outpatient health care is registered using each individuals' unique personal identifier. This register includes information on date of visit and the International Classification of Diseases (ICD) 10 diagnostic code(s) as determined by physicians' clinical examination. For the calendar years 2004–2011, we studied the population in southern Sweden, Skåne County (approx. 1.2 million individuals). We identified residents who had at least one visit to a physician with clinically diagnosed knee contusion (S80.0) or knee dislocation/distortion (S83 and all subdiagnoses). Consequently, knee fractures were not included. To calculate the annual cumulative incidence of clinically diagnosed soft tissue knee-injured subjects, stratified by age- and sex, the number of diagnosed patients during the calendar year formed the numerator of the rate and the population at risk at the start of the year, compensated for patients seeking private care (due to missing diagnostic codes), was the denominator. We then calculated the mean annual cumulative incidence over the 8-year period. In a second step, we investigated potential seasonal variations.

Results: The overall incidence of clinically diagnosed soft tissue knee-injured subjects was 718 per 100,000 per year (672 per 100,000 women and 766 per 100,000 men). The most frequently diagnosed injuries were contusion of knee (31.3% of subjects) followed by sprain and strain of knee (27.7%), injury to multiple structures of knee (22.3%), tear of meniscus (11.3%), collateral ligament injury (10.7%), and cruciate ligament injury (9.9%). The highest incidence of knee-injured subjects was found in those aged 15 to 19 years for both sexes (1424 per 100,000 women and 1658 per 100,000 men). After this age, there was a general decline but with an increase again in the incidence in the most elderly (figure). We found substantial seasonal variations in both genders with peaks in March-May and August-October.

Annual incidence of clinically diagnosed soft tissue knee-injured subjects (per 100,000 women and men, respectively. Data are means over the 8-year period (2004-2011).
Conclusion: Clinically diagnosed soft tissue knee injury occurs with marked age and seasonal variations. The high incidence among young people warrants further attention as the potential induction point for many cases of post-traumatic knee osteoarthritis.

917

Feasibility of Remote Activity and Functional Status Monitoring of Patients with Hip or Knee Pain. Pim Jetanalin[1], Hyeon Eui Kim[1], Zia Agha[2], Nathaniel Heintzman[1], Lucila Ohno-Macado[1] and Susan J. Lee[1]. [1]University of California, San Diego, La Jolla, CA, [2]San Diego Veterans Affairs Medical Center, San Diego, CA

Background/Purpose: The incidence of total hip and knee arthroplasties has risen over the past decade and by 2030, the demand of these arthroplasties is estimated to increase by 137% and 601%, respectively. Early ambulation is critical for timely recovery of functional independence. However, not all patients have access to rehabilitation due to lack of money, transportation, and/or time. Accelerometer has been validated in analyzing gait and physical activities among patients with arthritis. We assessed the feasibility of a wireless system that remotely monitors patient's physical activities, functional status, and pain among patients with hip or knee arthritis. This information can then provide feedback to patients to facilitate their post-operative rehabilitation regimen.

Methods: Patients with hip or knee arthritis who had internet access were asked to complete web-based patient-derived questionnaires and wear the SenseWear® armband (SWA) for 14 day except during sleep and shower. SWA collects heat flux, Galvanic Skin Response (GSR), 3-axis accelerometer, and skin temperature. Data on demographics (age, sex, highest level of education, marital status, and yearly household income) and baseline functional status using the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) were obtained. The web-based questionnaire comprised of WOMAC, visual analog scale (VAS) for pain, and self-reported duration of daily exercise. The web-based questionnaire was developed using a HIPAA compliant commercial survey tool called SurveyGizmo (www.surveygizmo.com).

Results: Convenient sample of 14 patients were recruited with 9 patients (64%) completing the study. The 2 most common reasons for incompletion were difficulty downloading the SWA software and inconvenience of wearing daily SWA. The majority of the completers were Caucasians (56%) and female (89%) with a mean age and body mass index (BMI) of 52.4 ± 12.3 years and 37.5 ± 9.2, respectively. Education level ranged from junior high to post-graduate levels with 77% having completed at least college. Majority (77%) had annual household income ≤ $40,000. Non-completers were older (70.0 ± 10.9 years) with lower BMI (29.5 ± 5.7). The majority of patients had significant arthritis with baseline VAS pain of 56.7 + 26.9 and WOMAC of 48.7 (out of 97). The paper- and web-based WOMAC score correlated well with intraclass coefficient (ICC) of 0.885 (p=0.0015). Patients wore SWA for mean 12hrs 25min daily with mean duration of exercise >3MET for 40min daily. The mean self-reported duration of exercise was higher than actual duration measured by SWA (94min vs 40min). There was no correlation between the level of pain and the duration of SWA-measured exercise.

Conclusion: As patients tend to overestimate their levels of physical activity, a wireless activity-monitoring tool such as SWA serves as a valuable tool to better assess the level of physical activity. This study demonstrated the feasibility of our activity and functional status monitoring system, which can be used to facilitate earlier return to independence after joint arthroplasties by providing a means to assist patients with home-based rehabilitation program.

Impact of Comorbidities On Measuring Indirect Utility by the Medical Outcomes Study Short Form 6D in Lower-Limb Osteoarthritis. Kossar Hosseini[1], Cécile Gaujoux-Viala[2], Joel Coste[1], Jacques Pouchot[1], Bruno Fautrel[3], Anne-Christine Rat[1] and Francis Guillemin[1]. [1]Université de Lorraine, Paris Descartes University, APEMAC, EA 4360, F- 54 000, France, Nancy, France, [2]Université de Lorraine, Paris Descartes University, APEMAC, EA 4360, F- 54 000, Nancy; Paris 6 – Pierre et Marie Curie University; Rheumatology, Pitié-Salpêtrière Hospital, Paris, France, [3]Paris VI University, Paris, France

Background/Purpose: Comorbidities refer to chronic co-occuring disorders and are inversely and negatively correlated with HRQoL. Because indirect utility measurement involves HRQoL, comorbidities probably affect utility assessment. We investigated the impact of comorbidities to assess indirect utility measured by the Medical Outcomes Study Short Form 6D (SF-6D) in patients with osteoarthritis (OA).

Methods: The 878 patients of the KHOALA (Knee and Hip OsteoArthritis Long term assessment) cohort were included in the study. KHOALA cohort is a multiregional population based study of patients aged 45–75 years with symptomatic knee or/and hip OA. comorbidities were assessed by the Functional Comorbidity Index (FCI) and grouped in 9 categories. Limitation in activities and pain was measured by the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC).

Two separate linear regression models, using the number of comorbidities or the different categories of comorbidities of the FCI, were fitted to determine predictors of utility score.

Results: For the 878 patients included, the mean (SD) utility score was 0.66 (11; range 0.32–1.00) and mean number of comorbidities 2.05 (1.58). In the first multivariate model, for each additional comorbidity (range 0–9) the mean utility score decreased of 0.01 point (beta= −0.010, p<0.0001). In the second model, including comorbidities by categories, only psychiatric disease (beta=−0.043, p<0.0001) and degenerative disc disease (beta=−0.014, p=0.018) predicted low utility score. In both regression models a worsened function (increased WOMAC function score) significantly decreased the utility score. The number of comorbidities explained 2% of the variance in utility score (partial R-square=0.02) and psychiatric and degenerative disc diseases explained 2% (partial R-square=0.025) and 0.7% (partial R-square=0.007), respectively, of the variance in utility score, whereas the WOMAC function score explained 38% of the variance in both models (partial R-square = 0.38).

Conclusion: Compared to greater negative effect of functional impairment, comorbidities have a negative but relatively marginal impact on indirect utility score. This suggests that clinically, considering the functional severity of OA remains a first priority.

Sedentary Time, Physical Activity, and Concurrent Blood Pressure in Osteoarthritis Initiative Participants. Min-Woong Sohn[1], Rowland W. Chang[1]. Grace Ahn[1], Linda S. Ehrlich-Jones[2], Marc C. Hochberg[3], Jungwha Lee[1], Michael C. Nevitt[4], Pamela A. Semanik[5], Jing Song[1], Kai Sun[6] and Dorothy D. Dunlop[1], [1]Northwestern University, Chicago, IL, [2]Rehabilitation Institute Chicago, Chicago, IL, [3]University of Maryland, Baltimore, MD, [4]University of California-San Francisco, San Francisco, CA, [5]Northwestern University, IL, [6]Northwestern University, Feinberg School of Medicine, Chicago, IL

Background/Purpose: The inactivity physiology hypothesis suggests that sedentarism is a cardiovascular risk factor independent of time spent in moderate-vigorous activity (MV). Previous research suggests that sedentary time may be associated with increased blood pressure. But research findings to date are mixed.

Methods: The Osteoarthritis Initiative accelerometer ancillary study includes 1760 with objective measures of physical activity, sedentary time, and blood pressure at the 48 month exam. Participants were classified into four quartile groups according to accelerometer measures of the percentage of wear time that was sedentary (<100 activity counts per minute).Systolic and diastolic blood pressures (SBP and DBP) were modeled as a function of sedentary quartiles, demographic factors (age, gender, race, income), health behaviors (average daily MV minutes, alcohol use) and general health (osteoarthritis status,Charlson comorbidity score, BMI, NSAID and antihypertensive medication use during the month preceding the 48⁻ month visit).

Results: Of 1,760 adults, 60% had knee OA, 42% used ≥1 antihypertensive medications within 30 days prior to the 48 month visit, and 24.4% had elevated BP (≥ 140/90 or 130/80 for diabetic or renal patients). BP values (see Table) show lowest SBP in the least sedentary group, while DBP is similar across all groups.Adjusted analyses found the least sedentary group on average had SBP 1.82 mm Hg lower (95% CI, 0.04 – 3.59) than the other combined groups. Also, SBP was significantly elevated in adults with OA (2.3 mm Hg), blacks (5.7 mm Hg), and obesity (3.3 mm Hg).But time spent in MV activity, NSAID use, and alcohol use were not associated with SBP.The effect of sedentary time on SBP was primarily observed among adults not taking antihypertensive medications. Sedentary and MV activity were not associated with DBP in adjusted analyses.

Relationship of Sedentary Behavior to Blood Pressure

Blood Pressure (mm Hg)	Quartile of Sedentary Behavior			
	Quartile 1 (Least Sedentary)	Quartile 2	Quartile 3	Quartile 4 (Most Sedentary)
Unadjusted Analysis				
Systolic, mean (SD)	122.0 (15.8)	124.9 (16.9)	124.2 (15.9)	126.4 (16.5)
Diastolic, mean (SD)	74.5 (10.1)	75.4 (9.8)	74.5 (9.8)	73.8 (10.7)
Multiple Regression Analysis				
Systolic, Adjusted* Mean Difference (95% CI)	Reference	2.44 (0.37–4.51)	1.03 (−1.12–3.17)	1.83 (−0.48–4.14) p = 0.045**
Diastolic, Adjusted* Mean Difference (95% CI)	Reference	1.23 (−0.05–2.50)	0.42 (−0.90–1.73)	0.29 (−1.12–1.71) p = 0.187**

* Adjusted for demographic factors (age, gender, race, income), health behaviors (average daily MV minutes, alcohol use) and general health (osteoarthritis status, Charlson comorbidity score, BMI, NSAID and antihypertensive medication use during the month preceding the 48⁻ month visit).
** Least sedentary Quartile 1 versus more sedentary Quartiles 2–4

Conclusion: Objectively measured sedentary time was significantly associated with increased SBP, while MV activity was not, in the model adjusted for all covariates. This finding supports the inactivity physiology hypothesis that, independent of MV physical activity, sedentary time is

associated with deleterious effect on cardiovascular risk. This is the first study to test this hypothesis using objectively measured sedentary time and simultaneously controlling for antihypertensive medication use.

A Multimodal Intervention to Improve Osteoporosis Care in Home Health Settings: Results From a Cluster Randomized Trial. Meredith Kilgore[1], Kenneth G. Saag[2], Jeroan Allison[3], Elizabeth Kitchin[4], Julie L. Locher[1], Amy Mudano[4], Ryan C. Outman[1] and Jeffrey R. Curtis[2]. [1]University of Alabama at Birmingham, Birmingham, AL, [2]Univ of Alabama-Birmingham, Birmingham, AL, [3]University of Massachusetts Medical School, [4]Birmingham, AL

Background/Purpose: Although very effective osteoporosis treatments are available, the rates of use are low, even among individuals who have already experienced a fracture and are thus at very high risk for a subsequent fracture. Since many patients commonly receive home health services care post-fracture, the home health setting is a promising venue for improving osteoporosis care.To assess the utility of a home health care based strategy for osteoporosis care improvement, we developed a multimodal intervention for home health care patients with a fracture history. Our intervention targeted nurses, physicians, and patients involved in home health care.

Methods: We conducted a cluster randomized trial of a multimodal intervention targeted at patients receiving care in a state-wide home health care agency in Alabama. The intervention included an educational component and a computerized nursing care plan for nurses, prepared order sheets to facilitate osteoporosis prescription medications ordering for physicians, and patient education materials for patients.Offices throughout the state were randomized to receive the intervention or to continue usual care. Following the randomized controlled study, we delivered the intervention to the offices randomized to the usual care arm. At that time, we implemented an automatic prompt for nurses in each office that identified those patients at high risk for a subsequent fracture and required the nurse to decide to activate the care plan.This allowed us to evaluate the additional effect of the automatic prompt compared with nurse identification alone.The primary outcome was the proportion of patients with a fracture history prescribed osteoporosis medications.

Results: For the randomized trial, among the offices in the intervention arm the average proportion of eligible patients receiving osteoporosis medications post-intervention was 19.1%, compared with 15.7% in the usual care arm (difference in proportions 3.4%, 95% CI: $-2.6 - 9.5\%$). The difference was not statistically significant. Within the intervention arm, a secondary analysis among the patients who had the care plan activated (27.5%) found 37.7% received osteoporosis medications compared with 11.6% of those who did not have the care plan activated ($p < 0.0001$). The implementation of the automatic prompt improved overall rates of prescription of osteoporosis medications (14.8% prior to activation vs. 17.6% after activation), but the difference was not significant.

Table 1. Enrollment and Drug Treatment Rates in Usual Care & Intervention Arms of the Home Health Care Osteoporosis Trial

	Usual Care Offices		Intervention Offices	
	Fracture Cases*	Proportion Treated†	Fracture Cases*	Proportion Treated†
	48	17%	46	17%
	42	21%	39	18%
	37	11%	38	18%
	36	25%	37	16%
	36	11%	36	28%
	29	10%	31	16%
	28	11%	28	18%
	25	20%	25	12%
	22	23%	21	10%
	19	11%	16	19%
	15	13%	13	38%
Averages	31	16%	30	19%

*Number of patients with fracture diagnoses who were eligible for the intervention
†Proportion of fracture patients receiving prescription osteoporosis medications during follow up after the intervention

Conclusion: The cluster randomized controlled trial conducted in a state-wide home health care agency did not significantly improve rates of prescribed osteoporosis medications. This was also the case for the before and after comparison of rates with respect to the activation of the automated alert feature in the EMR. Treatment rates did significantly improve when the nursing care plan was activated.

Association Between Metabolic Syndrome and Bone Mineral Density in a Community-Dwelling Older Women: The São Paulo Ageing & Health Study (SPAH). Luana G. Machado, Diogo S. Domiciano, Jaqueline B. Lopes, Camille P. Figueiredo, Valéria Caparbo, Liliam Takayama and Rosa M.R. Pereira. University of São Paulo, São Paulo, Brazil

Background/Purpose: Recent studies have shown a link between metabolic syndrome (MS) and bone mass. However, these results are uncertain about the positive/negative effect of the components of MS on bone mineral density (BMD) and risk of fragility fractures. Furthermore, the higher prevalence of MS among subjects with higher body mass index (BMI) is a confounding factor, since previous findings have demonstrated that obesity could be a protective factor against bone loss.In this way, the aim of this study was to evaluate the prevalence of MS in a community-dwelling older women with high frequency of overweight/obesity and its association with bone parameters.

Methods: 343 community-dwelling older women were evaluated by specific questionnaire (including history of clinical fractures and cardiovascular risk factors). Lumbar spine, femoral neck and total hip BMD were evaluated by DXA. Laboratory tests, including calcium, phosphorus, creatinine, lipid profile, insulin, glucose and uric acid were also performed. Thoracolumbar spine X-rays were assessed to identify vertebral fractures. National Cholesterol Education Program-Adult Treatment Panel III (NCEP-ATPIII) criteria were used to define MS. Logistic regression models were used to analyze the relationship between MS and bone parameters.

Results: The prevalence of MS was high (62.1%). Women with MS had higher BMI (30.7 ± 4.9 vs. 27.2 ± 4.9kg/m^2, $P<0.001$), body fat percentage(37.7 ± 5.0 vs. $34.9\pm6.5\%$, $P<0.001$), serum levels of creatinine (0.9 ± 0.2 vs. 0.8 ± 0.2mg/dl, $P=0.003$), insulin (12.7 ± 10.7vs. 8.7 ± 14.2U/mL, $P=0.004$), uric acid (5.6 ± 1.5 vs. 5.1 ± 1.3mg/dl, $P=0.001$), lumbar spine BMD (0.881 ± 0.171 vs. 0.837 ± 0.178g/cm^2, $P=0.025$), femoral neck BMD (0.684 ± 0.120 vs. 0.629 ± 0.121g/cm^2, $P<0.001$) and total hip BMD (0.814 ± 0.131 vs. 0.743 ± 0.140g/cm^2, $P<0.001$) compared to women without MS. After adjustments for BMI, logistic regression analyses demonstrated that hip BMD remained as an independent factor associated with MS (OR:10.73 95% CI:1.33–86.55, $P=0.026$).No significant difference concerning the prevalence of vertebral or nonvertebral fractures was observed between the women with and without MS.

Conclusion: A positive association between total hip BMD and MS was found in our community-dwelling older women, even after adjustment for BMI. Nevertheless, the frequency of vertebral and nonvertebral fractures was similar in women with and without MS. Taken together, these results suggest that higher BMI per se does not explain the positive association between higher BMD and MS and does not protect against osteoporotic fractures. Further studies are necessary to elucidate the effect of MS on bone mass and fracture risk, possibly related to bone quality.

Risk of Fracture Among Treated and Untreated Men with Osteoporosis. Karen Tomic[1], Joanne Lafleur[2], Liisa Palmer[1], David M. Smith[1], Carly J. Paoli[3], Irene Agodoa[3] and Nicole Yurgin[3]. [1]Truven Health Analytics, Washington, DC, [2]University of Utah College of Pharmacy, Salt Lake City, UT, [3]Amgen Inc, Thousand Oaks, CA

Background/Purpose: Osteoporosis (OP) affects an estimated 2 million men in the United States. The relationship between treatment and fracture outcomes has been reported from clinical trial populations, but little is known

about the impact of treatment on fracture risk among men with OP in the real-world setting.

Methods: The *MarketScan® Medicare Supplemental and Coordination of Benefits Database* was used to identify treated (received an OP medication) and untreated (had an OP diagnosis or fragility fracture but no OP medication) men with OP between 1/1/04 and 4/30/10 and at least 12 months pre-period and 3 months post-period follow-up in the database.Patients were matched on pre-period fracture and age ($\pm$ 2 years).Follow-up time was variable and ended with fracture, inpatient death, end of health plan eligibility, or on 4/30/10, whichever came first.Fracture incidence rates and time to fracture were reported.A Cox proportional hazards model was used to assess whether treated men had a lower risk of fracture compared to untreated men after controlling for demographic and clinical characteristics.

Results: Of the 3,072,696 men $\geq$65 years in the database, a total of 31,696 men met the inclusion and match criteria (15,848 in each cohort).In both cohorts, the mean age was 78 years and 55% had a pre-period fracture.1,990 treated men had a follow-up fracture [incidence = 5.98/100 person-years (p-y)] over 33,274 p-y of follow-up, compared to 2,231 untreated men with a follow-up fracture (incidence = 8.03/100 p-y) over 27,785 p-y.Treated men also had longer mean time to fracture (588 days, SD 426) than untreated men (401 days, SD 372, p<0.001).The adjusted risk of fracture was lower among treated men compared to untreated men (adjusted hazards ratio = 0.83, 95% CI: 0.78 to 0.89).Other pre-period factors associated with an increased risk of fracture were urban residence, no bone mineral density test, use of benzodiazepines, and a higher number of comorbidities and concomitant medications.

Conclusion: The fracture incidence rate was lower and time to fracture was longer for men with OP who received treatment than for those without treatment. After controlling for prior fracture and other risk factors, treated men had a lower adjusted risk of fracture.To better characterize the benefit of OP treatment, more research is needed into the role of medication adherence and risk of fracture among men with OP.

923

Low Bone Mineral Density and Higher Parathyroid Hormone Levels As Independent Factors to All-Cause Mortality in Community-Dwelling Older Adults: the São Paulo Ageing & Health Study (SPAH). Diogo S. Domiciano, Luana G. Machado, Jaqueline B. Lopes, Camille P. Figueiredo, Valéria Caparbo, Liliam Takayama, Eloisa Bonfa and Rosa M.R. Pereira. University of São Paulo, São Paulo, Brazil

Background/Purpose: Previous studies have shown a relationship between osteoporosis and increased risk of death. Moreover, secondary hyperparathyroidism has been linked to mortality amongst frail older hip fractures patients. However, none of these studies performed a concomitant evaluation of the parathormone(PTH)-calcium-vitamin D-axis and bone mass, and this is essential to determine more accurately the contribution of each of these parameters to survival in community-dwelling older subjects. The aim of this study was, therefore, to investigate the association between serum PTH status, calcium, vitamin D and bone mineral density (BMD) and all-cause mortality during a 5-year period in a community-dwelling older population.

Methods: 739 community-dwelling subjects (446 women and 293 men), aged over 65 years, were prospectively studied. Clinical data (including history of non-vertebral fractures and cardiovascular events as previous myocardial infarction, instable angina, stroke) were assessed by specific questionnaire. Serum 25(OH)D level, intact PTH, total calcium, phosphorus, creatinine, and alkaline phosphatase were also measured. BMD of the lumbar spine and hip were evaluated by DXA. Spine X-ray (T4-L4) was performed to identify vertebral fractures by the semiquantitative method. All analysis was done at baseline and after a 5-year period. Mortality was recorded during 5-year follow-up. Multivariate Cox regression analysis was used to compute hazard ratios for all-cause mortality.

Results: After 5-year follow-up, there were 104 (14.1%) deaths. Comparing with individuals who were alive at the end of follow-up, subjects who died were older (75.9±6.8 vs. 72.6±4.8 years, P<0.001), had lower weight (64.4±15 vs. 67.6±13.1 kg, P=0.03), lower glomerular filtration rate (GFR) (52.3±25.3 vs. 59.0 ±18.4 ml/min, P<0.001), higher PTH level (45.8±23.2 vs. 38.1±16.0 pg/dl, P=0.003) and lower 25(OH)D level (17.8±10.4 vs. 20.2±10.2 ng/ml, P=0.005). There was also difference between the groups (deceased vs. alive) related to frequency of *diabetes mellitus* (36.5 vs. 19.1%, P<0.001), prevalence of any cardiovascular event (26.0 vs. 13.1%, P=0.001) and low BMD (T-score $\leq$ −2: 74.0 vs. 61.3%, P=0.01). After adjustments for age, sex and GFR, low BMD (HR:1.8095% CI:1.1–2.9, P=0.02), PTH level (HR:1.1295% CI:1.01–1.23, P=0.003), *diabetes mellitus* (HR:2.77 95% CI:1.71–4.50, P<0.001) and any cardiovascular event (HR:1.97 95% CI:1.16–3.36, P=0.01) remained independently associated to all-cause mortality.

Conclusion: Low BMD and higher PTH level, but not vitamin D per se, were significantly associated with mortality in community-dwelling older adults. These findings support the notion that a careful screening of these bone parameters might improve the outcomes of elderly population.

924

Methods to Link a U.S. Arthritis Cohort with Medicare Administrative Claims Data. Jeffrey R. Curtis[1], Lang Chen[2], Timothy Beukelman[1], Aseem Bharat[2], Fenglong Xie[2], Kenneth G. Saag[1] and Elizabeth S. Delzell[2]. [1]Univ of Alabama-Birmingham, Birmingham, AL, [2]University of Alabama at Birmingham, Birmingham, AL

Background/Purpose: Linkages between clinical and administrative data may provide a valuable resource for pharmacoepidemiologic and health services research.

Objective: To describe methods and validity of a linkage between a de-identified national arthritis registry and U.S. Medicare data.

Methods: Data from 2006-9 for rheumatoid arthritis (RA) patients participating in the Consortium of Rheumatology Researchers of North America (CORRONA) was linked to Medicare (100% sample selected using ICD-9 codes). Deterministic linkage was performed using age (in years), sex, provider identification number, and U.S. state of the CORRONA site. Medicare data were restricted to rheumatology claims or with an RA diagnosis occurring in CORRONA provider's state. Visit dates from CORRONA were matched to Medicare visit dates. At least 1 visit date was required to match exactly.

An 'all-visit match' was defined when a CORRONA participant had all CORRONA visits match to all Medicare visits. If a CORRONA participant had an all-visit match to >1 Medicare beneficiary, unique matches selected to be the beneficiary with the greatest number of matched CORRONA visits.In the event of ties, the participant was considered not matched. A fuzzy match was done for CORRONA participants without any all-visit match allowing date mismatches of +− 2 week, or +−1 digit in month, day or year.

Linkage accuracy was evaluated in a sub-cohort with more complete information (including full date of birth [DOB]); exact match on full DOB was used as a gold standard.

Results: CORRONA participants with self-reported Medicare coverage at any time (n=9326) were identified to be matched to 32,788 Medicare beneficiaries with arthritis treated by CORRONA physicians. A total of 7,441 CORRONA participants matched exactly on at least 1 visit, and 4413 (59%) had an all-visit match to 1 or more beneficiaries; 4013 (54%) were uniquely matched with a median (IQR) of 3 (2, 6) matched visits. For those without any all-visit matches (n=3028), only 346 (11.4%) were able to achieve at least 1 all-visit match after fuzzy matching.

For the 837 participants in the validation subcohort with an all-visit match to a single Medicare beneficiary, match accuracy was 95% for patients with > 2 matched visits, 87% for patients with exactly 2 matched visits, and 73% for those with exactly 1 matched visit. For additional patients who initially matched exactly on at least one but not all visit dates and achieved an all-visit match after fuzzy matching (n=162), linkage accuracy was < 15%. Ongoing work is refining the linkage strategy for resolution of ties and improvement of matching validity and to expand the validation sample

Conclusion: A novel linkage between a national, de-identified outpatient arthritis registry and U.S. Medicare claims data on multiple non-unique identifiers appears both feasible and valid.

925

Use of Rheumatology Services for Arthritis: The Role of SES and Geographic Availability of Rheumatologists and Primary Care Physicians. E. M. Badley[1], Mayilee Canizares[2] and Aileen M. Davis[3]. [1]Division of Health Care and Outcomes Research,Toronto Western Research Institute; Dalla Lana School of Public Health, University of Toronto, Toronto, ON, [2]Division of Health Care and Outcomes Research,Toronto Western Research Institute, Toronto, ON, Toronto, ON, [3]Division of Health Care and Outcomes Research, Toronto Western Research Institute, Departments of Rehabilitation Science and Health Policy, Management and Evaluation, University of Toronto, Toronto, ON

Background/Purpose: Access to rheumatology is critical for timely treatment of new onset inflammatory arthritis (IA). Barriers to timely care include patient characteristics, the need for a referral from another physician (usually a primary care physician (PCP)), and the availability of a rheumatologist to be referred to.Treating patients with IA also needs to be balanced against the role of rheumatologists as the medical specialist with expertise in arthritis in general.There is a shortage of rheumatologist as well are large area variations in their availability. The objectives of this population-based study is to examine access to rheumatologists for IA and arthritis overall (AO) taking into account access to PCP, availability of rheumatologists, and population characteristics.

Methods: A population-based multilevel study of individuals aged 18+ living in 105 residential areas in Ontario, Canada (total population about 13 million) which has a publicly funded health care system covering all physician visits. The physician billing database was used to identify the number of patients seeing rheumatologists for IA and AO and to derive a measure of PCP availability by residential area.Census data were used to calculate indicators of socio-economic status (SES), population age and rurality. Data from a survey of rheumatologists gave postal code for practice locations and the number of clinic hours per week.Geographic Information System analysis was used to calculate a weighted measure of rheumatologist availability taking into account amount of clinic hours and distance to rheumatologist locations for each residential area. Multilevel Poisson regression was used to estimate rate ratios for visits to rheumatologists for IA and AO by rheumatologist availability, PCP access, and SES.

Results: 142,600 patients made at least one visit to rheumatologists (13.4 per 1000 population): only 47.7% of visits were for IA, with a seven-fold variation across residential areas.Comparing the highest to lowest quintile, rate of visits for IA were higher in areas of high SES (RR 1.3 95%CI:1.1–1.6) and areas with high PCP access (RR 1.2 95%CI:1.0–1.5).There was no association with rheumatologist availability.However higher rheumatologist availability was associated with visits for AO (RR 1.2: 95% CI 1.0:1.4), as were high SES (RR 1.4 95%CI:1.2–1.6) and high PCP access (RR 1.4 95%CI:1.2–1.7).

Conclusion: The lack of association with area-level rheumatologist availability for IA suggests that priority is given to these patients.The association of higher rheumatologist availability with patients seen with AO, raises questions of where these patients go for care when no rheumatologist is available. For both IA and AO, lack of PCP access may be a barrier to referral.This study also indicates that residents of high SES areas are more likely to see rheumatologists, suggesting inequalities in access to care. Models of care that incorporate the location and amount of rheumatologist and PCP resources are crucial to improve access to care for people with all types of arthritis particularly in areas of low SES.

Accuracy of Canadian Health Administrative Databases in Identifying Patients with Rheumatoid Arthritis Using a Random Sample of 7500 Patients Seen in Primary Care. Jessica Widdifield[1], Claire Bombardier[1], Sasha Bernatsky[2], J. Michael Paterson[3], Jacqueline Young[3], Diane Green[3], J. Carter Thorne[4], Noah Ivers[1], Debra Butt[3], R. Liisa Jaakkimainen[1], Myra Wang[3], Vandana Ahluwalia[5]. George A. Tomlinson[6] and Karen Tu[3], [1]University of Toronto, Toronto, ON, [2]Research Institute of the McGill University Health Ctre, Montreal, QC, [3]Institute for Clinical Evaluative Sciences, Toronto, ON, [4]Southlake Regional Health Centre, Newmarket, ON, [5]William Osler Health Center, Mississauga, ON, [6]Toronto General Hospital, Toronto, ON

Background/Purpose: The use of population-based health administrative databases in rheumatology research is well established, but there are ongoing concerns about validity. To date, previous validation studies have sampled patients primarily from rheumatology clinics, which may limit the usefulness of the results. Our aim was to evaluate the accuracy of administrative data algorithms to identify RA patients drawn from family physician records.

Methods: We performed a retrospective chart abstraction study using a random sample of 7500 adult patients, age 20 years and over, from the primary care Electronic Medical Record Administrative data Linked Database (EMRALD) in Ontario, Canada. Our reference standard definition for classifying patients as RA included physician-reported RA diagnoses and supporting evidence. RA and non-RA patients were then linked to administrative data to validate different combinations of physician billing (P) and hospitalization (H) diagnostic codes for RA to estimate sensitivity, specificity, positive predictive value (PPV) and negative predictive value (NPV).

Results: Based on our reference standard definition, we identified 69 patients with physician-reported RA for an overall RA prevalence of 0.92%. Most RA cases were female (64%) and the mean (SD) age was 62 (14) years.Among RA cases, 86% had a documented diagnosis by a specialist and 80% had documentation of a disease-modifying anti-rheumatic drug exposure. Test characteristics of selected RA case definition algorithms tested are reported in Table 1. All algorithms tested had excellent specificity (97–100%), however sensitivity varied (75–90%) among physician billing diagnosis algorithms. Despite the low RA prevalence, algorithms for identifying RA patients had modest PPV, which improved substantially with the requirement of having musculoskeletal specialist billing codes for RA (51–83%). Varying the observation window had little impact on the accuracy of the algorithms tested.

Table 1. Test characteristics of selected algorithms

Algorithm	Sensitivity (%)	Specificity (%)	PPV (%)	NPV (%)
1 H ever	22	100	88	99
1 P ever	90	97	20	100
2 P in 1 year	84	99	46	100
2 P in 2 years	84	99	45	100
2 P in 3 years	84	100	42	100
3 P in 1 year	80	100	63	100
3 P in 2 years	80	100	60	100
3 P in 3 years	80	100	59	100
1 P ever by a specialist	81	99	51	100
2 P in 1 year at least 1 P by a specialist	78	100	65	100
2 P in 2 years at least 1 P by a specialist	78	100	65	100
2 P in 3 years at least 1 P by a specialist	78	100	62	100
3 P in 1 year at least 2 P by a specialist	75	100	83	100
3 P in 2 years at least 2 P by a specialist	75	100	81	100
3 P in 3 years at least 2 P by a specialist	75	100	81	100
1 H or 3 P in 1 year at least 1 P by a specialist	78	100	77	100
1 H or 3 P in 2 years at least 1 P by a specialist	78	100	76	100
1 H or 3 P in 3 years at least 1 P by a specialist	78	100	76	100

H: Hospitalization code; P=physician diagnostic code; Specialist = rheumatologist, internal medicine, orthopedic surgeon

Conclusion: The RA case definition algorithms that we tested had excellent specificity. To our knowledge, this is the first study to rigorously evaluate the accuracy of RA administrative data algorithms in a random sample from family physician records. We are independently validating these algorithms in a random sample of patients from rheumatology clinics to support the findings of this work.

Shared Decision Making in Secondary Care: Rheumatologic Patient's Perspective. Raphael Battisti[1], Thiago D. Baumgratz[1], Mirella Cuziol[2], Ana Carolina Reiff Janini[2], Roger A. Levy Sr.[3] and Mirhelen M. Abreu[4]. [1]Medical Student, São Carlos, Brazil, [2]Medical Student at Universidade Federal de São Carlos, São Carlos, Brazil, [3]Hospital Universitário Pedro Ernesto, Rio de Janeiro, Brazil, [4]Universidade Federal de São Carlos, São Carlos, Brazil

Background/Purpose: This cross-sectional study aimed to analyze the willingness for shared decision making (SDM) of rheumatologic patients.

Methods: All rheumatic disease patients assisted at a specialty care unit were invited to participate in this study. A three parts questionnaire was applied (demographic, clinical data and 3 scenarios that simulate a clinical encounter). The scenarios presented the 3 typical steps of a consultation: 1) Diagnostic statement; 2) treatment options discussion; 3) decision-making. Each scenario was presented according to SDM process. For each step, interviewee was argued 3 questions: (a) To identify weather each part was similar to his/her clinical encounter or not; (b) to define whether SDM can be a feasible approach and (c) to answer if he/she wanted to be assisted in SDM process, justifying it. The outcomes were defined by the justification about the willingness for SDM. Descriptive and multiple correspondence analysis (MCA) techniques were performed to explore data.

Results: Demographic data (N=160): 89% female, 60% < 8 years of school, 76% < 3 folds the minimum wage (income), 24.3% employed and 10.6%, retired due to the disease; 75% of participants had a rheumatic diagnosis clearly defined, of which 48.8% had < 4 years of diagnosis and 30%, > 8 years of diagnosis. The first scenario showed that 97% would like to have SDM approach on their real clinical practice. They justified its desire according to 'communication empowerment' (75%) and 'patients' right relationship' (23%). For the scenario two, 98% would like to have this approach, although 65% declared that it never happen in his/her real life. They justified according to 'communication empowerment' (63%)'. Decision-making scenario showed that 65% of the participants never took part in the decision process. However, 98% would like to do it, justifying according to 'patients' right relationship' (30%), and 'communication empowerment' (28%). Despite these answers, 13% answered that the whole decision belongs to the physician because they have the technical knowledge. MCA plot illustrates that diagnostic statement correlates to 'communication empowerment', retired because of disease, and low literacy. To understand treatment option, communication empowerment and a practice of a patient's right was correlated with those who had < 4 years of diagnosis or > 8 years; > two rheumatic conditions, and low literacy. Finally, the desire for SDM was correlated among 'communication empowerment' and 'patient's right' with those with < 4 years of diagnosis, active working status, and age between 50– 59 years-old.

Conclusion: Communication empowerment and patient's right were the most common reasons for the willingness for SDM.

928

Is There an Optimal Treatment Strategy for Disease-Modifying-Antirheumatic-Drug Naïve Patients with Rheumatoid Arthritis?
Roopa Akkineni[1] and Daniel A. Albert[2]. [1]Dartmouth Hitchcock Medical Center, Lebanon, NH, [2]Dartmouth-Hitchcock Med Ctr, Lebanon, NH

Background/Purpose: There is a lack of head-to-head clinical trial data to determine the most effective treatment for rheumatoid arthritis (RA).However, these trials have had similar patient entry criteria and outcome measures allowing for meta-analysis.Patients with RA fall into three therapeutic groups: DMARD naïve (no prior exposure to conventional or biologic disease-modifying-anti rheumatic drugs [DMARD]), Biologic naïve (prior exposure to conventional DMARDs but not biologic DMARDs) and Biologic second-line (prior exposure to biologic DMARDs).

A decision analysis was designed to identify an optimal treatment strategy for DMARD naïve patients with RA.

Methods: A total of 270 studies were identified on ClinicalTrials.gov and Medline, of which 193 were eliminated in the abstract review phase.Seventy-seven studies were screened in full text and seventy were excluded for reasoning including lack of randomization, uncertain diagnoses, and non-standard treatment.Seven clinical trials were included for the DMARD naïve group corresponding to twelve treatment options.

The treatment options included placebo, methotrexate, biologic drugs alone and methotrexate plus biologic drugs.Drug effectiveness was measured by the ACR 20 and ACR 50 criteria and the rate of serious adverse events was modeled across different therapeutic options. Sensitivity analyses were conducted for probability of serious adverse drug reactions and the ACR 20 and ACR 50 effectiveness measures.

Results: In the biologic drugs group alone, treatment with etanercept 25mg bi-weekly resulted in the maximum quality-adjusted-life-year (QALY) gain of 23.24 years compared to placebo at 21.55 years (1 year and 8 months) and methotrexate at 22.12 years (1 year and 1 month).In the methotrexate plus biologic group, treatment with etanercept 50mg plus methotrexate resulted in 23.20 QALYs. Adalimumab 40mg (21.79 QALYs), Infliximab 3mg plus methotrexate (21.83 QALYs) and triple therapy (21.76 QALYs) resulted in the lowest QALY gain.

Sensitivity analysis showed at ACR 20 success criteria etanercept alone is preferred, while at ACR 50 criteria etanercept plus methotrexate is the preferred treatment option. At base case methotrexate was not a preferred treatment, however if methotrexate's ACR50 response rate exceeds 34% then it would become the optimal treatment strategy if all other factors were held constant. By contrast, treatment with etanercept 25mg on a bi-weekly basis and etanercept 50mg plus methotrexate are no longer the favored treatment options if their adverse drug reaction rates increase from 6% and 12% to 9% and 13% respectively.

Conclusion: Biologic therapy alone and biologic therapy plus methotrexate appear to be the favorable treatment strategies for the DMARD naïve group. The QALY gains for biologic therapy in rheumatoid arthritis are similar to that of biologic therapy in psoriasis and interferon therapy for multiple sclerosis (0.20–3.3 QALYs). The decision depends in part on the side effect profile and costs.Decision aids to elicit patient preferences and drug costs may override differences in drug effectiveness.

929

Epidemiology of the US National Burden of Pediatric Lupus Hospitalization From 2000–2009.
Andrea Knight[1]. Pamela Weiss[2], Knashawn Morales[3] and Ron Keren[1]. [1]Children's Hospital of Philadelphia, Philadelphia, PA, [2]The Children's Hospital of Philadelphia, Philadelphia, PA, [3]University of Pennsylvania, Philadelphia, PA

Background/Purpose: Studies indicate that of 11% of adult hospitalizations are related to systemic lupus erythematosus (SLE), with an average charge of $10,000 US per hospitalization and a 1 in 30 chance of death (1). There are few studies describing the hospitalization experience in pediatric SLE, and no national estimates for inpatient healthcare utilization. We aimed to characterize national US trends in inpatient healthcare utilization and mortality associated with pediatric SLE.

Methods: We performed a retrospective, serial, cross-sectional analysis of a nationally representative sample of pediatric SLE patients.Using the Kids' Inpatient Database (KID) for years 2000, 2003, 2006 and 2009, we identified patients with SLE by an *International Classification of Diseases, Ninth Revision, Clinical Modification* (ICD-9-CM) code of 710.0 listed as a primary or secondary diagnosis. The main outcome measures were: SLE hospitalization rate, length of stay (LOS), total hospitalization charges and mortality. Patient-specific demographic variables included: age, race, sex and insurance status. Hospital-specific variables included: type (general or children's), teaching status, location (urban or rural) and region (Northeast, Midwest, South or West). We used KID reported sampling weights to calculate national estimates of the main outcome measures and multivariate regression to evaluate for trends over time.

Results: An estimated 27,076 (SE 1509) pediatric SLE discharges were identified in the KID for the years of study, with a hospitalization rate of 7.9 per 100,000 children (SE 0.5). The median LOS was constant across years at 2 days (IQR 2,3). The mean total charges per hospitalization (inflated to 2009 USD) were $29,304 for 2000, $36,987 for 2003, $41,664 for 2006 and $42269 for 2009. (p value for trend <0.001). Factors associated with increased total charges were: male sex (p=0.03); age>=18 years (p=0.03); Black race (p=0.02) and Hispanic ethnicity (p=0.003); urban location (p<0.001); and West region (p<0.001). The death rate during hospitalization was 1% for 2000, 1.1% for 2003, 1.2% for 2006 and 0.6% for 2009, which was statistically different across years (p=0.03). Risk factors associated with death were: male sex OR=1.6 (p=0.03), age>=18 years OR=3 (p=0.01); Black race OR=2.6 (p=0.002); other race OR=2.5 (p=0.01); South region OR=2.1 (p=0.006) and West region OR=1.8 (p=0.03).

Temporal Trend in Pediatric SLE Hospital Charges

— Pediatric SLE Discharges   - ○ - All Other KID discharges

*mean total charges per hospitalization adjusted to 2009 USD
Conclusion: The length of stay for pediatric SLE has remained stable from 2000 to 2009. Total hospital charges have significantly increased, and mortality has decreased over time, with estimates differing by age, race, sex, hospital location and region. Further studies are needed to investigate the drivers of these differences in healthcare utilization and outcomes.

Disease Burden and Cost of Illness in SLE During 8 Years Follow up.
Andreas Jönsen[1]. Anders A. Bengtsson[2], Frida Hjalte[3], Minna Willim[2], Ragnar Ingvarsson[2], Ulf Persson[3], Ingemar F. Petersson[4] and Ola Nived[5]. [1]Section of Rheumatology, Lund, Sweden, [2]Department of Clinical Sciences Lund, Section of Rheumatology, Lund, Sweden, [3]Lund, Sweden, [4]Musculo-skeletal Scienes, Department of Orthopedics, Clinical Sciences, Lund, Sweden, [5]University Hospital - Lund, Lund, Sweden

Background/Purpose: To study the annual direct and indirect costs in SLE in a cohort, from a defined area in southern Sweden, and to find potential predictors of cost.

Methods: All 127 prevalent and incident cases of clinically confirmed SLE, all with at least 4 ACR classification criteria, being alive between January 1st 2003 and December 31st 2010 in a defined area with an adult population of 175.000, were included.Demographics, date of diagnosis, follow up period, phenotype, disease activity (SLEDAI), organ-damage (ACR/SLICC DI) and costs for SLE specific therapy was collected from the database of the rheumatology unit. From the population registry 508 individuals matched for age and sex constituted a reference group. For both cases and references the local Health Authorities database provided all costs for in-patient admissions, out-patient care with all types of health care personnel, and from the Swedish Social Security Agency data was obtained about sick leave and disability pensions. The data merge was done within the Epi-Centrum in Lund and the cost analysis at the Swedish Institute for Health Economics.

Results: Eighty-seven percent were females and the mean age in 2003 was 52 years with mean disease duration of 16 years and the total observed years were 869 for the patients and 4064 for the references.Annual median inpatient days for cases were 2.91, for subgroup with nephritis 5.68 and for references 0.70. Annual outpatient physician visits were for cases 6.25, for subgroup with nephritis 6.25 and for references 2.40. Annual net sick leave days for cases were 99.9, for subgroup with nephritis 111.6 and for references 35.6. The average total annual costs in SEK 2011, was per SLE patient 180 520 SEK (=$ 25 072) of which 72 percent were indirect costs, the corresponding costs for the subgroup with nephritis was 229 423 SEK(=$ 31 864) and for the references 59 985 SEK (=$ 8 331) of which 78 percent were indirect costs. Potential predictors of total costs were age at study year (p=0.001), disease activity measured by SLEDAI (p<0.001) and organ-damage measured by ACR/SLICC DI (p<0.001).

Conclusion: Disease burden for SLE was significantly increased compared with matched population references both for contacts with health care and loss of productivity, with indirect costs constituting 72 percent. Independent predictors of costs were age, disease activity and organ-damage.

Health Care Utilization Among Medicaid Enrollees with Systemic Lupus Erythematosus Preceding the Development of End-Stage Renal Disease: Sociodemographic Variation. Candace H. Feldman[1], Linda T. Hiraki[2], Graciela S. Alarcon[3], Jinoos Yazdany[4], Jun Liu[5], Michael A. Fischer[1], Wolfgang C. Winkelmayer[6] and Karen H. Costenbader[7]. [1]Brigham and Women's Hospital, Boston, MA, [2]Brigham and Women's Hospital/ Harvard School of Public Health, Boston, MA, [3]University of Alabama at Birmingham, Birmingham, AL, [4]University of California San Francisco, San Francisco, CA, [5]Brigham and Women's Hospital, Harvard Medical School, Boston, Boston, MA, [6]Stanford University School of Medicine, Stanford, CA, [7]Brigham and Women's Hospital, Harvard Medical School, Boston, MA

Background/Purpose: Extreme sociodemographic disparities exist among systemic lupus erythematosus (SLE) patients in the development of end-stage renal disease (ESRD) from lupus nephritis. Better resource allocation and improved access to care may reduce the incidence of this adverse outcome. We aimed to understand sociodemographic variation in health care utilization prior to ESRD development among SLE patients enrolled in Medicaid, U.S. health insurance for low income individuals.

Methods: From the Medicaid Analytic eXtract (MAX) data containing all U.S. Medicaid billing claims from 2000–2004, we identified adults, ages 18 to 65 years, diagnosed with SLE ($\geq$3 visits, ICD-9 code 710.0, >30 days apart). To determine progression to ESRD we matched these individuals with SLE to the U.S. Renal Data System (USRDS), which contains information on nearly all ESRD patients from 2000–2004. We assessed duration of Medicaid enrollment prior to ESRD onset, and age, sex, race/ethnicity and U.S. region for each individual. We determined residence in a Health Professional Shortage Area, number of rheumatologists per state, and county-level socioeconomic status (SES) using a previously validated composite score of 7 U.S. Census variables. We examined 3 outcomes: emergency department (ED), outpatient and inpatient visits per year. We used multivariate-adjusted general linear models to understand the relationship between sociodemographic factors and these health care utilization outcomes.

Results: Of the 34,339 adults with SLE enrolled in Medicaid, 1,475 (4.3%) developed ESRD during the study period. 86% were female, the mean age of ESRD onset was 30.7 years (SD 11.6), and 58.9% were African American, 17.4% were White and 16.1% were Hispanic. The mean number of months in Medicaid prior to ESRD diagnosis was 23.4 (SD 16.4). There were an average of 2.2 (SD 3.2) ED visits, 10 (SD 9.5) outpatient visits and 2.3 (SD 3.0) inpatient visits per year. In multivariate models, men had significantly fewer annual outpatient visits than women (p<0.001). Asian patients had nearly 1 less ED visit per year (p=0.03) and 2.4 fewer outpatient visits per year (p=0.05), compared to Whites. There were more annual ED visits in the Midwest (p=0.01), and outpatient visits in the Midwest (p=0.001) and West (p<0.001), compared to the Northeast. Patients in the lowest county-level SES group had significantly more ED visits per year than the highest SES group (p=0.02). There were no significant differences in inpatient visits according to the sociodemographic groups examined by multivariate analysis.

Conclusion: In this nationwide cohort of Medicaid enrollees with SLE who developed ESRD, we observed significant variation in ED and outpatient visits by sex, race/ethnicity, region, and county-level SES.Increased ED visits in low SES areas may indicate a lack of sustained access to subspecialty care. Further studies are needed to determine whether differences in health care utilization, particularly in underserved areas, contribute to increased rates of progression to ESRD in this high-risk population.

Medical Costs and Health Care Resource Use in Patients with Systemic Lupus Erythematosus in an Insured Population. Daniel E. Furst[1], Ann E. Clarke[2], Ancilla W. Fernandes[3]. Tim Bancroft[4], Kavita Gajria[3], Warren Greth[5] and Serban R. Iorga[4], [1]UCLA Medical School, Los Angeles, CA, [2]McGill University, Montreal, QC, [3]MedImmune LLC, Gaithersburg, MD, [4]OptumInsight, Eden Prairie, MN, [5]MedImmune, LLC, Gaithersburg, MD

Background/Purpose: Systemic lupus erythematosus (SLE) is a chronic autoimmune disease that may affect multiple organ systems. The clinical manifestations of SLE are heterogeneous, and subjects typically experience periods of disease flares and remission. The objective of this study was to investigate the economic burden and resource use associated with newly diagnosed and existing SLE patients in a large national US insurer.

Methods: Subjects at least 18 years of age and with claims-based evidence of SLE (ICD-9-CM 710.0x) were identified from a health plan database during 2003–2008. Subjects were divided into two cohorts; newly diagnosed and existing based on claims history of SLE. Subjects were matched based on demographic and clinical characteristics at a ratio of 1:3 to unaffected controls. Health care costs and resource use were captured during a 12 month post-index period. A generalized linear model (GLM) was used to predict costs, controlling for demographic and clinical characteristics.

Results: A total of 1,278 newly diagnosed SLE subjects were matched to 3,834 controls, and 10,152 subjects with existing SLE were matched to 30,456 controls. SLE subjects had significantly higher overall mean annual health care costs than matched controls (newly diagnosed: $19,178 vs. $4,909; existing: $15,487 vs. $5,156; both p<0.001).Inpatient costs were the largest component of medical costs for newly diagnosed subjects, while ambulatory costs were the largest component for existing SLE patients.When adjusting for clinical and demographic characteristics with a GLM model, the cost ratio of newly diagnosed SLE subjects to controls was 2.15 (95% CI: 1.90–2.42), and the cost ratio of subjects with existing SLE to controls was 2.05 (95% CI: 1.92–2.19).Presence of pharmacy claims for select medications (including corticosteroids, methotrexate, or cyclophosphamide), and evidence of specific organ involvement (including renal failure, CNS complications, and cardiovascular complications) were each associated with increased costs (all p<0.05). Health care resource use was significantly higher among SLE subjects than matched controls, including average annual numbers of primary care physician visits, specialist visits (nephrologist, rheumatologist, neurologist or dermatologist), emergency department visits, and inpatient hospital stays (all p<0.001).

Conclusion: Economic burden and resource use were high in both newly diagnosed and existing SLE patients compared to unaffected controls in this insured population. Serious complications and immunosuppressant use were associated with increased costs. These findings highlight the unmet need in SLE.

Economic Burden of Systemic Lupus Erythematosus by Flare Severity in a Commercially Insured Population in the United States. Siva Narayanan[1], Emily Durden[2], Alan Oglesby[3], Paul Juneau[4] and Kathleen L. Wilson[5]. [1]Human Genome Sciences, Inc., Rockville, MD, [2]Thomson Reuters, Austin, TX, [3]GlaxoSmithKline, Research Triangle Park, NC, [4]Truven Health Analytics, Washington, DC, [5]Thomson Reuters Healthcare, Cambridge, MA

Background/Purpose: Systemic Lupus Erythematosus (SLE) is a chronic autoimmune disease with an unpredictable disease course with sporadic periods of illness (flares). Little is known about how the severity of flares impacts the economic burden of SLE. The aim of the current study was to estimate the economic burden associated with SLE, stratified by flare severity among SLE patients in a commercially-insured population in the United States (U.S).

Methods: In this retrospective, observational study, commercially insured adults (employees or their dependents) ages 18–64 years with at least one SLE-related inpatient or emergency room (ER) claim or at least two SLE-related outpatient visits at least 30 days apart with a rheumatologist

between 7/1/2004 and 12/31/2008, and at least 6 months of pre-index and 12 months of post-index continuous medical/prescription coverage were identified in the MarketScan Commercial Claims database. Non-SLE controls were matched to SLE cases using propensity score matching. Mild, moderate, and severe flares were identified in the follow-up period for the SLE patients using a claims-based algorithm and patients were categorized according to their highest degree of flare. A log transformation was applied to the medical expenditures to accommodate specific observed data properties (e.g., skewness). A subsequent linear model was used to adjust for any remaining imbalances from matching and to estimate the incremental annual economic burden (all-cause direct medical cost, in 2010 U.S dollars) associated with SLE for different levels of flare severity for SLE patients in comparison to their matched non-SLE controls.

Results: 13,460 SLE cases (mean age: 45.6 years; 91.6% female; average length of follow-up: 2.9 years) were matched to 13,460 non-SLE controls (mean age: 47.1 years; 88.9% female; average length of follow-up: 2.0 years). During the follow-up period, SLE cases had a significantly higher overall comorbidity burden, (Charlson Comorbidity Index score 1.5, vs. 1.0; p<0.001) and a higher proportion had hospitalizations (49.7% vs. 27.7%; p<0.001) and ER visits (66.7% vs. 43.7%, p<0.001) compared to non-SLE controls. Among SLE cases with no flares, mild/moderate and severe flares as highest flare severity, annualized all-cause direct medical costs were $14,945, $21,606 and $64,578 respectively. In multivariate models comparing non-SLE controls, incremental adjusted annualized direct medical costs for SLE cases with no flares, mild/moderate and severe flares respectively were $441, $3,606 (p<0.05) and $18,953 (p<0.05).

Conclusion: Significantly greater proportions of patients with SLE had a hospitalization or ER visit over a 1-year follow-up than their matched non-SLE counterparts. The direct medical costs of patients with SLE were significantly higher than controls, with costs increasing substantially as the severity of flares increase.

Direct Medical Cost Associated with Organ System Involvement in a Commercially Insured Population with Systemic Lupus Erythematosus in the United States. Alan Oglesby[1], Emily Durden[2], Siva Narayanan[3], Paul Juneau[4] and Kathleen L. Wilson[5]. [1]GlaxoSmithKline, Research Triangle Park, NC, [2]Thomson Reuters, Austin, TX, [3]Human Genome Sciences, Inc., Rockville, MD, [4]Truven Health Analytics, Washington, DC, [5]Thomson Reuters Healthcare, Cambridge, MA

Background/Purpose: Systemic Lupus Erythematosus (SLE) is a chronic autoimmune disease that affects multiple organs including the heart, lungs, kidneys, as well as the joints and the nervous system. While the economic burden has been explored for specific organ systems in SLE with high associated morbidity (e.g. renal), less is known about the economic impact of other organ systems associated with SLE, particularly those with less perceived serious morbidity (e.g. musculoskeletal, etc.)The objective of this analysis was to describe the annual direct medical costs associated with select organ system comorbidities among SLE patients in a commercially-insured population in the United States (U.S).

Methods: This study employed a retrospective, observational design. Adults ages 18–64 years with at least one SLE-related inpatient or emergency department (ED) claim or at least two SLE-related outpatient visits with a rheumatologist at least 30 days apart between 7/1/2004 and 12/31/2008, and continuous medical/prescription coverage for at least 6 months prior and 12 months following the index diagnosis of SLE were identified in the MarketScan Commercial Claims and Encounters database. Select comorbid conditions representing SLE-related major organ/system damage were identified using primary or secondary ICD-9-CM codes and included neuropsychiatric, renal, pulmonary, cardiovascular, musculoskeletal, and mucocutaneous manifestations.All-cause healthcare utilization and costs were assessed in the follow-up period and reported by type of service (e.g. inpatient, outpatient, pharmacy and total). Total, all-cause healthcare costs, adjusted to 2010 U.S dollars, are reported as annualized rates per patient to account for variable follow-up.Costs reflect the paid amounts of adjudicated claims and patient co-pays.

Results: 13,460 SLE cases (mean age: 45.6 years; female: 91.6% female) were identified.Mean length of follow-up was 1,054.6 days (SD: 522.9

days).During the follow-up period, cardiovascular (49.0%) and musculoskeletal (40.3%) comorbidities were observed most frequently, followed by neuropsychiatric (16.7%), renal (14.2%), mucocutaneous (5.4%) and pulmonary (3.4%) comorbidities. Total annual, mean all-cause costs were $30,369 $\pm$ $58,344 in the overall SLE population.Among patients with evidence of SLE-related organ damage, annual mean costs were highest for pulmonary ($74,433; SD=$97,787) and renal ($65,442; SD=$111,541) comorbidities (all p-values<0.001). Compared to the overall SLE population, costs were also higher among SLE patients with cardiovascular ($44,066; SD=$75,161), neuropsychiatric ($43,820; SD=$62,646), mucocutaneous ($41,841; SD=$104,766), and musculoskeletal ($38,986; SD=$66,986) comorbidities (all p-values<0.001).

Conclusion: As expected, organ system involvement associated with high morbidity were associated with highest annual costs on a per diem basis.However, other comorbidities such as cardiovascular and musculoskeletal manifestations, also represent a substantial impact to the health care system, particularly given their higher prevalence.

935

Primary Care Preventive Services in Patients with Systemic Lupus Erythematosus Compared to Others in Their Community. Cristina Drenkard[1], Kimberley Rask[1], Gaobin Bao[1], Gnanesh Patel[1], Suparna Bagchi[2] and S. Sam Lim[1]. [1]Emory University, Atlanta, GA, [2]Georgia Department of Public Health, Atlanta, GA

Background/Purpose: Systemic lupus erythematosus (SLE) is a chronic illness frequently complicated by infections, cardiovascular disease (CVD) and cancer. Primary care preventive services (PCS) are recommended to prevent these complications among individuals at risk. Yet, the utilization of PCS in the US may be more challenging for SLE patients, especially given the worse SLE outcomes among ethnic minorities and those with low socioeconomic status. We compared the likelihood that a cohort of SLE patients from a large metropolitan area in Atlanta, GA, US received recommended PCS relative to the baseline rates of PCS in the same community from a national population-based survey.

Methods: The Georgians Organized Against Lupus (GOAL) is a cohort of validated SLE patients predominantly derived from the Georgia Lupus Registry, a population-based registry of lupus in the Atlanta metropolitan area. GOAL includes the full sociodemographic spectrum of SLE patients and collects self-reported measures on health care utilization and health conditions. Eleven self-reported PCS were assessed in 765 SLE GOAL participants (94% women, 78% blacks,18% uninsured) and 3 representative samples of individuals (9040 from the same community, 938 of them with diabetes, and 620 with CVD) derived from the Behavioral Risk Factor Surveillance System (BRFSS). We compared the proportion of eligible SLE and BRFSS individuals who received the recommended PCS on (1) immunizations, (2) cancer screening, (3) cholesterol monitoring, (4) counseling on medications and lifestyle modifications for high blood pressure (HBP), and (5) all 11 recommended PCS.

Results: Eligible SLE and BRFSS participants who received recommended PCS

PCS	SLE% (95% CI)	Community% (95% CI)	Diabetes% (95% CI)	CVD% (95% CI)
Immunizations (Influenza and/or Pneumococcal vaccine)	45 (41–49)	19 (18–21)	33 (29–37)	38 (33–43)
Cancer Screening (Pap smear and/or mammogram, and/or colonoscopy)	78 (74–81)	77 (76–79)	70 (65–75)	70 (64–76)
Cholesterol Monitoring	65 (62–69)	81 (79–83)	87 (81–92)	90 (84–93)
Counseling on HBP (Drugs and/or 4 lifestyle modifications)	48 (43–53)	38 (34–42)	50 (43–58)	42 (33–51)
All 11 recommended PCS	19 (17–22)	22 (21–23)	23 (20–27)	26 (22–31)

Conclusion: Although only 45% of eligible SLE participants received the recommended immunizations, the proportion was higher than in the community or those with diabetes, and similar to CVD. Over 78% of SLE received complete cancer screening services, which was comparable to the other BRFSS groups. However, only 65% of SLE participants were adequately screened for cholesterol, a lower proportion than in the BRFSS samples. Counseling on hypertension was reported by less than 50% of SLE, similar to the BRFSS groups. Less than 20% of SLE responders received all recommended PCS. Further research is needed to identify factors associated with gaps in the utilization of primary care among SLE patients.

Autoimmune Diseases: Declining Mortality Between 1999 and 2008 However Continuing to be a Leading Cause of Death in Children— A 10-Year Retrospective Review. Eric Y. Yen and Deborah K. McCurdy. Mattel Children's Hospital, University of California at Los Angeles, Los Angeles, CA

Background/Purpose: Autoimmune diseases are chronic illnesses that cause significant and chronic disability in children and may lead to death. Using mortality data from 1995, Walsh and Rau showed that autoimmune disease deaths were the leading causes of death among young women. The objective of this study is to examine the trends in crude mortality rate in children for autoimmune diseases in the United States.

Methods: We selected 24 autoimmune diseases (Table 1) chosen by Jacobson et al using the criteria of Rose and Bona, who defined autoimmune diseases as having direct proof or indirect evidence of autoimmune pathogenesis. Every autoimmune disease was classified with ICD-10 diagnosis code(s). Using the information provided by the Center for Disease Control (CDC), we reviewed all mortality data from the period of 1999–2008 in 3 year intervals. CDC reports that >99% of all deaths in the United States are registered. Each death certificate that lists an autoimmune disease as the underlying cause of death was identified and counted. Age groups, crude mortality rates per 100,000 persons (=number of deaths/population*100,000), and total mortality changes (percent change) between 1998 and 2008 were defined and calculated. We also compared the number of autoimmune disease deaths to the top ten leading causes of death by age in 2008.

Table 1. Autoimmune Diseases (ICD-10 codes).

Addison's disease (E27.1, E27.2, E27.4)	Relapsing polychondritis (M94.1)
Autoimmune hemolytic anemia (D59.1)	Polymyositis/dermatomyositis (M33)
Chronic active hepatitis (K73)	Primary biliary cirrhosis (K74.3)
Glomerulonephritis (N00, N01, N03, N05, N18)	Rheumatic fever and Rheumatic heart disease
Goodpasture's syndrome (M31.0)	(I00, I01, I02, I05, I06, I07, I08, I09)
Graves' disease/hyperthyroidism (E05.0)	Rheumatoid arthritis (M05, M06, M08)
Idiopathic thrombocytopenia purpura (D69.3)	Scleroderma (M34, L94.0, L94.1)
Insulin dependent diabetes (E10)	Sjogren's (M35.0)
Multiple sclerosis (G35)	Systemic lupus erythematosus (M32)
Myasthenia gravis (G70.0)	Thyroiditis (E06.3)
Myocarditis (I40.1, I40.8, I40.9, I51.4, I51.8)	Uveitis (H20.0, H20.1, H20.8, H20.9, H30)
Pemphigus vulgaris (L10.0)	Vitiligo (L80)
Pernicious anemia (D51.0)	

Results: Table 2 presents the crude mortality rates of autoimmune diseases from 1999, 2002, 2005, and 2008 and the percent change between 1999 and 2008. Mortality rates decreased from 5% to 33% in all age groups except for children younger than 5 years old. The absolute numbers of autoimmune disease death did not increase over time. Likewise, mortality rates for all causes decreased for all age group under 20 years old. Despite a sharp decline in mortality rates, autoimmune diseases continue to be a leading cause of death among children (Table 3).

Table 2. Trends in crude mortality rates for autoimmune diseases and all causes of death. Crude mortality rates are expressed per 100,000 persons.

	Age	Crude Mortality Rate (=Deaths/Population*100,000)				% Change Between 1999 and 2008
		1999	2002	2005	2008	
Autoimmune Diseases	1–4	0.33	0.22	0.26	0.35	6.06%
	5–9	0.19	0.11	0.14	0.18	−5.26%
	10–14	0.26	0.21	0.21	0.19	−26.92%
	15–19	0.60	0.56	0.49	0.40	−33.33%
	20–24	1.05	0.97	1.01	0.93	−11.43%
All Causes of Death	1–4	34.22	31.19	29.36	28.37	−17.10%
	5–9	16.86	15.17	14.52	12.47	−26.04%
	10–14	20.39	19.55	18.05	15.7	−23.00%
	15–19	68.6	67.79	65.13	57.67	−15.93%
	20–24	90.78	95.15	97.59	93.98	3.53%

Table 3. Relative ranking of autoimmune disease deaths when compared to the official 10 leading causes of death in 2008.

Age	Relative Rank
1–4	#8
5–9	#10
10–14	#9
15–19	#6
20–24	#6

Conclusion: Although mortality rates from autoimmune diseases appear to be declining in children 5–20 years of age, autoimmune diseases continue to rank within the top ten leading causes of death.

Disclosure: E. Y. Yen, None; D. K. McCurdy, None.

Changes in Ten Year Survival Among SLE Patients At an Academic Center in North America (1970–2011). Joseph F. Merola, Bonnie L. Bermas, Bing Lu, Peter Hsun Tsao, Tabatha Norton, Christina Iversen, Elizabeth W. Karlson, Peter H. Schur and Karen H. Costenbader. Brigham and Women's Hospital, Harvard Medical School, Boston, MA

Background/Purpose: Data from other large SLE cohorts have suggested improving survival among SLE patients in recent years with protective effects from antimalarial use and less favorable prognoses among males. We investigated whether a change in survival has occurred among patients with SLE in our large academic lupus center over the past 41 years.

Methods: Our lupus registry contains data on 5,030 patients seen in our lupus center for potential SLE (ICD-9 billing code 710.0) since the 1960s.For this study, we included 1,099 patients who had validated SLE per both treating rheumatologist and an SLE expert, ≥ 4/11 of the 1997 ACR Criteria for Classification of SLE, date of diagnosis on or after January 1, 1970, and > 2 visits to our center.Data ascertained from the medical record included age at SLE diagnosis, validated history of lupus nephritis, clinical manifestations, serologies, hematology and renal laboratories, medication use and date of death. Individuals were followed for ten years, or until death or end of follow-up period (April 30, 2011). Kaplan Meier curves with log rank tests and multivariable Cox proportional hazards models, adjusted for age at diagnosis, race, sex, nephritis and hydroxychloroquine use, were used to estimate the risk of death over time, and to investigate potential predictors of mortality in our cohort.

Results: The 1,009 SLE patients were divided into two periods at a point where each group contributed equal person-time.Date ranges were January 1, 1970-August 31, 1993 (54,000 person-months) and September 1, 1993-April 30, 2011 (54,000 person-months). Clinical characteristics of the patients diagnosed in each period are compared in **Table 1A**. All patients were ANA positive and approximately 60% in both periods were anti-dsDNA positive. More SLE patients in the recent periods were non-White. They were also older at diagnosis and a higher proportion was prescribed hydroxychloroquine. Overall mean follow-up of all patients was 8.8 years (SD±2.4). There were 70 deaths in period 1; 28 deaths in period 2. Ten year survival was 84.5% in period 1 and 95.0% in period 2 (log rank test p=0.01). In multivariable Cox proportional hazards model, the hazard ratio (HR) for 10 year mortality was 0.47 (95% CI 0.29–0.75) for those diagnosed in the later period, compared to those in the earlier time period. Older age at diagnosis and male sex were associated with increased 10 year mortality (**Table 1B**). There was no significant association between hydroxychloroquine use, race or nephritis with survival over this time period among our subjects.

Table 1A. Comparison of Clinical Characteristics of SLE Patients Diagnosed in Early vs. Late Periods

Demographics	Period 1 (1970–1993), n=451	Period 2 (1993–2011), n=558	p value*
Mean Age at Diagnosis (SD)	29.4 (12.2)	36.0 (13.6)	**<0.001**
Male, (%)	30 (6.7)	53 (9.5)	0.11
White, (%)	283 (62.8)	226 (40.5)	**<0.001**
ANA Positive, (%)	451 (100)	558 (100)	0.50
Anti-dsDNA Positive, (%)	268 (59.4)	336 (60.2)	0.85
Lupus Nephritis, (%)	145 (32.2)	167 (29.9)	0.45
Hydroxychloroquine Use, (%)	338 (75.3)	483 (86.6)	**<0.001**

* t-tests and Fisher exact tests

Table 1B. Factors Associated with 10 Year Mortality**

	Hazard Ratio for Death (95% Confidence Interval)
SLE Diagnosis in Period 2 vs. Period 1	0.47 (0.29–0.75)
Increasing Age at Diagnosis, per year	1.05 (1.03–1.07)
Male Sex	2.36 (1.32–4.20)

**HR= Hazard Ratio
Cox proportional hazards models adjusted for age at diagnosis, race (White, Black, Hispanic, Asian, other), sex, hydroxychloroquine use, lupus nephritis.

Conclusion: Despite changes in patient demographics, survival of patients with immunologically-rich, validated SLE followed in our lupus center has improved over the past 41 years. This improved survival may be related to better management of comorbidities and new modalities of treatment.

Hospitalizations in Systemic Lupus Erythematosus: A Longitudinal Study. Hong Fang, Jie Xu and Michelle Petri. Johns Hopkins University School of Medicine, Baltimore, MD

Background/Purpose: Hospitalizations are one of the major direct costs in SLE.A review of studies looking at the contributions of different medical components to the economic burden of SLE revealed that hospitalizations may count for 50% of the direct costs in SLE (Panopalis P, et al. Arthritis Rheum 2008; 59:1788–1795.).Lupus nephritis has been identified as one of the significant factors consistent with increased direct costs (Slawsky KA et al. Arthrit Care Res 2011; 63:1224–1232.).Identification of predictors of hospitalizations could lead to targeted interventions to reduce costs.

Methods: The medical resource use questionnaire was distributed to SLE patients in the Hopkins Lupus Cohort that covered the last 3 months before the baseline visit and then at the following two quarterly clinic visits. 359 patients (91% female, 55% Caucasian, 36% African-American, 9% other ethnicities, mean age at baseline 46±12 years) were included in the analysis.Exclusion criteria were diagnosis with lupus less than 6 months ago, age younger than 18 or older than 75, pregnant at baseline, and active HIV patients.

Results: Univariate analysis identified prednisone, disease activity (mean Physician's global assessment, SLEDAI), and renal lupus as predictors of hospitalization over the next 6 months (Table 1). In the multivariate model for number of hospitalizations, use of prednisone at baseline and mean SLEDAI were associated (Table 2).

Table 1. Predictors of hospitalizations (any vs none)—univariate analysis.

		Number (%) hospitalization during followup	P-value
Age at baseline (years)	≤ 40 (n=134)	11 (8.2)	0.21
	> 40 (n=225)	28 (12.4)	
Gender	Female (n=327)	35 (10.7)	0.77
	Male (n=32)	4 (14.3)	
Ethnicity	African-American (n=131)	19 (14.5)	0.096
	Caucasian (n=197)	17 (8.6)	
Family income ($)	≤ 50K (n=165)	21 (12.7)	0.30
	> 50K (n=194)	18 (9.3)	
Education (years)	< 12 (n=24)	2 (8.3)	>0.99
	≥ 12 (n=335)	37 (11.0)	
Use of prednisone at baseline	No (n=224)	17 (7.6)	0.010
	Yes (n=135)	22 (16.3)	
PGA[1] at baseline	≤1 (n=310)	32 (10.3)	0.41
	>1 (n=49)	7 (14.3)	
Mean PGA over year	≤1 (n=304)	28 (9.2)	0.018
	>1 (n=55)	11 (20.0)	
SLEDAI at baseline	≤2 (n=265)	23 (8.7)	0.026
	>2 (n=94)	16 (17.0)	
Mean SLEDAI over year	≤2 (n=242)	19 (7.9)	0.0083
	>2 (n=117)	20 (17.1)	
Anti-dsDNA at baseline	Negative (n=271)	28 (10.3)	0.39
	Positive (n=80)	11 (13.8)

	Yes (n=167)	23 (13.8)	
Urine Pr:Cr ratio at baseline	≤0.5 (n=314)	31 (9.9)	0.049
	>0.5 (n=26)	6 (23.1)	
Baseline history of hospitalizations	No (n=327)	34 (10.4)	0.37
	Yes (n=32)	5 (15.6)	

[1]PGA: Physician's global assessment (0–3 scale)

Table 2. Multivariate Linear Regression Model.

	Effect on number of hospitalizations	P-value
Age at baseline (per 10 years)	0.04 ± 0.02	0.061
Ethnicity (African-American)	0.06 ± 0.06	0.25
Education (<12 years)	−0.05 ± 0.10	0.61
Use of prednisone at baseline	0.14 ± 0.06	0.0091
Mean SLEDAI (per unit)	0.03 ± 0.01	0.0086
Urine Pr:Cr ratio at baseline (per unit)	0.01 ± 0.04	0.73

We next looked at hospitalizations due to lupus. In a multivariate linear regression model, baseline hospitalizations and mean SLEDAI were predictive.

Conclusion: Total hospitalizations are associated with prednisone use and disease activity. Hospitalizations due to SLE were also associated with disease activity captured by SLEDAI. Targeted therapies that reduce SLEDAI would thus be expected to reduce hospitalizations and direct costs.

Shared High Risk of Intensive Care Unit Admission in Three Autoimmune Inflammatory Diseases. Christine Peschken, Carol A. Hitchon, Allan Garland. Charles N. Bernstein, Randy Fransoo and Ruth Ann Marrie, University of Manitoba, Winnipeg, MB

Background/Purpose: Little is known about the influence of autoimmune inflammatory diseases on the risk of critical illness, as defined by Intensive care unit admissions (ICU). Using a large, population-based dataset we determined the incidence of ICU admissions in rheumatoid arthritis (RA), multiple sclerosis (MS) and inflammatory bowel disease (IBD). These conditions are highly prevalent in Western countries and often managed with immunomodulatory therapies.

Methods: In a stable population of over 900,000 adults, hospital claims from an administrative database were linked to a population based ICU database to determine the incidence of ICU admissions from 2000–2010. RA, MS, and IBD patients were compared to cohorts from the general population, matched on sex, year of birth and region of residence, with up to 5 controls per case. Individuals with any diagnostic codes (ICD-9/10) for autoimmune inflammatory disease were excluded from the control cohorts. We used previously published and validated definitions for RA, MS, and IBD. Annual incidence rates were estimated by age group, sex, and geographic region (number of persons in each cohort with at ≥ 1ICU admission/ number of persons alive in that cohort at year-end). Results were age and sex standardized to the general Canadian population. The incidence of ICU admission between the disease specific cohorts and matched cohorts were compared using incidence rate ratios (IRR). The 10 year cumulative incidence of ICU admission for the period 2000–2010 was compared: (number of persons with disease who had ≥ 1 episode of critical illness/ person-years at risk).Hazard ratios for the 10 year period were calculated after adjustment for age, sex, socioeconomic status and comorbidity.

Results: The annual incidence rates of ICU admission over the 10 year period were:RA 0.82–1.18%; MS 0.51–1.07%; and IBD 0.55–1.12%, compared to the matched cohorts; 0.32–0.60%. The IRR for the 10 year cumulative incidence rate was 1.62 (95% CI 1.46–1.80) for RA; 1.54 (95% CI 1.30–1.77) for MS; 1.52 (95% CI 1.36–1.68) for IBD. Hazard ratios over the 10 year period for the 3 diseases were: RA HR=1.86 (95%CI 1.68–2.05); MS HR= 1.65 (95%CI 1.36–2.01); IBD HR= 2.02 (95%CI 1.78–2.28).
Conclusion: The risk of ICU admission is significantly increased in RA, MS and IBD patients compared to the general population. Close to 1% of adults with these diseases develop critical illness each year; representing a substantial cost to the healthcare system.The risks between the 3 diseases are remarkably similar, suggesting shared risks from chronic inflammation and/or immunomodulatory therapy.

940

Incidence of Systemic Lupus Erythematosus in England, 1998–2010. Herve Caspard[1], Amy Steffey[2], Jie Li[2] and Trung N. Tran[2]. [1]MedImmune LLC, Gaithersburg, MD, [2]MedImmune, Gaithersburg, MD

Background/Purpose: Systemic Lupus Erythematosus (SLE) is a chronic auto-immune disease associated with a wide spectrum of clinical manifestations and increased mortality. The most recent data about incidence of SLE in England date back to 1999.

It has been suggested that the incidence of SLE and other auto-immune diseases has increased over time.

Our purpose was:

* To estimate the incidence of SLE in England from 1998 to 2010 and to describe the incidence rate distribution by demographic factors.

* To discuss the hypothesis that the incidence of SLE increased from 2001 to 2010.

Methods: We investigated the incidence of SLE among individuals documented in the Clinical Practice Research Datalink (CPRD) and linked with the Hospital Episode Statistics (HES) database. CPRD is a database of anonymized longitudinal medical records from primary care from over 600 practices in the United Kingdom. HES is a database documenting all admissions to the National Health System hospitals in England that can be linked with CPRD since 1997. All individuals documented in GPRD and HES prior to October 1st, 2010 and aged 18 years or older were retained in the analysis.

Patients with SLE were identified as individuals with at least one relevant diagnosis code in CPRD or HES (list of codes available upon request).

Incident cases were defined as patients with at least 12 months of registration in CPRD prior to the date of first diagnosis. Incidence rates were estimated each calendar year from January 1st 1998 to October 1st 2010.

Results: The incidence rate for the 2001–2010 time period is 5.5 per 100,000 patient*years (table 1): this estimate is very close to the 1998–2000 estimate (5.6 per 100,000 patient*years) and falls within the 95% confidence interval of each calendar year point estimate from 2001 to 2010.

Table 1. Incidence rate estimates per calendar year

Calendar year	Population exposed (patient*years)	Incident cases	Incidence rate (per 100,000 patient*years)
1998–2000	4,213,018	237	5.6 [4.9;6.3]
2001	1,504,620	83	5.1 [4.3;6.7]
2002	1,585,560	89	5.6 [4.4;6.8]
2003	1,639,386	87	5.3 [4.2;6.4]
2004	1,682,720	82	4.9 [3.8;5.9]
2005	1,720,965	88	5.1 [4.0;6.2]
2006	1,768,140	101	5.7 [4.6;6.8]
2007	1,812,779	109	6.0 [4.9;7.1]
2008	1,850,292	111	6.0 [4.9;7.1]
2009	1,859,559	93	5.0 [4.0;6.0]
2010 (through September 30)	1,359,960	79	5.8 [4.5;7.1]
2001-2010	16,784,884	922	5.5 [5.1;5.8]

Incidence rate is higher among women than men: 9.4 versus 1.5 per 100,000 patient*years. It reaches a maximum between 45 and 54 years of age in women (12.2 per 100,000 patient*years) while it keeps growing slightly with age in men; 25%(294) of the incident cases were documented in the HES database only.

Conclusion: These incidence rates of SLE in England from 1998 to 2010 are consistent with prior estimates and with estimates in other western countries.

We did not observe any significant change in the incidence of SLE in England from 2001 to 2010.

Disclosure: **H. Caspard**, None; **A. Steffey**, None; **J. Li**, None; **T. N. Tran**, None.

Validity and Reliability of the Systemic Lupus Activity Questionnaire (SLAQ): A Prospective Study. Yuko Okamoto, Yasuhiro Katsumata, Yasushi Kawaguchi, Sayumi Baba, Kae Takagi, Hisae Ichida, Takahisa Gono, Masanori Hanaoka, Yuko Ota and Hisashi Yamanaka. Tokyo Women's Medical University, Tokyo, Japan

Background/Purpose: Traditional assessments of systemic lupus erythematosus (SLE) disease activity, such as the SLE Disease Activity Index 2000 (SLEDAI-2K) and the Systemic Lupus Activity Measure (SLAM), rely on a physician-obtained history, physical examination, and laboratory evaluation and thus may prove impractical and costly especially for large epidemiologic studies. The Systemic Lupus Activity Questionnaire (SLAQ) was developed based on the SLAM as a more economical way of following and tracking large groups of SLE patients who may be at a distance from a center in epidemiologic studies. The purpose of the present study was to translate and adapt the SLAQ to Japanese and further investigate its validity and reliability using a prospective observational cohort of SLE patients followed at a single university clinic while their physicians score the SLEDAI-2K.

Methods: The English version of the SLAQ was translated, back-translated and culturally adapted to Japanese using standard methodology. Japanese SLE patients who had 4 or more revised American College of Rheumatology (ACR) criteria for SLE were approached during their outpatient attendance in our university clinic. Some of the hospitalized patients during the study period were also eligible to the study. Patients were asked to complete the SLAQ and other related demographic questionnaires such as Medical Outcomes Study Short Form-36 (SF-36) and physicians were asked to complete the SLEDAI-2K and the Systemic Lupus International Collaborating Clinics (SLICC)/ACR Damage Index (SDI). Laboratory items were omitted from SLEDAI-2K scores in this study and the instrument will be called SLEDAI-2K-nolab. Patients were prospectively followed for repeat assessment next year.

Results: A total of 246 patients and 30 physicians (all rheumatologists) participated. The acceptability of the SLAQ was high, with most of items having 100% response rate. The distribution of the SLAQ, the SLEDAI-2K, and the SLEDAI-2K-nolab all skewed to the right. The median SLAQ score was 5 (range 0–32) and the median SLEDAI-2K score was 2 (range 0–18). The SLAQ had a weak correlation with the SLEDAI-2K-nolab (Spearman's $\rho = 0.18$, $p = 0.005$) but not with SLEDAI-2K ($p = 0.71$). The SLAQ demonstrated acceptable internal consistency, with a Cronbach's alpha of 0.78. The SLAQ showed weak correlation with the SDI, and moderate correlation with physical and mental component summary scores of the SF-36 (Spearman's $\rho = 0.17$, -0.53, and -0.54, respectively). Twenty-five patients with stable disease were asked to repeat the SLAQ after 2 weeks and the intraclass correlation coefficient was 0.85, which means good test–retest reliability. These figures come from the first year research and the second year gave similar results. The SLAQ did not demonstrate a good responsiveness by the longitudinal analyses.

Conclusion: We have successfully translated, adapted and validated the Japanese version of the SLAQ. There is evidence of acceptable reliability and validity of the Japanese version of the SLAQ among Japanese patients with SLE. Our study provides evidence of the cross-cultural validity of this tool and can be used to assess disease activities among Japanese patients with SLE.

942

Validity and Reliability of the Lupus Damage Index Questionnaire (LDIQ): A Prospective Study. Yuko Okamoto, Yasuhiro Katsumata, Yasushi Kawaguchi, Sayumi Baba, Kae Takagi, Hisae Ichida, Takahisa Gono, Masanori Hanaoka, Yuko Ota and Hisashi Yamanaka. Tokyo Women's Medical University, Tokyo, Japan

Background/Purpose: The Systemic Lupus International Collaborating Clinics/American College of Rheumatology (ACR) Damage Index (SDI) is a validated instrument for assessing organ damage in systemic lupus erythematosus (SLE). Trained physicians must complete it, thus limiting utility where this is impossible. A self-administered questionnaire, modeled after the SDI, the Lupus Damage Index Questionnaire (LDIQ) has been previously developed and validated. It may allow the ascertainment of this construct in SLE patients followed in the community. The original English version of LDIQ

was subsequently translated into Spanish, Portuguese and French. The purpose of the present study was to translate and adapt the LDIQ to Japanese and further investigate its validity and reliability using a prospective observational cohort of SLE patients followed at a single university clinic.

Methods: The English version of the LDIQ was translated, back-translated and culturally adapted to Japanese using standard methodology. Japanese SLE patients who had 4 or more revised ACR criteria for SLE were approached during their outpatient attendance in our university clinic. Some of the hospitalized patients during the study period were also eligible to the study. Patients were asked to complete the LDIQ and other related demographic questionnaires such as Medical Outcomes Study Short Form-36 (SF-36) and physicians were asked to complete the SDI and the SLE Disease Activity Index 2000 (SLEDAI-2K). Patients were prospectively followed for repeat assessment next year.

Results: A total of 250 patients and 30 physicians (all rheumatologists) participated. The acceptability of the LDIQ was high, with most of items having 100% response rate. The distribution of the LDIQ and SDI both skewed to the right. The median LDIQ score was 2 (range 0–12) and the median SDI score was 1 (range 0–9). The LDIQ had a substantial correlation with the SDI (Spearman's $\rho = 0.71$, $p < 0.001$). Cohen's kappa coefficient, a statistical measure of agreement for qualitative items, between the individual SDI and LDIQ items varied between 0.07–1.00. The damage domains of the LDIQ were not associated with each other, which was reflected in low Cronbach's alpha (0.53). The LDIQ showed poor correlation with the SLEDAI-2K, and mental component summary scores of the SF-36, but had moderate correlation with physical component summary scores of the SF-36 (Spearman's $\rho = -0.08$, -0.11, and -0.41, respectively). Twenty-five patients with stable disease were asked to repeat the LDIQ after 2 weeks and the intraclass correlation coefficient was 0.85, which means good test–retest reliability. These figures come from the first year research and the second year gave similar results. The LDIQ demonstrated a good responsiveness: standardized response mean $= 0.40$ and effect size $= 0.32$ in patients with worsened SDI.

Conclusion: We have successfully translated, adapted and validated the Japanese version of the LDIQ. There is evidence of acceptable reliability and validity of the Japanese version of the LDIQ among Japanese patients with SLE. Our study provides evidence of the cross-cultural validity of this tool and can be used to assess SLE-related damage among Japanese patients with SLE.

943

Impact of Systemic Lupus Erythematosus On Work Productivity and Income in the United States. Alan Oglesby[1], Ellen Sulcs[2], Siva Narayanan[3], Mechele Lee[2] and Cindy Garris[1]. [1]GlaxoSmithKline, Research Triangle Park, NC, [2]Harris Interactive Inc., Rochester, NY, [3]Human Genome Sciences, Inc., Rockville, MD

Background/Purpose: Systemic lupus erythematosus (SLE) is a complex, chronic autoimmune disorder characterized by fluctuating periods of disease activity affecting multiple organ systems. This study was conducted to evaluate the impact of SLE on patients' employment and productivity.

Methods: A longitudinal cohort of employed SLE patients in the United States, recruited through a patient advocacy association and the Harris Chronic Illness Panel, was surveyed online (IRB approved) between Dec 2010 and Aug 2011. Inclusion criteria were 18 years old, self-reported SLE diagnosis, and ≥1 SLE flare in prior 3 months requiring medical attention (taking medications, calling or visiting a physician, or going to the ER or hospital). A control group of employed patients without SLE recruited from HarrisPollOnline (HPOL) were demographically matched (age, sex, race, income, and education) to the employed SLE cohort. Controls met the above inclusion criteria excluding the SLE related criteria and were also surveyed online. A group of unemployed SLE patients were also recruited for research, but not included in this analysis of employed cohorts. Both the employed SLE patients and controls completed baseline and follow-up surveys at the end of 6 months. Questions for the SLE cohort included perceived SLE disease activity over the past 3 months using a 10-point scale (mild: 0–3, moderate: 4–6, severe: 7–10), impact of SLE on work productivity and absenteeism. The control group answered similar questions about the impact of any health conditions on work. Employed and unemployed SLE patients were compared to controls by dependent sample t-tests.

Results: 281 employed SLE patients and 300 employed controls completed the survey; of the 300 control group respondents, 69% reported having ≥1 health condition(s). The mean age in the employed SLE group and control groups was 39.8 and 41.1 years, respectively (p<0.05). Of all surveyed respondents, 96%

were female and 79% were Caucasian (no significant differences across groups). The employed SLE cohort reported fewer overall hours worked per week (25.3 vs 32.8) and more lost work hours per week due to SLE (6.9 hours) than the employed control group due to any health condition (1.6 hours) (all p-values<0.05). While at work, patients reported significantly greater impact on productivity due to SLE (45%) compared to controls for any health reason (13%, p<0.05). In the SLE employed group, the number of work hours missed increased as self-reported disease severity worsened from mild, moderate, to severe (2.0, 4.2, and 7.9 hours, respectively (p<0.05). Hourly employees with SLE (52.3% of SLE cohort) reported losing an average of $346 per week due to their lupus. Similarly, lost income per week increased as SLE activity increased ($49 in mild to $522 in severe, p<0.05).

Conclusion: Patients with SLE reported significantly reduced ability to work compounded by worsening disease activity. For hourly employees with SLE, increased disease activity may have significant detrimental impacts to their earning potential.

944

Job-Related Burden and Effort-Reward Imbalance in Patients with Systemic Lupus Erythematosus.

Jutta G. Richter, Thomas Muth, Ralph Brinks, Tobias Koch, Johannes Siegrist, Nicole Hoffmann, Peter Angerer and Matthias Schneider. Heinrich-Heine-University, Duesseldorf, Germany

Background/Purpose: Working life factors influence patients' (life) satisfaction and well being. Effort at work is part of a social contract that reciprocates effort by adequate reward. Components of work-related rewards matter for health. Research on effort-reward imbalance (ERI) might contribute to the understanding of factors related to the well-being of patients (pts) with systemic lupus erythematosus (SLE). We studied pts' job-tasks-related burdens and stress levels measured by the ERI model.

Methods: In a cross-sectional nationwide study a set of standardized self-administered questionnaires was applied to SLE pts. ERI was assessed by the corresponding questionnaire in pts capable for work. Effort reward ratio (ERR) scores > 1 and upper tertile scores of overcommitment (OCS) reflect relevant values. Based on pts' reported occupations, occupational physicians categorized tasks-related burden into a developed, standardized coding system that included 'working environment burden', 'physical burden', 'mental burden', and 'other burden'. Ethical approval was obtained.

Results: 252 pts (95.2% female) contributed data. Mean age was 40.1 ± 9.4 years, mean disease duration 10.5 ± 7.3 years, mean HAQ 0.8 ± 0.4. 86.0% self-reported at least one comorbidity (range 1–10). 77.4% took at least one immunosuppressive drug (DMARD, range 1–3), 40.5% steroids ≤ 7.5mg, 16.3% steroids >7.5mg, 34.0% NSAIDS.

For ERI results see table 1. 79.5% showed relevant effort-reward imbalance (ERR>1). ERR>1 pts scored significantly lower in the esteem, job security and the job promotion/salary scales (p-values<0.05). Above mentioned personal and disease related factors, pts' self-categorized occupation groups, working environment burden, physical burden, mental burden and other burden did not differ significantly in ERR>1 and ERR≤1 pts.

39.0% had relevant OCS, see table 1. Except HAQ above mentioned personal and disease related factors, working environment burden, physical burden, mental burden and other burden did not differ significantly in pts with OCS in the lower tertiles compared to pts with relevant OCS.

Table 1. ERI and overcommittment scores

Effort mean ± SD	Reward mean ± SD	ERR>1 %	Esteem mean ± SD	Job Security mean ± SD	Job Promotion/ Salary mean ± SD	Overcommittment mean ± SD
15.6 ± 4.9	21.6 ± 9.2	79.5	9.6 ± 4.9	3.9 ± 2.6	8.2 ± 3.7	14.3 ± 4.0

Conclusion: In this first study investigating the ERI in SLE pts a high proportion had effort reward imbalance (ERR>1). Analysis on mechanisms potentially involved in the relation between ERI and SLE showed that job-tasks-related burden scored by occupational physicians and most disease related factors did not differ in ERI and OCS subgroups. Further study data analysis will address pts' perceptions of their job-related burden to develop appropriate support strategies.

945

Work Loss in Systemic Lupus Erythematosus, the General Public, and Other Chronic Conditions.

S. Sam Lim[1], Greg Dennis[2], Hong Kan[3], Priti M. Jhingran[4], Charles T. Molta[5], Gaobin Bao[1] and Cristina Drenkard[1]. [1]Emory University, Atlanta, GA, [2]Human Genome Sciences, Inc., Rockville, MD, [3]GlaxoSmithKline, Research Triangle Park, NC, [4]GlaxoSmithKline R&D, Research Triangle Park, NC, [5]GlaxoSmithKline, Philadelphia, PA

Background/Purpose: Systemic lupus erythematosus (SLE) predominantly develops in young groups, when many are establishing themselves in the workforce and can have a devastating impact on employment. We studied the impact of sociodemographic factors on work loss in SLE, the general public, and other major chronic conditions.

Methods: The Georgians Organized Against Lupus (GOAL) cohort is derived predominantly from the population-based Georgia Lupus Registry and collects annually self-reported measures from validated patients with SLE. The Behavioral Risk Factor Surveillance System (BRFSS) survey samples representative individuals from the general population on self-reported health conditions and behaviors. We studied GOAL SLE participants who lived in the Atlanta metropolitan area surveyed between August 2011 and April 2012, and 4 BRFSS samples (general population and self-reported diabetes, asthma, and cardiovascular disease [CVD]) from the same geographic area, surveyed between 2005-10. The effect of sociodemographic factors on being unemployed/disabled at survey completion in SLE and BRFSS participants aged >18 and <65 was analyzed with logistic regression. We reported the adjusted odds ratios (OR) of being unemployed/disabled for each sociodemographic variable within SLE and 4 BRFSS samples.

Results:

	SLE n=630	General n=6339	Diabetes n=473	Asthma n=783	CVD n=244
Age, mean	45	41	49	38	51
Females %	94	52	51	57	49
Whites %	19	59	51	61	46
Blacks %	81	42	49	39	54
Education ≤high school %	35	23	30	28	34
Unemployed/disabled% (95% CI)	47 (43–50)	12 (11–13)	23 (18–28)	19 (14–23)	33 (25–42)
OR (95% CI) of unemployed/disabled[1]					
Age (Per 5 year increase)	1.1 (1.0–1.2)	1.1 (1.1–1.2)	1.1 (1.0–1.3)	1.2 (1.1–1.3)	0.9 (0.7–1.2)
Gender (Male vs Female)	1.2 (0.6–2.4)	1.2 (0.9–1.5)	0.9 (0.5–1.7)	2.0 (1.0–3.9)	1.0 (0.5–2.2)
Race (Black vs White)	2.7 (1.7–4.3)	1.9 (1.4–2.5)	1.0 (0.6–2.0)	1.7 (0.9–3.2)	1.5 (0.7–3.1)
Marital Status (Married vs other[2])	0.5 (0.4–0.7)	0.5 (0.4–0.6)	0.4 (0.2–0.7)	0.3 (0.2–0.7)	0.2 (0.1–0.4)
Education (≤High School vs >High School)	2.1 (1.5–3.0)	3.0 (2.3–3.9)	4.0 (2.2–7.3)	2.9 (1.5–5.7)	2.5 (1.1–5.8)

[1]Adjusted by the other sociodemographics
[2]never married, separated, divorced, widowed

Conclusion: The burden of unemployment/disability was significantly higher in SLE than in other chronic diseases, even when the mean age of SLE and the education level were similar across groups. Less than 1/3 of individuals with diabetes, asthma and CVD were unemployed, as compared to almost 50% of SLE. Black race was associated with unemployment/disability in SLE and the general population, but not in other chronic diseases. Lower education and not being married increased the risk of unemployment/disability in all groups. Important factors, such as disease severity, treatment response, or access to care in black patients with SLE must be further explored in order to reduce the burden of work loss in SLE.

946

Self-Reported Disease Activity and Health-Related Quality of Life in a Longitudinal Cohort of Patients with Systemic Lupus Erythematosus.

Siva Narayanan[1], Ellen Sulcs[2], Alan Oglesby[3], Cindy Garris[4] and Mechele Lee[2]. [1]Human Genome Sciences, Inc., Rockville, MD, [2]Harris Interactive Inc., Rochester, NY, [3]GlaxoSmithKline, Research Triangle Park, NC, [4]GlaxoSmithKline R&D, Research Triangle Park, NC

Background/Purpose: Systemic lupus erythematosus (SLE) is a complex, multisystem autoimmune disease with variable clinical manifestations and an unpredictable waxing and waning disease course impacting patient health-related quality of life (HRQoL). The objective of this analysis is to portray the self-perceived burden of illness by assessing patterns of self-reported disease activity and HRQoL over the course of 6 months.

Methods: A longitudinal cohort of employed SLE patients in the U.S meeting the following inclusion criteria were recruited between Dec 2010 and March 2011 through a patient advocacy association and the Harris Chronic Illness Panel: ≥18 years old, self-reported SLE diagnosis, and ≥1 SLE flare in prior 3 months requiring medical attention (physician/ER/ hospital encounter or taking SLE medications). SLE patients completed a baseline (BL) and six monthly follow-up (FU) surveys online. Monthly surveys included assessments of self-perceived SLE disease activity (scale: 0 (no activity) to 10 (most activity); mild: 0–3, moderate: 4–6 & severe: 7–10), Lupus Impact Tracker (LIT; scale: 0 (low) to 100 (high); a 10-item HRQoL tool assessing disease impact on pain, fatigue, ability to perform daily activities, etc), self-reported flares & symptoms and work/productivity (data not shown).

Results: 272 SLE patients (mean age: 40.9 yrs; female: 96%; Caucasian: 78%; had at least college education: 63%) who completed the BL and $\geq=1$ FU survey during the 6-month follow-up period were included in the analysis. Time since first onset of SLE symptoms and time since SLE diagnosis were 12.5yrs and 7.8yrs respectively. At BL, mean disease activity score was 5.9; patients reporting different levels of severity of lupus disease activity at BL and each of the monthly FUs were clustered consistently over time as follows - Mild: 15–16%, moderate: 40–42%, severe: 43–45%. For all patients, at BL, mean LIT score was 49.3, and monthly FUs ranged between 44.3 & 48.7. Fatigue, pain, and difficulty concentrating were identified by over 55%, 55%, and 30% of patients respectively as occurring at least 'most or all of the time' at every evaluation period. LIT scores for patients reporting mild, moderate and severe disease activity across the individual surveys were in the range of: 30.2–40.9, 49.7–59.7 and 56.8–75.2 respectively. Mean LIT scores statistically significantly ($p<.001$) correlated to disease activity scores at BL and monthly assessments (pearson correlation coefficients range: 0.57–0.67).

Conclusion: Overwhelming majority of SLE patients in the study consistently rated their disease activity to be moderate-to-severe over the course of 6-months, and it significantly correlated with HRQoL measured by LIT. While patient self-assessment of disease activity may differ from physician's clinical assessment, consistently high patient disease severity reported by the study cohort highlights the perceived disease burden. Incorporating patient perspective in clinical decision making may be important to consider in managing patients optimally and alleviate their burden of illness.

The Impact of Dyspigmentation and Scarring in Cutaneous Lupus On Quality of Life. Saroj M. Verma[1], Joyce Okawa[2], Kathleen Propert[1] and Victoria P. Werth[3]. [1]University of Pennsylvania, Philadelphia, PA, [2]Perelman School of Medicine at the University of Pennsylvania and Philadelphia V.A. Medical Center, Philadelphia, PA, [3]University of Pennsylvania and Philadelphia V.A. Medical Center, Philadelphia, PA

Background/Purpose: Patients with more severe cutaneous lupus activity have poorer quality of life. The main objective of the current study was to evaluate the impact that lupus-related disease damage had on skin-specific quality of life and the differences observed within a population of CLE patients from different racial backgrounds with respect to disease damage and its impact on quality of life.

Methods: Patients were enrolled into our prospective database and evaluated with a validated cutaneous lupus-scoring tool (CLASI). Data collected included sex, race, diagnosis, Cutaneous Lupus Area Activity and Severity Index (CLASI) scores, and Skindex-29 QoL scores. These parameters were analyzed at the initial and last visits. CLASI damage scores (dyspigmentation and scarring) and CLASI activity scores were collected, grouped by race, and correlated with Skindex-29 domains.

Results: 223 patients were analyzed at baseline, with 141 of these patients completing more than one study visit. The majority of patients were Caucasians (63.7%), followed by African Americans (29.1%) and Asian Americans (4.0%). African Americans accounted for a disproportionate percentage of both localized (50% of cases) and generalized (48.9% of cases) DLE. Median CLASI damage scores significantly differed between African Americans, Caucasians, and Asian Americans, at both first (8.5, 4.0, 7.0) (Kruskal-Wallis $p<0.0001$) and last visit (10.0, 6.0, 8.5) (Kruskal-Wallis $p<0.01$), (Dunn's Multiple Comparison $p<0.0001, p<0.01$). CLASI damage scores in African Americans correlated with CLASI activity scores (Spear-

man's r=0.45, $p=0.0003$). There was no significant correlation between CLASI damage scores and Skindex domains overall. Individually, dyspigmentation and scarring also did not have a significant effect on Quality of Life.

Conclusion: In conclusion, disease damage does not affect quality of life, as measured by the Skindex-29.Differences were found in CLE patients of different races: African American patients with CLE, do exhibit a high rate of DLE, experience damage early in their disease course, frequently in conjunction with disease activity

Antibody-Based Prediction Rules for Connective Tissue Disease: Analysis of 12,555 Patients with Antinuclear Antibody Testing. Ryo Rokutanda[1]. Mitsumasa Kishimoto[1], Yasuharu Tokuda[2], Ken-ichi Yamaguchi[1], Hisanori Shimizu[1], Yasuhiro Suyama[1], Yuri Ohara[1], Yoichiro Haji[1], Chisun Min[1], Akira Takeda[1], Yukio Matsui[1] and Masato Okada[1], [1]St. Luke's International Hospital, Tokyo, Japan, [2]University of Tsukuba, Ibaraki, Japan

Background/Purpose: Antinuclear antibody (ANA) is widely used as a screening test for connective tissue diseases (CTDs). The sensitivity of this test is high in 3 CTDs--systemic lupus erythematosus (SLE), systemic sclerosis (SSc), and mixed connective tissue disease (MCTD). ANA-associated specific autoantibodies are also identifiable in 3 additional CTDs including polymyositis and dermatomyositis (PM/DM), as well as primary Sjögren syndrome (SS).However, appropriate cutoff points for ANA titers or in combination with other CTD-specific antibodies remains unclear.

Methods: We reviewed records for all patients (n=12,555) with ANA immunofluorescence assay testing from January 2003 to June 2012. Among 3302 patients with positive ANA (≥a40), 94 were excluded due to lack of information about ANA titers. Data collection also included specific CTD diagnoses, ANA titers, and results of specific antibody tests for DNA, Sm, U1RNP, Ro, La, centromere, Scl-70, and RNA polymerase III. We calculated sensitivity, specificity, and positive (PPV) and negative (NPV) predictive values for diagnosing each CTD at different ANA cutoffs. We then performed classification and regression tree (CART) analysis to develop prediction rules for each CTD. Potential predictors included ANA titers, ANA staining patterns, and specific antibody test results.

Results: Of 12,461 patients with ANA testing, 665 patients (5.3%) were diagnosed as having at least one of the 6 CTDs of interest. Area under the ROC curves of ANA testing were 0.943, 0.977, 0.926, 0.840, and 0.740 for SLE, MCTD, SSc, SS, and PM/DM, respectively. The sensitivities of ANA (≥a40) for SLE, SSC, MCTD, SS, PM/DM were 98.6%, 95.9%, 100%, 83.0%, and 69.6%, while PPV was 6.7%, 5.1%, 0.7%, 6.3, and 1.7%, respectively. Prediction rules developed by CART were as follows: (1) ANA (≥a40) with anti-DNA antibody (PPV: 70.3% for SLE), (2) ANA (≥a40) with anti-U1RNP antibody (PPV: 26.8% for MCTD), (3) ANA (≥a320) with anti-centromere antibody (PPV: 44.7% for SSc), and (4) ANA (≥a320) and anti-Ro without anti-DNA (PPV: 49% for SS).

Conclusion: ANA testing demonstrates substantial sensitivity, but has low PPV for CTDs. Nonetheless, in combination with other antibody testing, our prediction rules reveal a high specificity and PPV for diagnosing CTDs.

The Inverse Association Between Obesity and Anti-Nuclear Antibodies Is Modified by Systemic Inflammation and Maybe Associated with Body Composition. Irene Blanco, Monalyn Labitigan and Matthew Abramowitz. Albert Einstein College of Medicine, Bronx, NY

Background/Purpose: Obesity and abdominal adiposity have been frequently associated with inflammation. However, an association of obesity with a decreased likelihood of anti-nuclear antibodies (ANAs) was recently reported in the general population. We used data from adult participants ≥20 years of age in the National Health and Nutrition and Examination Survey 1999–2004 to further explore this association.

Methods: To rule out a possible previous history of autoimmune disease, participants were excluded if they reported a history of arthritis other than osteoarthritis, thyroid or liver disease, or steroid use. ANAs were screened

using indirect immunofluorescence (IF). Titers were done on samples with IF≥ 3+. We subsequently strictly defined positive ANA as an ANA titer ' 1:160. Overweight and obesity were classified by traditional BMI criteria. High and low C-reactive protein (CRP) were defined using the 75th percentile cutpoint as ≥0.42 and <0.42 mg/dL, respectively. Dual-energy X-ray absorptiometry (DEXA) was used to determine body composition. Logistic regression models were created to examine associations with ANA status and were adjusted for demographics, comorbidities, smoking status, and total cholesterol.

Results: 2552 participants were included in our analyses. Obese participants were older (p<0.001), more likely to be men (p=0.004) and to have comorbidities, and had higher levels of CRP (<0.001).After multivariable adjustment, obesity was associated with a decreased odds of having ANAs (OR 0.78, 95%CI 0.62–0.99). However when adding log-transformed CRP into our model, this association was no longer significant (OR 0.85, 95%CI 0.62–1.15), and there was evidence of effect modification by CRP (p=0.12). To study the effect of systemic inflammation, as measured by CRP, we then stratified our models based on the CRP cutpoint.Among participants with low CRP (<0.42), obesity was again associated with a reduced likelihood of ANA positivity (OR 0.69, 95%CI 0.48–0.99), but a trend was seen in the opposite direction among those with high CRP (≥0.42) (OR 1.77, 95%CI 0.81–3.88).When looking specifically at the 1143 obese and overweight participants with low CRP, ANA positivity was associated with a higher prevalence of cardiovascular disease (p=0.02) and higher % total body fat (p=0.007), trunk fat (p=0.02), and non-trunk fat (p=0.004). This association, however, was not found in the high CRP group.

Conclusion: In the general population the association of obesity with ANA is modified by the presence of systemic inflammation as measured by CRP, where the inverse association previously found is eliminated when controlling for CRP. While this inverse relationship remains among obese participants with low CRP, when these obese and overweight participants are ANA positive, it is associated with greater total body and trunk fat. Therefore it is possible that body composition, particularly fat distribution, is driving autoimmunity in the general population even in the absence of systemic inflammation. Further studies are needed to determine if in fact this is the case.

Performance of Various Anti-Nuclear Antibody Methodologies in the Assessment of Autoimmune Connective Tissue Diseases. Xiaoli Deng, Cynthia S. Crowson, Helen Khun, Melissa R. Snyder and Kevin G. Moder. Mayo Clinic, Rochester, MN

Background/Purpose: The anti-nuclear antibody (ANA) is the classic biomarker associated with autoimmune connective tissue diseases (CTDs). ANA testing is often ordered as part of the evaluation of patients with suspected CTD. Different methods, including indirect immunofluorescence assays (IFAs), enzyme immunoassays (EIAs), and multiplex immunoassays (MIAs) are currently used by clinical labs for general ANA screening. However, because the methodologies are very different, discordance between results may be observed, leading to challenges in interpretation. The purpose of this study is to analyze the performance of these methods in a subset of patients referred for rheumatology consultation.

Methods: A cohort of patients who had an ANA ordered for clinical assessment and a rheumatology consultation at our institution in 2010– 2011 were enrolled. ANA testing was performed by IFA (Zeus Scientific), EIA (BioRad), and MIA (BioRad). A titer of ≥1:40 for the IFA and a value >1.0 for the EIA were identified as positive. Autoantibodies to dsDNA, chromatin, ribosome P, SS-A, SS-B, Sm, Sm/RNP, RNP, Scl-70, Jo-1 and centromere B were detected by MIA; positivity for at least 1 specific autoantibody identified the ANA as positive. Sensitivities and specificities were computed and were compared using McNemar's test.

Results: In the study cohort (n=327; 81% female; mean age 52 [sd: 16] years), a subset had no identifiable autoimmune disease (non-auto; n=87) and the remaining patients had a diagnosed autoimmune CTD (auto CTD; n=240), including systemic lupus erythematosus (SLE; n=51), Sjogren syndrome (SS; n=34), mixed CTD/undifferentiated CTD (MCTD/UCTD; n=51), rheumatoid arthritis (RA; n=33), and various other miscellaneous CTDs (n=71). Sensitivities and specificities of the IFA, EIA and MIA within these groups are shown in the table.

| | | Sensitivity | | | Specificity |
	Auto CTD (n=240)	SLE (n=51)	SS (n=34)	MCTD/UCTD (n=51)	Non-Auto (n=87)
IFA	92%	100%	100%	100%	25%
EIA	92%	98%	100%	100%	28%
MIA	75%	92%	100%	82%	62%

In the auto CTD group overall, IFA and EIA had similar sensitivities (p=0.83), both of which were significantly higher than MIA (p<0.001). However, in the non-auto group, the MIA demonstrated significantly improved specificity compared to both the IFA and EIA (p<0.001). In specific CTD groups, all SS patients were ANA positive by all 3 methods. In SLE patients, the EIA and IFA had similar sensitivities (p=0.32); the sensitivity of the MIA was significantly lower than the IFA (p=0.046) and marginally lower than the EIA (p=0.08). In the MCTD/UCTD group, the EIA and IFA were positive in all patients, and the MIA had significantly lower sensitivity (p=0.003).

Conclusion: The sensitivities of IFA, EIA, and MIA vary significantly depending on the specific diagnostic category. Although the sensitivities of IFA and EIA tend to be improved over the MIA, the specificities of these methods are a significant issue. Further comparisons of methods used for ANA screening can provide valuable information that could lead to improved interpretation and utilization of lab testing.

A Systematic Review of Quality of Prognosis Studies in Systemic Lupus Erythematosus. Lily Siok Hoon Lim[1], Senq-J Lee[1], Brian M. Feldman[2], D. D. Gladman[3], Eleanor Pullenayegum[4] and Earl D. Silverman[5]. [1]Hospital for Sick Children, Toronto, ON, [2]The Hospital for Sick Children, Toronto, ON, [3]Toronto Western Hospital and University of Toronto, Toronto, ON, [4]McMaster University, Hamilton, ON, [5]Pediatric Rheumatology Collaborative Study Group (PRSCG), Toronto, ON

Background/Purpose: Prognosis studies study future outcomes and/or seek to identify predictive or associative factors associated with outcomes. Strong and consistent prognostic factors can be used to individualize management and better outcomes of patients. Many prognostic factors have been identified in SLE but few have been consistent. We hypothesize that this is due to flawed study design. We aim to systematically assess methodological quality of prognosis studies in SLE.

Methods: A systematic search of prognosis studies in SLE was performed in MEDLINE and EMBASE, from January 1990 to June 2011. Non-English literature, non-original research, non- full length reports and animal studies were excluded. Of 5419 articles subjected to a title and abstract screen, 1039 articles were found. A representative sample of 150 articles was selected using a random number generator and assessed by 2 reviewers. Studies were classified according to design and the clarity of research question was assessed. Each study was assessed by a risk-of-bias tool "QUality In Prognosis Studies" (QUIPS) in 6 domains: study participation, study attrition, measurement of prognostic factors, measurement of outcomes, measurement/adjustment for confounders and appropriateness of statistical analysis. Information on missing data was also collected.

Results: Of 150 articles, 15 were pediatric studies, 3 made comparisons of pediatric and adult patients and the remainder were adult studies. The majority were published in rheumatology journals (69%). Cohort design was used in 67% of studies; the remainder used cross-sectional (21%), case-control (5%) and other designs (7%). The research question clearly included study population in 92%, prognostic factor in 54% and outcome in 61% of studies. High risk of bias (QUIPS) was noted in 57% of studies for study participation, 57% for attrition, 20% for prognostic factor, 18% for outcome, 65% for confounders and 36% for statistical analyses. Confounders were named in the methods section in only 12% of studies. Some consideration for confounding was built into the design of 21% of studies. The amount of missing data could not be assessed in 39% of studies.

Conclusion: Inadequate articulation of research questions for prognostic factors, poor design addressing confounding, study participation and attrition and inadequately reported information on missing data limited the quality of prognosis studies in SLE. Future prognosis studies should be designed with better consideration to the above factors to improve methodological rigor.

Cognitive Behavioral Therapy and Milnacipran in Combination Appears to Be More Efficacious Than Either Therapy Alone. Dennis C. Ang[1], Mark P. Jensen[2], Jennifer L. Steiner[3], Janna Hilligoss[1], Richard Gracely[4] and Chandan Saha[5]. [1]Indiana University, Indianapolis, IN, [2]Seattle, WA, [3]Indianapolis, IN, [4]Chapel Hill, NC, [5]Indiana University

Background/Purpose: The two treatment options that have received the significant attention in fibromyalgia (FM) management are cognitive behavioral therapy (CBT) and medications. Given the fact that either therapy alone appears to only produce modest improvements in clinical symptoms, we completed a 3-arm randomized attention-controlled trial whose primary aim was to obtain preliminary estimates of the effects of combined CBT and milnacipran on primary clinical endpoints: changes in weekly average pain intensity (daily electronic recording of pain scores) and physical function (SF-36 physical component summary score).

Methods: Fifty eight patients with FM were randomized to one of the 3 treatment arms: (1) combination therapy (n=20), (2) drug + education attention (n=19), and (3) placebo + CBT (n=19). Throughout the 21-week study, subjects received either milnacipran (50 mg BID) or placebo (BID). Subjects also received 8 sessions of telephone-delivered CBT or educational instructions, but only from baseline to week 9. Assessments were conducted at baseline, week 9 and 21. Secondary clinical endpoints included changes in PHQ-8 depression severity (0–24), and evoked (thumb) pressure pain scores (0–20), a measure of pain sensitivity.

Results: Characteristics of the 58 FM subjects: mean age= 46.6 (10.4) years; female=93%; whites= 81%; high school graduates=71%; concomitant opioid analgesics=43%; PHQ-8 depression=10.55 (4.79); evoked pressure pain= 8.8 (0.59); weekly average pain intensity = 6.31 (1.27); and SF-36 physical function= 45.26 (22.4).

Compared to drug alone, combination therapy demonstrated a medium effect on reducing weekly average pain intensity (effect size/ES=0.67) and in improving SF-36 physical function (ES=0.60). The magnitude of change in the pain intensity score in the combination group was more than twice the magnitude of change in the drug monotherapy group.Compared to drug alone, CBT alone was marginally efficacious in improving SF-36 physical function. No significant between group differences were seen in improvement in depression severity and change in evoked pain scores. Interestingly, subjects in the drug groups (i.e., combination and drug alone) became less sensitive to pressure stimuli compared to subjects in the CBT monotherapy group, *albeit* this difference was not statistically significant.

Table 1.

	Combination therapy N=17	Drug monotherapy N=17	CBT monotherapy N=15	P values Combo vs. drug Combo vs. CBT Drug vs. CBT	Cohen's d (Effect sizes)
Primary Outcomes					
Δ Weekly average¶ pain intensity score	−2.15 (0.43)†	−0.97 (0.43)†	−1.67 (0.45)†	*0.067*	0.67
				0.441	0.27
				0.286	0.40
Δ SF-38 physical component summary score	13.47 (3.74)†	4.05 (3.84)	15.04 (4.01)†	*0.092*	0.60
				0.775	0.10
				0.058	0.70
Secondary Outcomes					
Δ PHQ-8 depression score	−2.65 (1.06)†	−2.93 (1.07)†	−3.19 (1.11)†	0.860	
				0.727	
				0.865	
Δ Evoked pain scores	−0.76 (1.20)	−0.41 (1.22)	0.78 (1.27)	0.838	
				0.379	
				0.504	

Δ: Baseline to week 21 change in the specified variable; Values represent means and standard error
†Significant <u>within</u> group difference (p<0.04)

Conclusion: Based on the observed effect sizes, our preliminary data justifies pursuing a larger definitive trial to test the superiority of combination therapy vs. monotherapy.Additionally, a direct comparison of CBT vs. drug monotherapy is warranted to inform future health care decisions.

Comparative Symptom Severity of Patients Satisfying Chronic Widespread Pain and Fibromyalgia Criteria. Frederick Wolfe[1], Brian Wallitt[2], Robert S. Katz[3] and Winfried Häuser[4]. [1]National Data Bank for Rheumatic Diseases, Wichita, KS, [2]Washington Hospital Center, Baltimore, MD, [3]Rush University Medical Center, Chicago, IL, [4]Klinikum Saarbrücken, Saarbrücken, Germany

Background/Purpose: Chronic widespread pain (CWP) is often used as a surrogate for fibromyalgia in epidemiological research, particularly in Europe and in whiplash-related injuries. This CWP substitution occurred because it was operationally impossible to perform tender point examinations in epidemiological and survey research. CWP is a requirement for fibromyalgia diagnosis when the American College of Rheumatology (ACR) 1990 criteria are used. 20–35% of patients with CWP will also satisfy fibromyalgia criteria. Despite the common use of CWP, it is not clear how closely CWP positive patients resemble those with fibromyalgia, and whether CWP is a valid substitution for fibromyalgia. In this report we determined the relative severity of patients satisfying the CWP and fibromyalgia criteria.

Methods: We studied 6,583 rheumatic disease patients who completed a research questionnaire that contained assessments of criteria and severity variables. Fibromyalgia was diagnosed using the 2010 American College of Rheumatology (ACR) criteria for fibromyalgia, as modified for survey research. Widespread pain used the 1990 ACR definition: pain above and below the waist, on the left and right sides of the body, and involving the axial skeleton. Severity measures included the Polysymptomatic Distress Scale (PSD) and the Symptom Severity (SS) scale from the 2010 criteria. In addition, we employed other standard assessments of severity, including measures of pain, sleep, fatigue and quality of life. We categorized patients as a) without CWP, b) with fibromyalgia, c) with CWP assuming 20% of CWP cases had FM, and d) with CWP assuming 33% of CWP cases had fibromyalgia (Table 1).

Table 1. Severity status of patients with fibromyalgia or chronic widespread pain

Variable	Not Widespread pain Mean (95% C.I.)	FMS Mean (95% C.I.)	Widespread Pain At 20% FM Prevalence	Widespread Pain At 33% FM Prevalence
VAS Pain (0–10)	2.8 (2.7, 2.9)	6.1 (6.0, 6.3)	4.3 (4.2, 4.4)	4.6 (4.5, 4.7)
VAS Fatigue (0–10)	3.2 (3.1, 3.3)	7.0 (6.9, 7.1)	4.4 (4.3, 4.5)	4.8 (4.7, 5.0)
VAS Sleep problem (0–10)	3.1 (3.0, 3.2)	6.5 (6.3, 6.6)	4.3 (4.2, 4.5)	4.7 (4.6, 4.8)
Mood (0–10)	2.4 (2.3, 2.4)	4.1 (4.0, 4.2)	2.9 (2.8, 2.9)	3.1 (3.0, 3.2)
HAQ (0–3)	0.7 (0.6, 0.7)	1.5 (1.4, 1.5)	1.1 (1.0, 1.1)	1.1 (1.1, 1.2)
VAS Pt. Global (0–10)	2.8 (2.8, 2.9)	5.8 (5.7, 5.9)	4.1 (4.0, 4.2)	4.3 (4.2, 4.4)
SS Scale (0–12)	3.3 (3.2, 3.4)	7.7 (7.6, 7.8)	4.3 (4.2, 4.4)	4.9 (4.8, 5.0)
WS Pain Index (0–19)	2.1 (2.0, 2.3)	12.3 (12.1, 12.4)	8.2 (8.0, 8.4)	8.9 (8.7, 9.1)
PSD scale (0–31)	6.0 (5.8, 6.2)	20.6 (20.4, 20.9)	13.5 (13.2, 13.8)	14.7 (14.5, 15.0)
EQ-5D (0–1)	0.80 (0.79, 0.80)	0.56 (0.55, 0.57)	0.7 (0.7, 0.7)	0.7 (0.7, 0.7)
PCS	41.8 (41.4, 42.1)	29.3 (28.9, 29.8)	34.8 (34.3, 35.2)	33.9 (33.6, 34.3)
MCS	50.5 (50.1, 50.9)	39.5 (39.0, 40.0)	47.6 (47.1, 48.2)	46.3 (45.8, 46.8)
VAS QOL (0–100)	71.2 (70.5, 71.9)	52.6 (51.7, 53.5)	63.4 (62.5, 64.3)	61.8 (61.0, 62.7)

Results: Figure 1 shows the relation of both measures to PSD in the overall sample.X and y lines cross when probability of diagnosis is >= 0.5. This occurs at 9.3 and 13.3 on the PSD scale for CWP and FM, respectively. Table 1, adjusted for age and sex, demonstrates that patients with fibromyalgia have more severe symptoms than those with CWP at 20% and 33% prevalence levels. For the 3 clinical VAS scales, fibromyalgia patients are approximately 30% more severe than those with CWP.
Conclusion: Patients satisfying fibromyalgia criteria have a more severe illness than those with CWP. The use of CWP as a surrogate measure of fibromyalgia substantially underestimates fibromyalgia severity, but still identifies a group of severe patients.

Post–Surgical Outcome Is Correlated with Pre–Surgical Symptoms of Fibromyalgia in Patients Undergoing Spinal Surgery. Jacob N. Ablin[1], Mark Berman[1], Eyal Behrbalk[2], Dan Buskila[3], Gilad Regev[2] and Zvi Lidar[2]. [1]Tel Aviv Sourasky Medical Center, Tel Aviv, Israel, [2]Department of Neurosurgery and Orthopedic, Tel Aviv Sourasky Medical Center, Tel Aviv, Israel, [3]Beer-Sheva, Israel

Background/Purpose: Chronic pain is a major symptom for which patients undergo spinal surgery. At the same time, chronic pain is considered an entity in and of itself, often constituting part of the clinical spectrum of central sensitization (e.g. fatigue, cognitive impairment etc) thus overlapping with the fibromyalgia syndrome (FMS).

The impact of surgical intervention on chronic pain is not well known. While such interventions may remove a local "pain generator" they may simultaneously constitute a form of physical trauma, as well as entailing prolonged immobilazion, both potentially detrimental for fibromyalgia patients.

The aim of this study was to evaluate patients who undergo spinal surgery for presence of central pain and central sensitization symptoms and evaluate the correlation between these symptoms and the surgical outcomes.

Methods: Participants were patients scheduled for spinal surgery. Pre-surgical evaluation included physical examination and manual dolorimetry, documenting the 1990 ACR FMS classification criteria. In addition, patients filled out the widespread pain index (WPI) and the Symptom Severity Scale (SSS) which are part of the suggested 2010 diagnostic criteria of fibromyalgia, as well as the fibromyalgia-Impact Questionnaire (FIQ) and SF-36.

Eight weeks after surgery, patients underwent follow-up evaluation. Statistics: Spearman correlations were calculated between the pre-surgery parameters (WPI and SSS) and the change in SF-36 items. P values under 0.05 were considered significant.

Results: Twenty eight patients (18 male, 10 female) were recruited. The average age was 56.3 (23–85). The average BMI was 26.7 kg. Three patients fulfilled ACR 1990 fibromyalgia criteria (10.7%), whereas 8 patients fulfilled the 2010 diagnostic criteria (28.6%).Thirteen patients were available for post–surgical evaluation.

Table 1 presents the correlations calculated between the pre–surgical WPI and SSS and the change in the SF-36 domains: Physical Functioning (PF), Role–Physical (RP), Bodily Pain (BP), General Health (GH), Vitality (VT), Social Functioning (SF), Role Emotional (RE), Mental Health (MH) as well as the Mental Component Score (MCS) and Physical Component Score (PCS). A significant negative correlation was observed between the WPI and the delta RP item; a significant negative correlation was also observed between the SSS and the delta of the GH and RE items.

	ΔTP	ΔPF	ΔRP	ΔBP	ΔGH	ΔVT	ΔSF	ΔRE	ΔMH	ΔPCS	ΔMCS
WPI-correlation	0.03	−0.04	**−0.72**	0.15	−0.33	0.09	0.15	−0.31	−0.01	−0.28	0.06
WPI-P value	0.95	0.88	**0.006**	0.63	0.27	0.77	0.62	0.30	0.96	0.34	0.84
SSS–correlation	0.25	0.20	−0.32	−0.41	**−0.69**	0.51	0.31	**−0.56**	0.04	−0.31	−0.18
SSS-P value	0.58	0.51	0.28	0.16	**0.008**	0.077	0.31	**0.047**	0.90	0.30	0.55

Conclusion: FMS symptoms were highly prevalent among patients scheduled for spinal surgery (28.6%). A negative correlation was observed between pre-surgical severity of FMS symptoms and components of the post-surgical SF-36. Patients with symptoms of FMS may have a poor outcome after spinal surgery. The clinical utility of surgical intervention in such patients should be carefully evaluated and treatment specific for FMS considered, before embarking on a surgical course.

Learning Disability in Fibromyalgia Patients: FMS Patients Report More Language and Spatial Difficulties. Robert S. Katz[1], Alexandra Small[2]. Carlen Katz[3] and Susan Shott[1], [1]Rush University Medical Center, Chicago, IL, [2]University of Illinois Medical School, [3]Rheumatology Associates, Chicago, IL

Background/Purpose: Fibromyalgia patients are reported to have central sensitization and abnormal central processing of sensory input. Fibromyalgia patients alsohave more neurocognitive complaints and abnormalities on certain types of neurocognitive testing, especially the Stroop test for naming speed and a distraction test, the Auditory Consonant Trigram.To evaluate other possible central nervous system dysfunction, we asked fibromyalgia patients and patients with other rheumatic diseases in a questionnaire whether or not they had symptoms and features of a learning disability.

Methods: Office patients and controls were asked to complete a questionnaire about difficulties in reading, writing, body awareness/spatial relationships, and oral expressive language. A score consisting of the percentage of items for which the respondent reported difficulty was obtained for each of these areas. Four diagnosis groups were compared with respect to questionnaire responses: 85 FMS patients, 39 RA patients, 21 SLE patients, and 14 controls without rheumatic diseases. The Kruskal-Wallis and Mann-Whitney tests were used to compare scores and the chi-square test of association was used to compare percentages, with a 0.05 significance level.

Results: Compared to controls, FMS patients had significantly worse reading and oral expressive language scores (p = 0.001). FMS patients had significantly worse scores for all four areas than the RA and SLE groups (p < 0.001–0.007). There were no statistically significant differences between the RA, SLE, and control groups with respect to any of the scores. FMS patients were significantly more likely to report the following difficulties: making mistakes when reading like skipping words or lines (FMS 43%, controls 0%, RA 3%, SLE 5%, p < 0.001); reading the same line twice (FMS 57%, controls 14%, RA 15%, SLE 19%, p < 0.001); problems remembering what was read (FMS 59%, controls 0%, RA 11%, SLE 24%, p < 0.001); difficulty understanding the main idea or identifying the important details from a story (FMS 27%, controls 0%, RA 5%, SLE 14%, p = 0.007); problems with grammar or punctuation (FMS 28%, controls 14%, RA 8%, SLE 0%, p = 0.004); tendency to be clumsy or uncoordinated (FMS 41%, controls 7%, RA 10%, SLE 10%, p < 0.001); difficulty with eye-hand coordination (FMS 27%, controls 7%, RA 5%, SLE 5%, p = 0.004); difficulty expressing self in words (FMS 42%, controls 7%, RA 8%, SLE 5%, p < 0.001); trouble finding the right words to say in a conversation (FMS 57%, controls 8%, RA 11%, SLE 24%, p < 0.001); and trouble talking about a subject or getting to the point of a conversation (FMS 43%, controls 7%, RA 5%, SLE 5%, p < 0.001).

Conclusion: Fibromyalgia patients, compared to rheumatic disease controls, are found to haveproblems in reading, writing, body awareness, and spatial relationships and problems in oral expressive language.Fibromyalgia patient responses suggested frequent symptoms of a learning disability.

Learning disability may be another part of central nervous system dysfunction in fibromyalgia patients.Patients, practitioners and educators should be made aware of the association between fibromyalgia and learning disabilities.

Key Psychological Processes Associated with the Fibromyalgia Phenotype Exist On a Continuous Spectrum with Asymptomatic People. Katrina Malin[1] and Geoffrey O. Littlejohn[2]. [1]Monash University, Clayton, Australia, [2]Monash Medical Centre and Monash University, Clayton, Victoria, Australia

Background/Purpose: The core features of the fibromyalgia phenotype, the widespread pain and widespread tenderness, represent one extreme of a continuous spectrum with asymptomatic people at one end and those meeting criteria for fibromyalgia at the other. A number of key central processes associate with fibromyalgia, such as personality [neuroticism and Type A] and psychological characteristics, including attitude, control, coping, catastrophizing and stress-reactivity.We hypothesized that these psychologically linked processes also exist on a single continuous spectrum from normal in asymptomatic people to abnormal in fibromyalgia, and that increasing the "gain" of these processes will increase the features contributing to the fibromyalgia phenotype.

Methods: We identified 98 women with fibromyalgia diagnosed according to standard ACR criteria. Applied questionnaires included the Big 5 Personality Inventory, Type A scale, Fibromyalgia Impact Questionnaire, Perceived Control of Internal States, Mastery scale, the Coping Scale and Perceived Stress scale and the depression, anxiety, confusion and optimism scales of the Profile of Mood States questionnaire. Normallity assessment using Shapiro-Wilk test and correlations and regression modelling and comparisons between smallest and largest tertileswere used to explore the relationships between personality and psychological variables in both the healthy controls and in the patients with fibromyalgia.

Results: There was a significant relationship between lower and higher tertiles of neuroticism, internal and external control, attitude, coping and stress and the characteristic fibromyalgia phenotype features of fatigue, sleep and confusion, in both the healthy control and the fibromyalgia groups [p all <0.001]. Pain was also significantly different in the healthy controls [p<0.001] but showed a non-significant ceiling effect between lowest and highest tertiles in the fibromyalgia group. Personality and psychological variables also correlated significantly in both healthy controls and fibromyalgia with depression and anxiety [p<0.001]. The absolute levels of all characteristics in healthy controls and fibromyalgia patients differed significantly [p<0.001].Normality plots indicated that the psychological characteristics examined existed on a spectrum with healthy controls at one end and fibromyalgia patients at the other.

Conclusion: The personality and psychological variables that associate with fibromyalgia exist on a continuous spectrum, linking normal asymptomatic persons to the fibromyalgia phenotype.Increasing certain centrally important psychological variables will increase fibromyalgia clinical features. This is suggestive of a key role for central psychological factors in the pathogenesis of fibromyalgia.

Prevelance of Spondyloarthropathy in Fibromyalgia Patients. A.Eftal Yucel, Derya Kaskari and Muhtesem Agýldere. Baskent University, Ankara, Turkey

Background/Purpose: Most of the tender points typical for fibromyalgia syndrome (FMS) are also entesis points. Besides, FMS and spondyloarthropathy (SpA) can co-exist. Both disease groups have negative effects on the life quality of patients. Our aim is to document the prevalence of SpA in patients diagnosed as FMS by physical therapy specialists and to emphasize evaluation of spondyloartropathy before diagnosing with FMS.

Methods: he patients diagnosed to have FMS in the department of Physical Therapy and Rehabilitation at our center between 2006 and 2011 were involved. Patients were called by phone and asked 3 questions about their inflammatory back pain. Questions were about the presence of 1.Nontraumatic pain, swelling and stiffness in any joint 2.Low back pain or back stiffness on awakening, which lasted over a period of at least 3 months and which improved with exercise 3.Heel pain more in the morning which lasted over a period of at least 3 months and improved with activity. The patients who answered positive to at least one of these three questions were invited for further evaluation and to be involved in this study. The study included 71 patients (70 female and 1 male).In all patients, comparative sacroiliac radiographies were taken for sacroiliitis and lateral radiographies of both feet were taken for enthesitis. Patients with stage 1 and stage 1–2 sacroiliitis on direct radiography, were examined with sacroiliac MR. In order to diagnose FMS, 1990 and 2010 ACR Classification were applied while ESSG Criteria were applied to diagnose SpA.

Results: According to 1990 ACR criteria, 23 patients out of 71(32.3%) were diagnosed as FMS however 33 patients (46.4%) were diagnosed as FMS according to 2010 ACR criteria.Fifteeen (21.1%) patients were diagnosed according to both 1990 and 2010 ACR criteria; however 41(57.7%) patients were diagnosed with either 1990 ACR criteria or 2010 ACR criteria.Of our 71 patients, 20 (28.1%) were diagnosed as SpA according to ESSG criteria.Ten (43.4%) FMS patients out of 23 who were diagnosed according to 1990 ACR criteria were rediagnosed as SpA according to ESSG criteria. Eleven (33.3%) patients out of 33 who were diagnosed as FMS with 2010 ACR criteriawere rediagnosed as SpA according to ESSG criteria. We determined 9(39.1%) patients out of 23 patients diagnosed with 1990 ACR criteria and 13 (39.3%) patients out of 33 diagnosed with 2010 ACR criteria were found to have stage 2 and higher sacroiliitis. According to sacroiliac MR examinations of 10 patients, 3 (30.0%) patients had sacroiliitis on MR who had stage 1 and stage 1–2 sacroiliitis on direct radiography who were diagnosed with SpA according to ESSG criteria Twelve (60.0%) out of 20 patients diagnosed as SpA

according to ESSG criteria were found to have 2nd stage and higher sacroiliitis. We determined that 14 (60.8%) out of 23 patients diagnosed with ACR's 1990 and 17 (51.5%) out of 33 patients diagnosed with ACR's 2010 found to have enthesopathy.

Conclusion: There is a meaningful percentage of patients who have clinically insidiously progressive SpA among the patients who were thought to be diagnosed as FMS or the patients who were diagnosed as FMS according to ACR's criteria

Treatment of Lateral Epicondylitis with Injection of Platelet-Rich Plasma or Corticosteroid Versus Saline: A Randomized, Double-Blind, Placebo-Controlled Trial. Thoger Krogh[1], Ulrich Fredberg[1], Kristian Stengaard-Pedersen[2], Pia Jensen[1], Robin Christensen[3] and Torkell Ellingsen[1]. [1]Diagnostic Centre Region Hospital Silkeborg Denmark, Silkeborg, Denmark, [2]Arhus University Hospital, Aarhus, Denmark, [3]Copenhagen University Hospital at Frederiksberg, Copenhagen, Denmark

Background/Purpose: Lateral epicondylitis (LE) is a common musculoskeletal disorder for which an effective treatment strategy still remains absent. The objective is to examine whether one injection with Platelet-rich plasma (PRP) is more effective than saline and corticosteroid (CS) in reducing pain in adults with LE.

Methods: A block randomized, double-blind, placebo-controlled trial with primary outcome assessed at 3 months, and with a 12 months follow-up, conducted between January 2009, and June 2011. Patients who did not achieve a satisfying treatment response (assessment made by patient and doctor) at 3 month had the option to discontinue the study and receive other treatment. In total, 60 patients with chronic LE were randomized (1:1:1) to receive either a blinded injection of PRP, saline or CS. The primary outcome was change in pain compared to baseline using the Patient Rated Tennis Elbow Evaluation (PRTEE) questionnaire at 3 months. Secondary endpoints were all assessed at 1 month, plus ultrasonographic changes in tendon thickness and color Doppler activity at 3 months.

Results: The 60 enrolled patients in the intention to treat population had an average PRTEE pain score at baseline of 26.8 (SD 7.6). All randomized patients completed the study. At endpoint 3 months from baseline pain reduction was observed in all three groups, with no statistical significant difference between the groups. CS vs. saline −3.76 (95% CI −9.94 to 2.42), PRP vs. saline −2.64 (95% CI −8.80 to 3.52) and CS vs. PRP −1.12 (95% CI −7.23 to 4.99). However, at one month CS reduced pain more efficiently than both saline and PRP. The mean difference at one month between CS and saline was −8.11 (95% CI −14.29 to −1.93), between CS and PRP −9.27 (95% CI −15.38 to −3.16). CS was more efficient than PRP and saline in reducing both color Doppler activity and tendon thickness at three months. Only 16 of 60 patients completed the entire 12 months follow-up. The huge attrition rate was due to lack of treatment efficacy.
Figure. Changes in pain from baseline at 1 and 3 months using the PRTEE (Patient-Rated Tennis Elbow Evaluation) in patients treated with 1 injection of PRP (platelet-rich plasma), glucocorticoid, or saline. Values are Least Squares Means ± Standard Error.

Conclusion: This RCT showed no superiority of either PRP or CS compared to saline in pain reduction in LE at primary endpoint. However, anticipating immediate relief, CS had a short term pain reducing effect at one month in contrast to the other therapies. At 6 and 12 months the attrition rates in all treatment arms were too high for any meaningful conclusions to be made.

Cyclobenzaprine (CBP) and Its Major Metabolite Norcyclobenzaprine (nCBP) Are Potent Antagonists of Human Serotonin Receptor 2a (5HT2a), Histamine Receptor H-1 and á-Adrenergic Receptors: Mechanistic and Safety Implications for Treating Fibromyalgia Syndrome by Improving Sleep Quality. Bruce Daugherty, Leland Gershell and Seth Lederman. Tonix Pharmaceuticals, Inc., New York, NY

Background/Purpose: Bedtime cyclobenzaprine (CBP) improves fibromyalgia symptoms (pain, fatigue, tenderness, and mood) and improves sleep quality (decreases Cyclic Alternating Pattern Type A2 + A3) (1).CBP is metabolized by the hepatic P450 isoforms CYP1A1/2 and CYP3A4 into desmethyl, or norcyclobenzaprine (nCBP)(2), but plasma nCBP has only been detected in cases of overdose (3–5). Although CBP has been shown to interact with both the serotonergic (6,7) and noradrenergic (8,9) receptor systems, the functional interactions of CBP with isolated receptors are not fully characterized and those of nCBP are unknown. Therefore, plasma nCBP was measured in healthy subjects after ingesting CBP and the binding and functional activity of CBP and nCBP was studied on a set of CNS targets with potential relevance to CBP actions.

Methods: Plasma CBP and nCBP were measured over 168 hr in ten healthy, fasting subjects who received 5 mg po immediate release CBP HCl.Equilibrium receptor binding assays were performed on cell lines expressing select recombinant human serotonin, adrenergic, histamine, and muscarinic receptors. Select receptors were analyzed in ligand-induced intracellular Ca^+ mobilization.

Results: The oral bioavailability of CBP was similar to published results (C_{max} = 4.12 ng mL^{-1}, t_{max} = 3.5 h, $T_{1/2}$ = 31.0 h, $AUC_{0-\infty}$ = 103.1 ng hr mL^{-1}), but plasma nCBP was unexpectedly high and persistent (C_{max} = 1.27ng mL^{-1}, t_{max} = 24.0 h, $T_{1/2}$ = 72.8 h, $AUC_{0-\infty}$ = 169.5 ng hr mL^{-1}).Unlike CBP, nCBP does not form a stable N^+-glucuronide, which may affect its clearance.In vitro, CBP and nCBP exhibited high affinity binding (K_i) to receptors: 5HT2a (5.2 and 13 nM, respectively) and 5HT2c (5.2 and 43 nM), adrenergic α-1A (5.6 and 34 nM), α-2B (K_i = 21 and 150 nM) and α-2C (K_i = 21 and 48 nM,); H1 (1.3 and 5.6 nM); and M1 (7.9 and 30 nM). Like CBP, nCBP is a functional antagonist at 5HT2a (IC_{50} = 92 nM) by Ca^+ mobilization.CBP is also an antagonist on 5HT2b (IC_{50} = 100 nM). CBP and nCBP are functional antagonists on 5HT2c (IC_{50} = 0.44 and 1.22 μM) and on α-2A (IC_{50} = 4.3 and 6.4 μM). In contrast, both CBP and nCBP are functional agonists on 5HT1a (EC_{50}= 5.3 and 3.2 μM).

Conclusion: CBP is metabolized to nCBP which persists in plasma at biologically relevant concentrations after oral CBP in healthy subjects.CPB and nCBP are potent antagonists of 5HT2a, 5HT2b, H-1, adrenergic α-1A, α-2B and α-2C receptors.CBP's antagonist activity on 5HT2b is consistent with the lack of any association with heart valve pathology.Antagonists of 5HT2a and H-1 are known to have effects on sleep and sleep maintenance.Adrenergic antagonists may have effects on autonomic dysfunction.The accumulation of biologically active nCBP without N^+-glucuronidation may affect responses to CBP therapy in a chronic bedtime dosing regimen.

Cerebral Grey and White Matter Changes in Fibromyalgia Depend On Patients' Age. Marta Ceko, Mary-Ann Fitzcharles, M. Catherine Bushnell and Petra Schweinhardt. McGill University, Montreal, QC

Background/Purpose: Fibromyalgia (FM) patients show accelerated age-related decrease of grey matter (GM). Similarly, brain imaging studies in other chronic pain populations suggest interaction between age and GM changes. We investigated the relationship between age and GM alterations in FM patients categorized according to age.

Methods: This female study cohort comprised 29 FM patients and 29 controls matched for handedness, education, physical activity, and socioeconomic status. The sample was split at median age (50 yrs) into younger and older groups [mean age (SD)], FM vs. controls 42.4 (5.9), vs. 43.1 (5.3), p=0.7, and 54.9 (2.8) vs.55.7 (3.7), p=0.5. FM age groups were similar for disease duration, pain intensity, and medication use.All subjects underwent magnetic resonance imaging (MRI) in a 3T Siemens Trio scanner. T1-weighted images were obtained for GM analysis and diffusion-weighted images for interrogation of white matter.GM was analyzed using voxel-based morphometry (VBM)(SPM8, Wellcome Trust for Neuroimaging, London, UK), as well as cortical thickness analysis [CIVET 1.9.9. and Surfstat (MNI, Montreal, Canada)]. Diffusion data were analysed with FSL (FMRIB, Oxford, UK). For all analyses, voxel-wise differences between groups were examined using independent sample t-tests controling for age.

Results: The GM in the medial prefrontal cortex (MPFC), left superior frontal gyrus (SFG), and premotor cortex (PMC) was reduced in FM patients compared to controls.Total GM was negatively correlated with age in FM (p=0.009), but not in controls (p=0.6). Similar relationships with age were observed for the clusters in MPFC (FM p=0.02, controls p=0.9) and SFG (FM p=0.02, controls p=0.4). Older FM patients compared to controls showed pronounced GM decreases:patients had less GM in the MPFC/anterior cingulate cortex, right PMC, left inferior frontal gyrus (IFG), right posterior cingulate cortex, and right temporo-occipital gyrus. There were no regions where older FM patients had more grey matter. White matter adjacent to the posterior cingulate showed decreased fractional anisotropy (FA) in older FM patients. In contrast, younger FM patients showed exclusively grey matter increases compared to matched controls in the left putamen/insula, right putamen/globus pallidum, and IFG, with no region showing decreased GM. White matter adjacent to the left putamen showed increased FA.

Conclusion: FM-related brain changes depend on age with findings driven predominantly by older, postmenopausal patients. Younger, premenopausal patients showed regions of increased GM compared to age-matched controls, in line with previous findings in younger pain patients (Schweinhardt et al., 2008). Furthermore, GM alterations were partly paralleled by alterations of the adjacent white matter, with integrity compromised in older and increased in younger FM patients respectively.These findings highlight the interaction between age and cerebral changes in chronic pain states.

Pain, Sleep Disturbance, and Depression Mediate the Association Between Body Mass Index and Fatigue in Fibromyalgia. Mary O. Whipple[1], Loren L. Toussaint[2], Daniel J. Clauw[3], David A. Williams[4], Terry H. Oh[1], Jeffrey M. Thompson[1], Connie A. Luedtke[1] and Ann Vincent[1]. [1]Mayo Clinic, Rochester, MN, [2]Luther College, Decorah, IA, [3]University of Michigan, Ann Arbor, MI, [4]Univ of MI Hlth System-Lobby M, Ann Arbor, MI

Background/Purpose: Previous research and clinical observation suggest that patients with chronic disease who are obese report significant fatigue. Our objective was to explore similar relationships in patients with fibromyalgia and the extent to which pain, sleep disturbance, and depression mediated this relationship.

Methods: 3917 patients who consented to be part of a fibromyalgia registry were included in this analysis. Registry measures included demographics, body mass index (BMI), the modified 2010 American College of Rheumatology Fibromyalgia Survey Criteria, and selected items from the Multidimensional Assessment of Fatigue. Data were analyzed using the INDIRECT macro for SPSS which allows multiple mediator models to be specified. All analyses controlled for age and sex. INDIRECT provides unstandardized regression coefficients (reported below as "B") which are the preferred metric in mediation models.

Results: BMI was positively associated with fatigue (B =.03, p <.0001). BMI was also positively associated with pain (B =.06, p <.0001), sleep

disturbance (B =.004, p <.05), and depression (B =.003, p <.01). After controlling for pain, sleep disturbance, and depression, the relationship between BMI and fatigue (B = 02, p <.0001) was reduced by over 33% (.02/.03). In spite of this, pain, sleep disturbance, and depression remained statistically significant (all p's <.0001). Hence, we examined the partial mediating effects of these variables.Results indicated that pain, sleep disturbance, and depression combined mediate the association between BMI and fatigue (B =.01, p <.05). Additionally, pain (B =.01, p <.05), sleep disturbance (B =.01, p <.05), and depression (B =.002, p <.05) also had unique indirect effects on fatigue.

Conclusion: Statistically significant total and direct effects were present for the association between BMI and fatigue in patients with fibromyalgia.Hence, the association between BMI and fatigue was only partially explained by pain, sleep disturbance, and depression. While these data provide insight into a potential relationship between obesity and fatigue and possible mechanisms, these are cross-sectional results and do not offer insight into causality. These types of analyses should also be examined through longitudinal research.

Efficacy of Long-Term Milnacipran Treatment in Patients Meeting Different Thresholds of Clinically Relevant Pain Relief: Subgroup Analysis of a Double-Blind, Placebo-Controlled Discontinuation Study. Daniel J. Clauw[1], Philip Mease[2], Robert H. Palmer[3], Joel M. Trugman[3] and Yimin Ma[3]. [1]University of Michigan, Ann Arbor, MI, [2]Swedish Medical Center and University of Washington, Seattle, WA, [3]Forest Research Institute, Jersey City, NJ

Background/Purpose: Patients with fibromyalgia (FM) who received up to 3.25 years of milnacipran (MLN) in a flexible-dose (≤200 mg/d) open-label (OL) study were eligible to continue into this randomized, double-blind (DB), placebo (PBO)-controlled discontinuation study, which demonstrated loss of therapeutic effect after withdrawal of long-term MLN treatment in patients who had achieved ≥50% pain improvement. The present analysis was conducted to determine whether patients from this study who met lower thresholds of pain improvement also experienced loss of therapeutic effect after discontinuing long-term MLN treatment.

Methods: After 4 weeks (OL) of continuing MLN treatment at the dose received in the prior long-term study, patients were evaluated for pain response and randomized (2:1) to continue MLN or discontinue treatment (ie, switch to PBO) for the 12-week DB withdrawal period. In patients who had received MLN ≥100 mg/d, 3 subgroups were identified based on percent of pain reduction from pre-MLN exposure: 1) ≥50%, n=150; 2) 30 to <50%, n=61; and 3) <30%, n=110. Efficacy assessments included visual analog scale pain (VAS, 0–100 mm), SF-36 Physical Component Summary (SF-36 PCS), Fibromyalgia Impact Questionnaire Revised (FIQR), and Beck Depression Inventory (BDI).

Results: In both subgroups of patients with clinically meaningful pain relief (≥50% and 30 to <50% subgroups), mean worsening of VAS pain scores from randomization to end of the DB withdrawal period was significantly greater (P<.05) in patients switched to PBO (≥50%, +17.7 mm; 30% to <50%, +8.5 mm) than in patients continuing MLN (≥50%, +8.3 mm; 30% to <50%, −0.5 mm). The absolute difference between treatment arms was similar in both subgroups (≥50%, −9.4 mm; 30 to <50%, −9.0 mm), as was the percentage of lost treatment effect after withdrawal (≥50%, 37.7%; 30 to <50%, 31.2%). Patients with ≥50% pain response also experienced notable worsening in SF-36 PCS and FIQR total scores after treatment withdrawal (P<.01, MLN vs PBO; both measures). In the subgroup with <30% pain improvement, no worsening in pain was observed in either treatment arm at endpoint (PBO, −1.1 mm; MLN, −5.3 mm; P=.14). However, patients in this subgroup experienced significant worsening in FIQR scores after withdrawal from MLN relative to those who continued treatment (P<.001). Additionally, patients in this subgroup who were withdrawn from MLN had worsened SF-36 PCS and BDI scores while patients continuing MLN experienced no worsening in these domains.

Conclusion: Significant worsening in pain after drug withdrawal was found in both subgroups of FM patients that had shown clinically meaningful responses to long-term MLN therapy (≥50%, 30 to <50% pain improvement), suggesting that the traditional ≥30% pain responder cutoff may be adequate to demonstrate efficacy in randomized withdrawal studies. Patients with <30% pain response did not experience worsening in pain following withdrawal, but did experience worsening in other symptoms, suggesting that these patients may have received long-term benefit from milnacipran treatment for some FM symptom domains despite only modest improvements in pain.

High-Energy Extracorporeal Shock Wave Therapy Is Effective for Treating Chronic Calcific Tendonitis of the Shoulder: A Meta-Analysis. Nina E. Flavin, Raveendhara R. Bannuru, William F. Harvey and Timothy E. McAlindon. Tufts Medical Center, Boston, MA

Background/Purpose: Calcific tendonitis (CT) and noncalcific tendonitis (NCT) of the shoulder is a common cause of shoulder pain and can be unresponsive to conventional therapies. Based on several randomized controlled studies (RCTs), extracorporeal shock wave therapy (ESWT) has been considered an effective alternative treatment. We performed an updated meta-analysis using all available data to analyze the efficacy of ESWT on CT and NCT.

Methods: We searched Medline, Cochrane database, and Google Scholar from inception to May 2012 for human RCTs comparing ESWT versus placebo for shoulder pain due to CT or NCT. We hand searched review articles, manuscripts, and medical journal supplements for additional references. Inclusion criteria were outcome measures of pain (VAS score; low score = less pain), functional assessment (Constant score; high score = better function), and resolution of calcifications (for CT trials). Two reviewers independently determined eligibility, assessed the quality of each trial, and extracted means and variances for these outcome measures. We computed effect sizes for mean change from baseline to 6 months or 3 months if not reported, using Hedges' g statistic. Effect sizes were pooled using random effects model. We assessed heterogeneity and performed sensitivity analyses removing the outlier trials. Subgroup analyses for CT and NCT, and high energy (HE) and low energy (LE) trials were also performed.

Results: Fifteen trials met inclusion criteria; 11 for CT, 4 for NCT. Overall there were 1221 participants with mean age of 51 years (range 46–56). The proportion of women was 56% (range 39%–76%). Among all trials, the effect size (ES) for VAS pain favored HE (−2.17; 95%CI [−2.85, −1.49]; I² 51%, p=0.15) and LE showed no effect (−1.15; [−2.63, 0.32]; I² 96%, p=0.00) and the ES for Constant score favored HE (1.77; [1.41, 2.14]; I² 29%, p=0.24) and LE (0.53; [0.16, 0.89]; I² 28%, p=0.24). In CT trials, any level of ESWT improved VAS scores (−2.18; [−3.55, −0.8]; I² 95%, p=0.00) and Constant scores (1.39, [0.81, 1.97]; I² 84%, p=0.00). In NCT trials, any level of ESWT had no effect on VAS scores (−0.15; [−0.57, 0.27]; I² 0%, p=0.35) or Constant scores (0.65; [−0.51, 1.82], I² 75%, p=0.04). Among CT, effect sizes for VAS, Constant scores and resolution of calcifications favored HE over LE (VAS: −0.57; [−1.10, −0.03]; I² 74%, p=0.01; Constant: 0.57; [0.28, 0.87]; I² 56%, p=0.03; Resolution of calcifications: 3.95; [1.55, 10.03]; I² 70%, p <0.01). Sensitivity analysis removing outlier trials yielded comparable results. The overall trial quality was moderate.

Table 1. Characteristics of included studies

Study	Treatment 1	Treatment 2	N	Age (Mean, Years)	Female (%)
Calcific Tendonitis					
Rompe, 1998	0.28 mJ/mm2, 1500 pulses, 1 dose	0.06 mJ/mm2, 1500 pulses, 1 dose	100	48	56

Cosentino, 2003	0.28 mJ/mm2, 1200 pulses, 4 doses weekly	0 mJ/mm2, 1200 pulses, 4 doses weekly	70	52	61
Gerdesmeyer, 2003*	0.32 mJ/mm2, 1500 pulses, 2 doses, 2 weeks apart	0.08 mJ/mm2, 6000 pulses, 2 doses, 2 weeks apart	144	50	60
Perlick, 2003	0.42 mJ/mm2, 2000 pulses, 2 doses, 3 weeks apart	0.23 mJ/mm2, 2000 pulses, 2 doses, 3 weeks apart	80	48	55
Peters, 2004*	0.44 mJ/mm2, 1500 pulses, up to 5 doses, 6 weeks apart	0.15 mJ/mm2, 1500 pulses, up to 5 doses, 6 weeks apart	90	52	61
Pleiner, 2004	0.28 mJ/mm2, 2000 pulses, 2 doses, 2 weeks apart	<0.07 mJ/mm2, 2000 pulses, 2 doses, 2 weeks apart	43	52	72
Cacchio, 2006 ‡	0.1 mJ/mm2, 2500 pulses, 4 doses weekly	0.1 mJ/mm2, 25 pulses, 4 doses weekly	90	56	39
Albert, 2007	0.45 mJ/mm2, 2500 pulses, 2 doses, 2 weeks apart	0.02–0.06 mJ/mm2, 2500 pulses, 2 doses, 2 weeks apart	80	47	76
Hsu, 2008	0.55 mJ/mm2, 1000 pulses, 2 doses, 2 weeks apart	0 mJ/mm2, 0 pulses, 2 doses 2 weeks apart	46	56	51
Farr, 2011	0.3 mJ/mm2, 3200 pulses, 1 dose	0.2 mJ/mm2, 1600 pulses, 2 doses, weekly	30	49	47
Noncalcific Tendonitis					
Schmitt, 2001‡	0.11 mJ/mm2, 2000 pulses, 3 doses weekly	0 mJ/mm2, 2000 pulses, 3 doses weekly	39	52	50
Speed, 2002‡	0.12 mJ/mm2, 1500 pulses, 3 doses, 4 weeks apart	0.04 mJ/mm2, 1500 pulses, 3 doses, 4 weeks apart	74	52	58
Schofer, 2009	0.35 mJ/mm2, 2000 pulses, 3 doses weekly	0.11 mJ/mm2, 2000 pulses, 3 doses weekly	40	53	53
Galasso, 2012‡	0.068 mJ/mm2, 3000 pulses, 2 doses weekly	0 mJ/mm2, 3000 pulses, 2 doses weekly	20	51	45

*Trial also included placebo group: Energy level 0 mJ/mm2, pulses and dosing equivalent to treatment 1 group.
‡Low Energy: ≤ 0.27 mJ/mm²

Conclusion: High energy shock wave therapy is effective for improving pain and shoulder function in patients with chronic calcific shoulder tendonitis, and can result in complete resolution of calcifications. Limitations include

the heterogeneous nature of the included studies. Despite this, ESWT may be an underutilized therapy for a condition that is difficult to manage otherwise.

Increased Number of Painful Body Sites Is Associated with Worse Pain and Disability-Associated Outcomes Among Returning Operations Enduring Freedom/Operation Iraqi Freedom Service Members.

Dennis C. Ang[1], Jingwei Wu[2], Samantha Outcalt[2], Zhangsheng Yu[2] and Matthew Bair[2]. [1]Indiana University, Indianapolis, IN, [2]Indiana University School of Medicine

Background/Purpose: Chronic pain is a critical health problem among Operations Enduring Freedom/Operation Iraqi Freedom service members. The deleterious impact of chronic pain on quality of life and function are well described in the literature. However, little is known about the relationship between the number of chronically painful body sites and pain severity and disability-associated outcomes. In this secondary data analysis of a randomized clinical trial of a stepped-care intervention for OEF/OIF veterans with chronic musculoskeletal pain, we evaluated the association between the number of chronically painful body sites with long term pain-related outcomes.

Methods: We analyzed 222 subjects (92% of the original cohort) with available data at baseline and at the last follow-up visit (i.e., month 9). Consistent with the 2010 ACR criteria for fibromyalgia*, we dichotomized the number of chronically painful body sites (primary independent variable) as ≥ 3 (yes or no).We measured baseline to month 9 changes on our two primary outcomes: 1) pain intensity (as measured by Graded Chronic Pain Scale/GCPS), and 2) pain-related disability (as measured by Brief Pain Interference (BPI). Secondary outcomes included changes in SF-36 Physical Component Summary (SF-36 PCS), depression (PHQ-9) and anxiety (GAD-7) measures. We used multiple linear regression analyses to determine the relationships of the number of painful body sites with the outcome measures.

Results: Characteristics of the 222 subjects at study entry: mean age (SD)=37.3 (10.2) years; male=88%; whites= 78%; married=57%; # comorbidity=1.0 (1.0); GCPS pain intensity=65.6 (13.7); BPI pain interference=5.3 (2.2); SF-36 PCS=37.6 (7.2); PHQ-9=10.8 (5.8); GAD-7=8.5 (5.2); # of pain-related medications=1.7 (1.2); # of physical symptoms=2.0 (1.8); and 69% (n=154) had $\geq$ 3 painful body sites.

Table 1.

Baseline Predictors	OUTCOMES Parameter estimate (standard error/SE), p values		
	Improvement in GCPS pain intensity	Improvement in BPI pain interference	Improvement in SF-36 PCS
Number of painful sites ≥ 3 (reference group: <3)	−4.9 (2.4), p=0.0396	−1.0 (0.3), p=0.0016	4.2 (1.0), p<0.0001
Treatment group Stepped care (vs. usual care)	6.9 (2.2), p=0.0017	0.9 (0.3), p=0.0034	−1.9 (0.9), p=0.0362
Number of comorbidity	−2.2 (1.2), p=0.0636	−0.3 (0.2), p=0.0911	−0.04 (0.5), p=0.9364
Response variable at study entry	0.2 (0.1), p=0.0172	0.4 (0.1), p<0.0001	0.3 (0.1), p<0.0001

Age, gender, race, and marital status were included on each of the multivariate models but were all non-significant (p>0.10)
Neither the number of painful sites nor the treatment group assignment was significantly associated with changes in PHQ-depression and GAD-7 anxiety. Only the number of comorbid medical conditions was associated with changes in depression (estimate (SE) =−0.9 (0.4), p=0.0184) and anxiety (estimate (SE) =−0.7 (0.3), p=0.0179).

Conclusion: Compared to veterans with <3 painful body sites, veterans with $\geq$3 painful body sites improved significantly less during the 9 months of the trial. Our findings suggest more aggressive treatment interventions are needed in this population of veterans with multiple pain sites.

A Systematic Review of Evidence for the Effectiveness of Practitioner-Based Complementary and Alternative Therapies in the Management of Fibromyalgia.

Gareth T. Jones[1], Priya Paudyal[2], Gary J. Macfarlane[1] and the Arthritis Research UK Working Group on Complementary and[3], [1] University of Aberdeen, Aberdeen, United Kingdom, [2]University of Plymouth, Plymouth, United Kingdom, [3]Aberdeen

Background/Purpose: Approximately one-quarter of the UK population uses complementary or alternative treatments (CAM) each year, and this is higher among persons with pain, or musculoskeletal conditions such as arthritis.A recent review has summarised the evidence relating to the use of CAM medicines (anything taken orally or applied topically) in the treatment of fibromyalgia.The aim of the current study was to review the evidence relating to CAM therapies (treatments delivered by a practitioner).

Methods: Randomised controlled trials (RCTs), published in English up to May 2011, were identified using systematic searches of bibliographic databases and searching of reference lists.Data were extracted by a single reviewer, and checked by a second, and the Jadad (J) score was used to assess methodological quality of the RCTs (0=poor; 5=high quality).All outcomes were considered but with a focus on patient global assessment and pain reporting.

Results: From 525 articles, 25 RCTs were identified, examining 14 therapies.The effectiveness of biofeedback has been tested in five RCTs (median J = 3), ranging from 30 to 143 patients.One RCT that compared biofeedback against anti-depression medication reported positive findings in terms of pain and fatigue.However, four RCTs comparing biofeedback with sham biofeedback, usual care or fitness training found no significant difference in the same outcomes.Three RCTs examined progressive muscle relaxation (median J = 3) ranging from 24 to 45 patients.In two RCTs, no significant benefit was observed, compared to hydro-galvanic bath therapy or hypnotherapy, and one RCT demonstrated progressive muscle relaxation to be inferior to massage therapy in terms of pain, stiffness, fatigue and a number of other outcomes.

Aromatherapy, chiropractic, healing therapy, hypnotherapy, imagery and qigong were each examined in two RCTs (median J = 4.5; 2.5; 3.5; 1.5; 2.0 and 3.5 respectively).With the exception of hypnotherapy, there was generally no improvement in outcome in the intervention group, compared to various control treatments.In hypnotherapy, in one RCT patients receiving hypnotherapy reported significantly greater improvements in pain, fatigue, sleep and general health compared to those receiving in physical therapy; and in the second RCT, patients receiving hypnotherapy with analgesia suggestions reported improvements in pain intensity compared to those receiving hypnotherapy with relaxation suggestions, or relaxation alone.

Finally, one RCT each examined the effectiveness of autogenic training (J=3), craniosacral therapy (J=5), music therapy (J=3), static magnet therapy (J=4), meditation (J=5) and Tai-chi (J=4).Only in Tai chi was there evidence of positive effect of treatment: patients in this group reported significantly greater improvements in health, disease impact, mental health and sleep compared to a control group who received wellness education and stretching exercises.

Conclusion: The major limitation in reviewing the evidence for practitioner-based CAM therapies in the treatment of FM is the paucity of RCTs.The available studies provide no consistent evidence that these treatments are effective, but the lack of RCTs means that it is hard to reach firm conclusions.

Haplotypes of GTP Cyclohydrolase Gene Polymorphisms Are Protective in the Susceptibility of Fibromyalgia Syndrome.

Hwajeong Lee[1], Shin-Seok Lee[2], Seong-Kyu Kim[3], Jung-Yoon Choe[1], Seong-Ho Kim KIM[4], Seong-Su Nah[5], Ji Hyun Lee[6], Seung-Jae Hong[7], Hyun-Sook Kim[8], Hye-Soon Lee[9], Hyun Ah Kim[10] and Chung-Il Joung[11]. [1]Catholic University of Daegu School of Medicine, Daegu, South Korea, [2]Chonnam National University Medical School, Gwangju, South Korea, [3]and Autoimmunity Research Center, Catholic University of Daegu School of Medicine, Daegu, South Korea, [4]Inje University Haeundae Paik Hospital, Busan, South Korea, [5]Soonchunhyang University, College of Medicine, Cheonan, South Korea, [6]Maryknoll Medical Center, Busan, South Korea, [7]Kyung Hee University, Seoul, South Korea, [8]Internal Medicine, Chosun University Hospital, Gwangju, South Korea, [9]Hanyang University Guri Hospital, Guri, South Korea, [10]Hallym university sacred heart hospital, Kyunggi, South Korea, [11]Konyang University Medical School, Daejeon, South Korea

Background/Purpose: Guanosine triphosphate cyclohydrolase 1 (GCH1) is the rate-limiting enzyme in the synthesis of tetrahydrobiopterin, which is an essential co-factor in nitric oxide (NO) production. Polymorphisms in the GCH1 gene have been implicated in protection against pain

sensitivity. Our study was to determine whether single nucleotide polymorphisms (SNPs) in the GCH1 gene affect susceptibility and/or pain sensitivity in fibromyalgia syndrome (FMS).

Methods: A total of 409 FMS patients and 422 controls were enrolled. The alleles and genotypes at four positions, rs3783641(T>A), rs841(C>T), rs752688(C>T), and rs4411417(T>C), in the GCH1 gene were analyzed. The associations of the GCH1 SNPs with susceptibility and clinical parameters in FMS patients were assessed.

Results: The frequencies of alleles and genotypes of the four SNPs did not differ between FMS patients and healthy controls. Among 13 constructed haplotypes, we further examined four (CCTT, TTCT, TTCA, and CCTA) with >1% frequency in both FMS and controls. No associations of GCH1 polymorphisms with FMS-related activity or severity indexes were found, although the number and total score of tender points in FMS patients differed among the four haplotypes (p = 0.03 and p = 0.01, respectively). The CCTA haplotype of GCH1 was associated with significantly lower pain sensitivity and occurred less frequently than the CCTT haplotype in FMS patients (OR = 0.45; 95% CI, 0.21–0.96).

Conclusion: This study provides evidence that certain GCH1 haplotypes may be protective against susceptibility and pain sensitivity in FMS. Our data also suggest that NO is responsible for pain sensitivity in the pathogenesis of FMS.

Sympathetic Nervous System Dysfunction in Fibromyalgia and in Overlapping Central Sensitivity Syndromes. A Systematic Review of Controlled Studies. Laura Aline Martinez, Tania Mora, Angelica Vargas, Mario Fuentes and Manuel Martinez-Lavin. National Institute of Cardiology, Mexico City, Mexico

Background/Purpose: Fibromyalgia often coexists and overlaps with other common painful syndromes such as chronic fatigue, irritable bowel and interstitial cystitis. Yunus proposed the label "central sensitivity syndromes" as an umbrella term for these related maladies. Sympathetic nervous system dysfunction has been reported in these central sensitivity syndromes raising the possibility that such dysautonomia could be the common underlying pathogenesis that cluster fibromyalgia with these interrelated clinical entities.

Our objective: To carry out a systematic review of all published comparative case-control studies investigating sympathetic nervous system performance in fibromyalgia, chronic fatigue syndrome, irritable bowel syndrome and interstitial cystitis.

Methods: PubMed and Embase were accessed using the following key words: autonomic (OR) sympathetic (AND) fibromyalgia, chronic fatigue syndrome, irritable bowel syndrome and interstitial cystitis. All entries up to April 30 2012 were reviewed by three investigators searching for case-control studies in humans. The Method for Evaluating Research and Guidelines Evidence (MERGE) adapted to the Scottish Intercollegiate Guidelines Network (SIGN 50) was used to rank the level of evidence contained in the selected articles. "Sympathetic predominance" was defined as statistically significant data suggesting higher sympathetic activity, decreased parasympathetic activity or both. Reverse definition applied for "parasympathetic predominance".

Results: See table. Heart rate variability analysis (36%) was the most often used method to assess sympathetic system performance. Other less frequently used methods were: Tilt table testing (9%), sympathetic skin response (9%) and genetic studies (5%).

Selected articles	Overall assessment MERGE - SIGN 50			Participants average age (years)
	Quality	n	%	
Fibromyalgia n = 58	High	18	31.03	43.6
34.9%	Medium	38	65.52	
	Low	2	3.45	
Chronic fatigue n = 49	High	22	44.90	33.4
29.5%	Medium	25	51.02	
	Low	2	4.08	
Irritable bowel n = 50	High	9	18.37	36.0
30.1%	Medium	33	67.35	
	Low	7	14.29	
Interstitial cystitis n = 9	High	3	33.33	49.3
5.4%	Medium	5	55.56	
	Low	1	11.11	

Total = 166

Source: PubMed only =24.09 %, Embase only = 21.08 %, both databases = 54.81%

The overwhelming majority of case-control studies described sympathetic predominance in these painful syndromes (figure). Heart rate variability analyses and tilt table testing disclosed a clear pattern of sympathetic dysfunction; basal sympathetic hyperactivity accompanied by sympathetic hypo-reactivity to stress.
Conclusion: This systematic review suggests that sympathetic nervous system predominance is very common in these overlapping central sensitivity syndromes. This concordance raises the possibility that these syndromes may share similar clinical and pathogenic mechanisms.

969

Presence of Small Fiber Neuropathy in a Cohort of Patients with Fibromyalgia. Todd Levine[1], Victoria Lawson[2], Aidan Levine[1], Kevin V. Hackshaw[3] and David Saperstein[1]. [1]Phoenix Neurological Associates, Phoenix, AZ, [2]Ohio State University, Columbus, OH, [3]Ohio State Univ/Wm Davis Res, Columbus, OH

Background/Purpose: The pain associated with fibromyalgia is classically described as deep, muscular, aching and flu-like; however, a significant percentage of patients with fibromyalgia also describe neuropathic symptoms. The pain in these patients can be categorized and burning, tingling or stabbing.These clinical descriptors may raise the concern for a coexistent neuropathy. Yet, EMG/NCS in fibromyalgia patients are typically unrevealing. The constellation of neuropathic pain with normal nerve conduction studies, raises the possibility of a neuropathy confined purely to the small unmyelinated nerve fibers: a small fiber neuropathy. These small fiber neuropathies can be diagnosed through a 3-mm punch biopsy and may offer insight into the pathogenesis of some cases of fibromyalgia.

Methods: We retrospectively examined 56 patients referred for neurological evaluation who met diagnostic criteria for fibromyalgia. The patients were seen in neuromuscular consultation atthe Ohio State University or at Phoenix Neurological Associates. Patients were included if they met either the ACR criteria or the revised criteria of 2010 forfibromyalgia. Patients underwent 3 mm punch biopsies at a proximal and a distal site of one lower limb.PGP 9.5 immunolabelling was performed and the epidermal nerve fiber density was counted on 50 micron sections. The patients who were found to have reduced epidermal nerve fiber density underwent a standard serologic evaluation looking for identifiable causes for their neuropathy.

Results: 34/56 (61%) of the cases were diagnosed with small fiber neuropathy on the basis of reduced epidermal nerve fiber density. Of these 34 patients only 5 had evidence for neuropathy on EMG/Nerve conduction studies. Further, this evidence was subtle enough as to be inconclusive for diagnosis.24/34, 71%, of the patients with fibromyalgia and small fiber neuropathy had serologic evidence of an underlying etiology for their neuropathy that had not been detected prior to identification of the neuropathy: errors of glucose metabolism (n=11), vitamin D deficiency (n=5), elevated ESR (n=2), B6 deficiency (n=1), B12 deficiency (n=1), Sjogrens (n=2), elevated ANA (n=1), mutation in alpha galactosidase (Fabry's Disease) (n=1).

Conclusion: In this retrospective series, 61% of patients with fibromyalgia and neuropathic pain were found to have small fiber neuropathy based on

reduced epidermal nerve fiber density on a standard 3-mm punch biopsy. In 71% of these patients, a diagnosis was made based on serologic evaluation. These results suggest that testing for small fiber neuropathy in patients with fibromyalgiawill allow for earlier diagnosis of underlying conditions such as glucose dysmetabolism, toxicities, connective tissue disorders, and others. Further, identification of patients who have both fibromyalgia and small fiber neuropathy may suggest earlier therapeutic trials of neuropathic agents in treating the pain in these patients. It is unclear whether our patients had two separate disorders or whether patients had small fiber neuropathy and not fibromyalgia as the cause of their symptoms. A larger, prospective study is needed to answer this question.

Background/Purpose: Genome-wide and candidate gene studies have supported a role for genes involved in immune complex processing as being important contributors to development of SLE.The association of *ITGAM* variants and SLE highlights the importance of complement and complement receptors in the SLE diathesis.We hypothesized that there may also be statistical interactions between variants in genes that encode proteins in the complement system.We have developed a gene-based analysis strategy and present data that support a role for genetic interactions between variants in genes involved in the complement system.

Methods: A newly developed variation of the Rank Truncated Product (RTP) statistic was used to assess the combined genetic contribution of loci involved in complement component 3 (C3), C3 activation (*C2, C3, C4, CFH, CRP, MBL2*), and C3 recognition (*CR1, CR2, CR3 (ITGAM/ITGB2), CR4 (ITGAX/ITGB2)*)).The significance of the RTP statistic for each gene pair was assessed using a parametric bootstrap procedure.The study population included 16,105 unrelated SLE affecteds and controls from four different ancestry backgrounds (European (EA), African (AA), Hispanic (Hisp), Asian). All participants were of self-reported sex and race/ethnicity. Affecteds met 1997 American College of Rheumatology revised criteria for the classification of SLE.347 SNPs in these loci were genotyped on an Illumina iSelect custom array as part of the Large Lupus Association Study 2 (LLAS2).

Results: We identify new SNP associations across multiple race/ethnicities in the C2 locus with SLE ($p < 10^{-11}$/ $< 10^{-7}$, OR=1.8/1.7 in EA/AA) and confirm trans-racial associations of *ITGAM* and SLE ($P < 10^{-27}$/ 10^{-11}/10^{-12}OR=1.7/1.6/2.1 in EA/AA/Hisp respectively).

We hypothesized that there are genetic interactions between variants in genes encoding proteins in the C3 pathway that are known to functionally and/or physically interact.Indeed, significant gene-by-gene genetic interactions were identified between receptor-ligand, between C3 and complement regulators and between C3 receptor loci.Specific interactions included *C3-ITGAM* ($p < 0.001$ in AA), *C3-ITGB2* ($p=0.002$ in Hisp), *C3-CRP* ($p=0.003$ in AA), *C3-CFH* ($p=0.009$ in AA), *ITGAM-ITGB2* ($p < 0.001$ in Hisp) and *ITGAX-ITGB2* (with trans-racial association in both Hisp and EA, $p=0.02/0.045$).

Conclusion: We demonstrate significant and replicated genetic association of genes in the C3 pathway with SLE.These associations extend beyond the *ITGAM* locus to include other C3 receptor genes and regulators of C3 activation.The elucidation of genetic interactions between genes in this pathway demonstrates that the contribution of variants in the C3 pathway act both independently and jointly.

971

Association of adam33 Polymorphisms with Systemic Lupus Erythematosus.

Seung Cheol Shim, Mi Kyoung Lim, Donghyuk Sheen and Hyo Park. Eulji University Hospital, Daejeon, South Korea

Background/Purpose: A Disintegrin and Metalloprotease 33 (ADAM33) is a member of a family of genes that encode membrane-anchored proteins with a disintegrin and a metalloprotease domain, and is located on chromosome 20p13. Recently, the polymorphisms in Adam33 have been found to be associated with asthma. Among the rheumatic diseases, systemic lupus erythematosus (SLE) is a prototypic Th2-mediated autoimmune disease like allergic disorders. To assess whether genetic functional variants of ADAM33 are associated with susceptibility to SLE or development of specific phenotypes in patients with SLE.

Methods: We have identified 48 SNPs, and nine SNPs were selected with regard to the LD pattern. Genotyping for g.10918G>C, g.12433T>C and g.13506C>G in the ADAM33 gene was conducted with PCR-RFLP methods, and genotyping for g.-330C>T, g.517 A>G, g.8227 G>A, g.9511 G>T, g.12462 C>T, g.12988 C>A polymorphisms was performed by single-base extension (SBE), using the ABI Prism[R] SNaPshot™ Multiplex kit (Applied Biosystems). We conducted an association study for ADAM33 polymorphisms in 190 SLE patients, 469 healthy controls, and 390 rheumatoid arthritis (RA) patients as a disease control. Haplotype analyses of related variants were performed as well.

Results: Significant associations of ADAM33 polymorphisms with susceptibility to SLE were found at g.8227 G>A, g.12988 C>A, and g.13506 C>G (P value were all below 0.001) (Table 1). Polymorphisms at g.8227 G>A was associated with the ANA titers among SLE patients ($P = 0.012$). In addition, we analysed the haplotype, and found a positive association of susceptibility to SLE with the major haplotype CGCG ($P = 3.5E-11$) (Table 2). There was no association between ADAM33 polymorphisms and RA as expected.

Associations of Genetic Polymorphisms of Microrna-146a and Its Target Interleukin-1-Receptor-Associated Kinase 1 with Ankylosing Spondylitis.
Chun-Huang Huang[1], Jia-Yan Zhan[1], Kai-Jieh Yeo[2], James C. Wei[3], Chih-Shien Chuang[1] and Ruey-Hong Wong[1]. [1]Chung Shan Medical University, Taichung, Taiwan, [2]Chung Shan Medical University Hospital, Taichung, Taiwan, [3]Chung Shan Med Univ Hospital, Taichung, Taiwan

Background/Purpose: Tumor necrosis factor-α (TNF-α) and interleukin-1 (IL-1) were important mediators of inflammation response in the development of ankylosing spondylitis (AS). Especially, microRNA (miR)-146a targets TNF-receptor-associated-factor-6 (TRAF-6) and interleukin-1 receptor-associated kinase 1 (IRAK1) to suppress nuclear factor kB (NF-kB) activity and lipopolysaccharide (LPS)-induced inflammatory response. Here, we evaluated the effects of *miR-146a* rs2910164 G/C, *IRAK1* rs3027898 A/C, and *IRAK1* rs1059703 T/C genetic polymorphisms on the development of AS and clinical characteristics.

Methods: A total of 450 AS patients and 438 healthy controls were included, *miR-146a* genotypes were identified by polymerase chain reaction-restriction fragment length polymorphism, and *IRAK1* genetic polymorphisms were determined by the Taqman system.

Results: Our results showed that subjects possessing *miR-146a* rs2910164 GG genotype had 1.71-fold (95% confidence interval [C.I.] = 1.15–2.56) risk for AS development than those with GC/CC genotypes. Subjects with *IRAK1* rs3027898 A allele (odds ratio [OR] = 1.54, 95% C.I. = 1.20–1.99) also had a significantly increased risk of AS than those with C allele. Further, subjects carrying both of *miR-146a* rs2910164 GG genotype and *IRAK1* rs3027898 A allele had the highest risk (OR = 2.63, 95% C.I. = 1.25–5.55) for AS development than those with rs2910164 GC/CC genotypes and rs3027898 C allele, followed by subjects with rs2910164 GG genotype and rs3027898 C allele (OR = 1.75, 95% C.I. = 1.29–2.37) and subjects with rs2910164 GC/CC genotypes and rs3027898 A allele (OR = 1.57, 95% C.I. = 1.20–2.06). These results were also observed in males, but not in females. In addition, *IRAK1* rs3027898 A/C and *IRAK1* rs1059703 T/C polymorphisms were significantly associated with the abnormal erythrocyte sedimentation rate (ESR) level of AS patients, respectively. AS patients with both of *miR-146a* rs2910164 GG genotype and *IRAK1* rs3027898 A allele had a 6.68-fold (95% C.I. = 2.83–15.73) risk for uveitis development than patients without.

Conclusion: *MiR-146a* rs2910164 G/C and *IRAK1* rs3027898 A/C polymorphisms might be associated with the development of AS, as well as its clinical manifestations.

New Genetic Risk Loci for the Radiographic Severity of Rheumatoid Arthritis.
Diederik P.C. de Rooy[1], Sacha Zhernakova[1], Roula Tsonaka[2], Fina Kurreeman[1], René E.M. Toes[1], Tom W. J. Huizinga[1], Jeanine Houwing-Duistermaat[2], Peter K. Gregersen[3] and Annette H.M. van der Helm-van Mil[1]. [1]Rheumatology, Leiden University Medical Center, Leiden, Netherlands, [2]Statistics, Leiden University Medical Center, Leiden, Netherlands, [3]Feinstein Institute Medical Research and North Shore-Long Island Jewish Health System, Manhasset, NY

Background/Purpose: The severity of joint destruction is highly variable between Rheumatoid Arthritis (RA) patients; approximately 54% of this variance is explained by genetic factors. Many of the genetic factors responsible for the severity of joint destruction are unknown. We aimed to identify new genetic risk factors by studying genetic susceptibility loci of several auto-immune diseases.

Methods: In the first phase, 646 Dutch RA-patients with yearly X-rays of hands and feet over 7 years of follow-up were studied. These patients were genotyped for 148,880 SNPs by Immunochip which contains 186 loci previously associated with autoimmune diseases. Following quality control, association of SNPs with MAF >0.01 (130,841 SNPS) with joint destruction was analyzed using a marginal regression model. Correction for multiple testing was done using the Bonferroni correction for the number of uncorrelated SNPs (threshold p<1.1 $\times$ 10^{-6}). In the second phase, 686 North American RA-patients with repeated hands X-rays over 15 years of follow-up, for which Immunochip genotyping data were also available, were studied. SNPs that were significantly associated in phase 1 were selected and evaluated. All X-rays were scored by the Sharp van der Heijde score (ICC 0.91 and 0.98 for phase 1 and 2 respectively).

Results: In phase 1, 109 SNPs were significantly associated with joint destruction in Dutch RA-patients (threshold p<1.1 $\times$ 10^{-6}). Of these, 76 were located in the HLA-region in chromosome 6; since the association of this region with joint damage is already known, these SNPs were not analyzed in phase 2. The other 33 non-HLA genetic variants, though several were in high LD, were studied in the North-American RA-patients.

After correction for the number of number of uncorrelated SNPs (threshold $p<0.0036$), two variants were associated with the severity of joint destruction. These were rs451066 on chromosome 14 ($p_{uncorrected}=0.002$, MAF=0.20)) and rs11908352 on chromosome 20 ($p_{uncorrected}=0.002$, MAF=0.21). In the presence of a risk allele of rs451066 and rs11908352 respectively Dutch RA-patients had a 3.7% and 2.7% higher rate of joint destruction per year, which equals 29% and 20% more joint destruction over a seven years period.

Conclusion: Two new risk loci for progressive joint destruction in RA were identified. The region of rs451066 on chromosome 14 has previously been linked to susceptibility to type-1 diabetes. The other SNP is located at chromosome 20 and in low LD with rs4810485 (R^2 0.062), a variant that has previously been identified as RA risk locus. Altogether, the current data indicate that two loci that confer risk to other autoimmune disease may also affect the severity of RA.

Identification of Susceptibility Loci for Inflammatory Arthritis.
K. J. A. Steel[1], Anne Hinks[1], John Bowes[1], Joanna Cobb[1], Edward Flynn[2], Carl D. Langefeld[3], Sampath Prahalad[4], Johannes Peter Haas[5], John F. Bohnsack[6], Stephen Guthery[6], Anne Barton[1], Susan D. Thompson[7] and Wendy Thomson[1]. [1]Arthritis Research UK Epidemiology Unit, University of Manchester, Manchester, United Kingdom, [2]University of Manchester, Manchester Academy of Health Sciences, Manchester, United Kingdom, [3]Wake Forest School of Medicine, Winston-Salem, NC, [4]Emory Children's Center, Atlanta, GA, [5]Childrens Hospital, Erlangen, Germany, [6]University of Utah, Salt Lake City, [7]Cincinnati Children's Hospital Medical Center, Cincinnati, OH

Background/Purpose: One of the principal findings of genome wide association studies in autoimmune diseases has been the substantial overlap of genetic susceptibility loci identified. This has underpinned fine mapping initiatives such as the Immunochip (IC) project in which custom chips were designed to fine-map regions of associations common to a number of autoimmune diseases. Samples from patients with rheumatoid arthritis (RA), juvenile idiopathic arthritis (JIA) and psoriatic arthritis (PsA) have been genotyped using IC; given that all are types of inflammatory arthritis (IA) which exhibit common pathology and some overlap of associated loci, the data emerging from IC provides a unique opportunity to identify novel overlapping regions and determine whether the causal variants within overlapping loci are the same or different for each disease.

Methods: As part of the IC project, genotyping, quality control and association analysis was performed for RA (11475 cases and 15870 controls), JIA (2816 polygoarticular and oligoarticular JIA cases and 13056 controls) and PsA (929 cases and 4537 controls). Some controls were shared between cohorts. For this analysis all SNPs with a minor allele frequency $>1\%$ which reached $p<10^{-3}$ in any of the 3 diseases were first selected. IC regions were defined as including all SNPs from the 1000 Genomes Project CEU population (September 2009 release) that were in 0.1-cM (HapMap3 CEU) recombination blocks around each GWAS region lead marker. IC Regions which contained SNPs associated with more than one type of IA were considered overlapping.

Results: 49 regions showed association at $p<10^{-3}$ with more than one type of IA, of these, in RA and JIA 4 loci (*PTPN22 STAT4, ANKRD55* and *TYK2*) reached genome wide significance (5×10^{-8}), with a further 7 associated at $p<10^{-5}$ in both diseases. Interestingly 4 of these loci are also associated with PsA at $p<10^{-3}$ (*TNFAIP3, PTPN2. RUNX1* and *TYK2*). 6 of these loci have been previously associated with both RA and JIA (*PTPN22, STAT4, AFF3, TNFAIP3, PTPN2* and *IL2RA*) whilst 5 are novel overlapping regions *(DNASE1L3, ANKRD55, TYK2, RUNX1* and *IL2RB)*. For the *PTPN22, STAT4, DNASE1L3, ANKRD55, TYK2* and *RUNX1* regions the RA and JIA associated SNPs are either identical or highly correlated ($r^2>0.8$), the direction of effect is the same in both diseases and odds ratios similar. For *AFF3, TNFAIP3* and *PTPN2* the associated SNPs are different and weakly correlated ($r^2>0.4<0.8$) but the direction of effect is similar for each disease. An interesting finding is that for *IL2RA* and *IL2RB* the pattern of association in the region is completely different.

Conclusion: These findings add to the body of evidence that there are shared susceptibility genes for inflammatory arthritis. Further investigation is required to fully explore whether the regions contain the same or different causal effect, including functional studies to determine whether, in overlapping loci with the same causal variant, the variant predisposes to disease by the same mechanism.

Dense Genotyping of Risk Loci in Black South Africans with Rheumatoid Arthritis: An Association Study.
Nimmisha Govind[1], Ananyo Choudhury[2], Bridget Hodkinson[1], Claudia Ickinger[1], Jacqueline Frost[3], Annette T. Lee[4], Peter K. Gregersen[4], Richard J. Reynolds[5], S. Louis Bridges Jr.[5], Scott Hazelhurst[2], Michèle Ramsay[3] and Mohammed Tikly[1]. [1]Division of Rheumatology, University of the Witwatersrand, Johannesburg, South Africa, [2]Wits Bioinformatics Department, University of the Witwatersrand, Johannesburg, South Africa, [3]Division of Human Genetics, National Health Laboratory Service, University of the Witwatersrand, Johannesburg, South Africa, [4]Feinstein Institute for Medical Research, Manhasset, NY, [5]Division of Clinical Immunology and Rheumatology, University of Alabama at Birmingham, Birmingham, AL

Background/Purpose: Genome wide association studies (GWAS) have identified numerous rheumatoid arthritis (RA) risk loci in patients of European and Asian ancestry but the causal variants have rarely been identified. These studies have also identified susceptibility loci that are common to various autoimmune diseases. The need to identify casual variants prompted the design of the Immunochip, a custom Illumina Infinium high density genotyping array, with 196 000 single nucleotide polymorphisms (SNPs) from 186 loci previously associated with 12 autoimmune diseases. Little is known about the genetics of RA in black South Africans. We aimed to test associations with known genetic loci and to identify novel risk loci in black South Africans with RA.

Methods: Consenting black RA patients fulfilling the 1987 ACR criteria for RA, >18 years at disease onset, and seen at a single centre in Johannesburg, South Africa were studied and compared to ethnically and geographically matched controls. Genotyping of 716 samples was performed using the Immunochip. Only samples with $\geq94\%$ call rate and individual SNPs with $\geq95\%$ call rate, were polymorphic, in Hardy-Weinberg equilibrium ($p\geq5 \times 10^{-7}$) and with a minor allele frequency of ≥0.02 were analyzed. The cohort was further pruned for relatedness and ancestral outliers. After quality control, 117 353 SNPs were tested for association in 263 cases and 365 controls. The statistical analysis was performed using PLINK vers1.07. A p value = $<5 \times 10^{-8}$ was considered significant based on previous genome wide association studies.

Results: The strongest associations were found in the MHC region with 64 SNPs reaching statistical significance. The most significant associations were in the intergenic region of the *HLA DRB1- HLA DQA1* alleles (rs3104413, OR=3.88, $p=5.49 \times 10^{-21}$; rs3129769, OR=3.91, $p=4.60 \times 10^{-21}$; rs6931277, OR=3.97, $p=1.03 \times 10^{-21}$). There were 2 non HLA SNPs that reached genome wide significance, rs9283487 (OR=3.25, $p=7.96 \times 10^{-18}$) in the *PRKRA* gene, and rs35198051 (OR=0.34, $p=2.94 \times 10^{-8}$) in the intergenic region of *C11orf76* and*LOC100133306*. In addition there were suggestive associations of 2 SNPs on chromosome 1, rs12739262 (OR=0.36, $p=1.36 \times 10^{-7}$) in the *PPP1R12B* gene and rs12738883 (OR=0.36, $p=1.69 \times 10^{-7}$) in the intergenic region of *PLD5* and *LOC400723*, both SNPs reached statistical significance in the rheumatoid factor (RF) positive subgroup (n=240/254) (rs12739262, OR=0.33, $p=9.10 \times 10^{-8}$ and rs12738883, OR= 0.33, $p=9.10 \times 10^{-8}$).

Conclusion: In keeping with previous studies the HLA class II region confers the strongest genetic risk for RA in black South Africans. We also found 2 novel SNPs in the overall cohort and a further 2 SNPs in the RF positive subgroup. The association of the *PRKRA* gene with RA is of interest

because of its recent association with Sjogren's Syndrome. Further studies in larger cohorts of African patients are required to validate these findings and to better understand the functional role of these novel loci in the pathogenesis of RA in black South Africans.

976

Effect of Interactions Between Validated Rheumatoid Arthritis Genetic Factors and Environmental Factors On Rheumatoid Arthritis Risk.

Chia-Yen Chen[1], Linda T. Hiraki[2], Susan Malspeis[3], Jing Cui[4], Bing Lu[4], Robert M. Plenge[3], Karen H. Costenbader[4] and Elizabeth W. Karlson[4]. [1]Harvard School of Public Health, Boston, MA, [2]Brigham and Women's Hospital, Harvard School of Public Health, Boston, MA, [3]Brigham and Women's Hospital, Boston, MA, [4]Brigham and Women's Hospital, Harvard Medical School, Boston, MA

Background/Purpose: Studies have shown associations between environmental factors and rheumatoid arthritis (RA) risk. Also, genome-wide association studies (GWAS) have identified genetic markers associated with RA risk. We examined additive and multiplicative gene-environment interactions between 44 RA genetic markers and smoking, parity/breast-feeding, body mass index (BMI), and BMI at age 18 in determining RA risk.

Methods: We used a pooled nested case-control sample of 541 RA cases, including 303 seropositive (CCP+ and/or RF+) cases, and 549 matched controls from the Nurses' Health Study and Nurses' Health Study II. Controls were matched on age, menopausal status, and post-menopausal hormone use. All participants were Caucasian. We genotyped 36 single nucleotide polymorphisms identified in previous GWAS and meta-analysis, and 8 HLA-DBR1 shared epitope (SE) genotypes at 4 digit resolution. The information on cumulative pack-years of smoking, parity and months of breast-feeding prior and BMI variables determined prior to RA diagnosis, and BMI at age 18 was extracted from questionnaires. We examined the main effects of the genetic and environmental factors. We tested for additive interactions using the attributable proportion (AP) due to interaction and tested for multiplicative interactions using a 1 d.f. test. We used unconditional logistic regression models, adjusted for matching factors. Bonferroni correction was used to adjust for multiple comparisons. We further stratified the cases into seropositive RA and seronegative RA phenotypes and tested for interactions separately.

Results: We found significant main effects of HLA-DBR1*0401 (OR=1.77, 95% CI=1.32–2.38), any HLA-DBR1 SE (OR=1.80, 95% CI=1.41–2.29), and smoking (OR=1.55, 95% CI=1.21–1.99) on RA risk. For the interaction analyses, combined HLA-DRB1 SE and HLA-DBR1*0401 showed significant interaction with smoking in all RA and seropositive RA. Also, PTPN22 showed significant interaction with smoking in all RA (**Table**). The effect of interaction between BMI prior to RA diagnosis and PXK on RA risk was significant in all RA (AP=0.74, p<0.005) and seropositive RA (AP=0.80, p<0.005). We also found significant interaction effects on RA risk between BMI at age 18 and HLA-DBR1*0401 in all RA (AP=0.66, p=0.013) and seropositive RA (AP=0.67, p=0.031). However, we did not find any significant interaction between genetic factors and parity/breast-feeding. Also, there was no significant interaction found in the seronegative RA phenotype. Several multiplicative interactions were significant, but none remained significant after multiple comparisons correction.

Table 1. Summary of significant additive interactions for 44 RA risk alleles after multiple comparison adjustment and corresponding stratified analyses

Genetic factors	Environmental factors	All cases		Seropositive cases

[1]cumulative pack-years of smoking none −10 vs. ≥10
[2]<30 vs. ≥30 kg/m² defined as obese by World Health Organization
[3]<25 vs. ≥25 kg/m² defined as overweight by World Health Organization
[4]P-values were corrected for multiple comparisons. We used unconditional logistic regression model with 3 indicator variables for genetic factor, environmental factor, and interaction, adjusting for age, menopausal status, and postmenopausal hormone use.
RA: rheumatoid arthritis; OR: odds ratio; CI: confidence interval; AP: attributable proportion due to interaction; SE: shared epitope; BMI: body mass index

Conclusion: We found significant gene-environment interaction effects on RA risk with stronger associations for the seropositive RA phenotype. We also found HLA-DBR1*0401 had different AP when interacting with different environmental factors, which suggests different mechanisms for these interactions. 14-3-3 Eta Is a Novel Citrullination Target in Rheumatoid Arthritis That Enhances Diagnostic Utility in Anti-CCP Negative Patients.

Walter P. Maksymowych[1], Vivian P. Bykerk[2], Désirée van der Heijde[3], R. Landewe[4] and Anthony Marotta[5]. [1]University of Alberta, Edmonton, AB, [2]Hospital for Special Surgery, New York, NY, [3]Leiden University Medical Center, Leiden, Netherlands, [4]Academic Medical Center/University of Amsterdam, Amsterdam, Netherlands, [5]Augurex Life Sciences Corp, North Vancouver, BC

Background/Purpose: 14-3-3 eta is normally an intracellular protein and only in the disease state is it released into the extracellular space. We have previously presented data describing serum 14-3-3 eta's diagnostic utility as a marker that complements RF and anti-CCP in early and established RA and is associated with joint damage in RA and PsA. Circulating autoantibodies directed to citrullinated proteins are highly specific for RA, but a significant percentage of patients are or remain sero-negative for anti-CCP. Given that 14-3-3 eta is liberated into the synovial space where PAD enzymes are present, we investigated whether 14-3-3 eta represents a novel citrullination target that could identify anti-CCP negative RA patients.

Methods: Assays to measure the autoantibody levels to either non-citrullinated (non-cit) or citrullinated (cit) 14-3-3 eta were developed using full-length recombinant human 14-3-3 eta. Full-length cit-14-3-3 eta was generated by citrullinating the protein with purified PAD. Reactivity to non-cit and cit-14-3-3 eta was evaluated in 3 anti-CCP positive RA patients to confirm the presence of autoantibodies to cit-14-3-3 eta. To evaluate whether these novel autoantibodies are detectable in anti-CCP negative RA patients and differentially expressed compared to healthy controls, reactivity to both non-cit and cit-14-3-3 eta was measured in 30 anti-CCP negative RA patients and 30 confirmed anti-CCP negative healthy controls. Mean and median fluorescence intensity [1 MFI = 1 unit (U)] was evaluated and corresponding t-tests and Mann-Whitney U-tests were used to determine differences within and between groups. The area under the ROC curve (AUC) was generated for diagnostic utility estimates and to determine likelihood ratios (LR) for various anti-cit-14-3-3 eta cut-offs.

Results: Compared to non-cit 14-3-3 eta, up to 25X higher reactivity was observed to cit-14-3-3 eta in 2 of the 3 anti-CCP positive RA patients, revealing the novel expression of autoantibodies to the citrullinated form of 14-3-3 eta in RA. Within the anti-CCP negative RA group, significantly higher reactivity was observed to cit versus non-cit-14-3-3 eta at 1943U versus 395U, p=0.01. No significant differences in reactivity were observed within the healthy group. Anti-cit-14-3-3 eta expression was significantly higher in anti-CCP negative RA patients with means (SD) and medians (min-max) of 1943U (3045U) and 306U (68–8982U) compared to 155U (122U) and 100U (45–564U) for healthy controls, p<0.002.The corresponding ROC AUC for anti-cit-14-3-3 eta differential expression in anti-CCP negative RA patients compared to healthy controls was 0.79 (95% CI 0.68–0.91; p<0.0001). At a cut-off of 320U, the specificity and sensitivity were 90% and 50% delivering an LR positive of 5 increasing to 14 at 439U with a corresponding specificity of 97% and sensitivity of 47%.

Conclusion: Extracellular 14-3-3 eta protein has been described as an RA diagnostic biomarker with prognostic and therapy monitoring applications. 14-3-3 eta also represents a novel citrullination target that is differentially expressed in anti-CCP negative RA patients versus healthy controls, indicating that anti-cit-14-3-3 eta may improve RA diagnosis.

A Genome-Wide Interaction Study with Smoking Suggests New Risk Loci for Two Different Subsets of Rheumatoid Arthritis; Results From Swedish Epidemiological Investigation of Rheumatoid Arthritis Study. Xia Jiang[1], Henrik Källberg[1], Leonid Padyukov[2], Lars Klareskog[2] and Lars Alfredsson[1]. [1]Karolinska Institutet, Stockholm, Sweden, [2]Rheumatology Unit, Karolinska Institutet, Stockholm, Sweden

Background/Purpose: Rheumatoid arthritis (RA) is believed to have a multifactorial etiology, involving both genetic and environmental components, and can be divided into two major subsets according to the presence/absence of anti-citrullinated protein/peptide antibodies (ACPA). Smoking is the most established environmental risk factor. Despite progress from genome-wide association studies (GWAS), identified genetic variants only explain a small proportion of RA occurrence. Hypothetically, gene-environment interaction could add etiologic understanding of the disease. The aim of current study was to investigate gene-environment interaction between smoking and SNPs from an Immunochip, with selected SNPs of interest from an inflammatory point of view, for each of the two major RA subsets.

Methods: Data from Swedish EIRA case-control study was analyzed by means of logistic regression models. Smoking history was collected through questionnaires. Heavy smoking was defined as more than 10 pack-years. Genetic information was obtained from an Immunochip scan. Interaction between smoking intensity and 133648 genetic markers that passed quality control were examined for the two RA subsets (1590 ACPA positive cases, 891 ACPA negative cases; compared with 1856 matched controls). Attributable proportion due to interaction together with 95% confidence interval was evaluated for each smoking-SNP pair.

Results: For ACPA positive RA, 390 SNPs were found to significantly interact with heavy smoking after Bonferroni correction, with a majority located in the HLA region (328 out of 390, 84.10%), all of which displayed high linkage disequilibrium (LD); for ACPA negative RA, 56 SNPs passed threshold for significance, most located outside the HLA region (51 out of 56, 91.07%). After adjusting for *HLA-DRB1* shared epitope (SE), 37 SNPs remained significant for ACPA positive RA, with 17 (45.95%) confined to HLA region and the rest spread across 9 other chromosomes; for ACPA negative RA, 19 SNPs stood out, all of them outside the HLA region. Through functional prediction and pathway annotation, 24 candidate genes/regions were identified for ACPA positive RA, several of them (*C6orf10, GRB10, HCG9, TAP2, PPT2, HLA-E, SMAD3*) together with *HLA-DR* presented a network of antigen presentation pathways; for ACPA negative RA, 13 genes were demonstrated, 6 of them (*GP1BA, AFF3, ICOSLG, NOTCH2, TGS1, LYN*) constitute T helper cell differentiation pathways. For ACPA positive RA, besides those SNPs in LD with known susceptibility variant at *HLA-DRB1*, none of the others have previously been identified.

Conclusion: Our study presents the most explicit picture to date, with regard to the patterns of gene-smoking interaction in ACPA positive/negative RA, suggesting fairly contrasting etiology of the two subsets. Our findings support the, by far, greatest influence from HLA-region on ACPA positive RA; while for ACPA negative RA, more genes outside HLA-region contribute to the etiology. Noticeably, for both RA subsets, new SNPs that are not significant in association analyses stand out in interaction analyses, indicating that genetic factors should be considered together with environmental factors in studies of RA etiology.

Cell-Type Specific Type I Interferon Signatures in Systemic Lupus Erythematosus and Viral Infection: What Makes the Difference? Chieko Kyogoku[1], Joachim R. Grün[1], Tobias Alexander[2]. Robert Biesen[2], Falk Hiepe[2], Thomas Häupl[2], Andreas Radbruch[1] and Andreas Grützkau[1], [1]German Rheumatism Research Centre Berlin (DRFZ), an institute of the Leibniz Association, Berlin, Germany, [2]Charité University Hospital Berlin, Berlin, Germany

Background/Purpose: Gene expression profiling experiments using peripheral blood mononuclear cells (PBMCs) revealed a crucial role of type I interferon (IFN) in the pathogenesis of systemic lupus erythematosus (SLE). However, it is almost unknown how particular leukocyte subsets contribute to the overall type I IFN signature described for PBMCs. Furthermore, a detailed analysis of how IFN signatures differ in autoimmune disease from that observed after viral infection is missing so far. Therefore, we compared expression levels of 2442 IFN signature genes in peripheral CD4+ T helper cells, CD16-negative inflammatory and CD16-positive resident monocytes (Mo) isolated from patients with SLE, healthy donors (ND) and ND vaccinated against yellow fever by global gene expression profiling.

Methods: Peripheral blood from 6 patients with SLE and 4 ND for CD4+ T cells, 4 patients with SLE and 4 ND for CD16-negative Mo, and 4 patients with SLE and 3 ND for CD16-positive Mo were recruited. Same ND were examined before and after immunization by yellow fever vaccine. After sorting cells, isolated RNA were applied to Affymetrix Human Genome U133 Plus 2.0 Array. Data analysis was done using BioRetis database, Genesis Software and Ingenuity Pathway Analysis (IPA). A reference list of 2442 IFN-related genes was obtained from recent publications and used to estimate IFN imprints.

Results: When compared total significantly differentially expressed probe sets, 9/3/2 (CD4+ T cells/CD16-negative Mo/CD16-positive Mo, respectively) times more number of probes were detected in patients with SLE compared to immunized ND. The contribution of IFN signature to total gene signature was 20.7/23.3/23.3 % in patients with SLE, whereas 48.6/35.2/30.5 % in immunized ND. 98/165/173 probe sets (fold change>=2, <=−2) were detected as a "common" IFN signature observed both in autoimmunity and in immunized ND. 111/164/120 probe sets were detected as an "autoimmune-specific" IFN signature, whereas only 0/8/5 probe sets were detected to be specific for the "virus-induced" IFN signature. Expression pattern of these IFN signature genes clearly distinguished patients with SLE from immunized ND by hierarchical cluster analysis. Although major IFN signature genes were commonly expressed in CD4+ T cells and Mo of patients with SLE and immunized ND, expression magnitudes of them were higher in patients with SLE compared to immunized ND. In SLE, in addition to the typical "viral-induced" IFN signature, genes that are involved in apoptosis signaling, antiviral PKR signaling, Fcγ receptor-mediated phagocytosis and IL-10-/ IL-9-/ IL-15-mediated JAK/Stat signaling pathways were identified by IPA.

Conclusion: This study demonstrated that IFN signature in autoimmunity and that in viral infection are quite different in the number of IFN-related genes activated and their expression magnitudes. Autoimmunity is characterized by a much stronger expression of IFN signature genes and is obviously modulated by a separate set of co-regulated genes defining the "autoimmune-specific" IFN signature. "Common" and "autoimmune-specific" IFN signature genes can be applied as a clinical biomarker to diagnose SLE flare discriminating from viral infection.

Background/Purpose: Systemic Lupus Erythematosus (SLE) is a complex autoimmune disease with an estimated prevalence of 40:100,000 cases in European populations. SLE has a strong genetic risk component (sibling relative risk 30). Positional candidate studies have identified the association of *HLADRB1*, *STAT4* and *IRF5* loci with SLE risk. However, Genome-Wide Association Studies (GWAS) have allowed to expand the number of SLE risk loci to more than 20. In order to identify additional risk loci we have performed a GWAS in a Southern European population.

Methods: 510 SLE cases and 1,540 controls of Spanish origin were genotyped for more than 550,000 SNPs using Illumina Quad-610 platform. Only SNPs having >95% call rate and individuals having 95% of SNPs genotyped were included. Principal Component Analysis was used to identify the main axis of variation and discard any population outlier. After QC-filtering 489 SLE cases and 1490 Controls were included to test for association. In order to evaluate the association of all previously known SLE-risk loci all GWASs published from 2,008 to 2,012 where evaluated. Loci associated at a nominal *P*-value < 5e-5 were included. Within each SLE risk locus (n=43), the SNP having the highest statistical evidence was selected. For those SNPs not directly genotyped (n=3) genotype was imputed using MACH v1.0 software.

Results: From the 24 loci previously showing Genome-Wide level of association (*P*<5e-8) with SLE risk, loci *HLA-DRB1, ITGAM, STAT4* and *MSH5* were also replicated at Genome-Wide level. Four additional loci were also replicated at nominal (*P*<0.05) level of significance. From the remaining 19 loci still requiring additional evidence (5e-8 < P < 5 e-5) we were able to nominally replicate three loci. 20 SNPs within genomic regions previously not associated with SLE were also identified (*P*<5e-5).

Conclusion: The present study has validated previous SLE risk loci in an independent population and gives additional support to loci with suggestive association. The association of the new candidate risk loci for SLE identified in this GWAS is currently being tested for validation.

Aggregated Genetic Information Explains Variations On Hand Radiographic Scores in Rheumatoid Arthritis Patient. Jing Cui[1], Nancy A. Shadick[2], Katherine P. Liao[1], Michael Weinblatt[3], Robert M. Plenge[1] and Elizabeth W. Karlson[4]. [1]Brigham and Women's Hospital, Boston, MA, [2]Department of Medicine, Division of Rheumatology, Immunology and Allergy, Brigham and Women's Hospital, Boston, MA, [3]Rheumatology & Immunology, Brigham & Women's Hospital, Boston, MA, [4]Brigham and Women's Hospital, Harvard Medical School, Boston, MA

Background/Purpose: Rheumatoid arthritis (RA) has an estimated heritability of approximately 60%. Joint destruction as a severity measure of RA is influenced by genetic factors, however the heritability of this trait remains unclear. Our objective was to determine the genetic heritability of joint destruction,

quantified as Sharp/van der Heijde scores (SHS), and to conduct a genome wide association study (GWAS) to identify SNPs associated with quantitative joint damage in RA patients.

Methods: We studied 422 anti-CCP+ RA subjects in a prospective observational RA cohort at an academic hospital with baseline bilateral hand radiographs and blood samples. Using the SHS method, 4 radiologists assigned an erosion score (0–5) for 16 joints, and a joint space narrowing score (0–4) for 15 joints in each hand (total SHS range 0–280). The inter-rater reliability for the SHS in our study was 0.93. SHS measures were normalized by taking the inverse normal of the rank. Samples were genotyped on the Affymetrix 6.0 platform. We applied standard quality control procedures, followed by imputation to 2.5M SNPs using IMPUTE with HapMap2 CEU. Clinical predictors of SHS such as age. gender, disease duration were studied using general linear regression.We applied mixed linear model analysis to estimate the proportion of variance explained by genotyped SNPs from the whole genome to determine heritability. We studied the association between each SNP and SHS using linear regression assuming a genetic additive model adjusting for the first three principal component values from Eigenvector analysis and RA disease duration.

Results: The 422 RA cases had mean age of 59 yrs, mean disease duration of 17 yrs, and 81% were female. The SHS range was 0–270 with median of 40. Clinical predictors including age and disease duration were significant in univariate analyses, and only disease duration was significant (P <0.0001) in multivariate analyses. Heritability analysis adjusted for disease duration and 3 principal components estimated 22% (p=0.39) of SHS variation was attributable to genetic variants using all genotyped SNP information. From the GWAS, we found 2 SNPs that exceeded the genome-wide significance threshold of 5E-8 (rs16925520 p=4E-9, rs2832760 p=3E-8) for association with SHS. The independent top 10 findings are shown in the table. The MHC region was not significantly associated with SHS. No known RA risk alleles (50 loci) were associated with SHS.

Table. Top 10 SNPs associated with Sharp/van der Heijde Hand Score

chr	rs	gene	Base pair	Allele A	Minor allele frequency	beta	P value
9	rs16925520	*JMJD2C*	7162354	C	0.01	3.52	4.3E-09
21	rs2832760	CLDN8	30584023	G	0.30	0.31	3.3E-08
5	rs10079663	VDAC1	133384433	C	0.41	0.28	1.1E-07
8	rs13256240	-	83633555	A	0.01	-3.38	2.2E-07
9	rs10901313	FUBP3	132275229	C	0.02	-2.13	1.1E-06
4	rs1980037	GYPB	145136964	A	0.02	2.73	1.2E-06
19	rs4801371	ZNF71	61926872	A	0.04	-1.28	1.8E-06
4	rs10024454	IGFBP7	57942964	C	0.32	-0.27	2.2E-06
8	rs1471705	ZFHX4	77880207	A	0.01	-2.79	2.7E-06
1	rs6674099	DISC2	230033485	A	0.45	0.23	3.2E-06

Conclusion: Our study suggests that joint damage in RA (as measured by SHS) is a heritable trait where genetic factors explain 22% of the phenotypic variance.These findings corroborate with a previous study where heritability was estimated to be higher at 45%-58%. Although several SNPs were associated with SHS at genome-wide significance, none were known RA risk alleles.These findings require confirmation in an independent sample.

982

Genetic Variants near Insulin-Like Growth Factor Binding Protein 3 (IGFBP3) Are Associated with Hip Osteoarthritis. Daniel S. Evans[1], Neeta Parimi[1], Ana M. Valdes[2], Hanneke J.M Kerkhof[3], Frederic Cailotto[4], Michael C. Nevitt[5], Steven R. Cummings[1], Rik J. Lories[4], Timothy D. Spector[2], Nigel K. Arden[6], Joyce B. van Meurs[3] and Nancy E. Lane[7]. [1]California Pacific Medical Center Research Institute, San Francisco, CA, [2]Dept of Twin Research and Genetic Epidemiology, St. Thomas' Hospital, King's College London, London, United Kingdom, [3]Department of Internal Medicine, Erasmus Medical Center and The Netherlands Genomics Initiative-Sponsored Netherlands Consortium for Healthy Aging, Rotterdam, Netherlands, [4]Laboratory for Skeletal Development and Joint Disorders, Department of Development and Regeneration, KU Leuven, Leuven, Belgium, [5]University of California-San Francisco, San Francisco, CA, [6]Oxford NIHR Musculoskeletal Biomedical Research Unit, University of Oxford, Oxford, UK, Oxford, United Kingdom, [7]UC Davis School of Medicine, Sacramento, CA

Background/Purpose: Hip osteoarthritis (HOA) is one of the most common joint disorders and can result in pain and disability.HOA is heritable,

Monday, November 12

but the particular genes contributing to the development of HOA are not well defined.To identify genetic associations with HOA, we conducted a two-stage genome-wide association study (GWAS).

Methods: All analyses were restricted to individuals of European ancestry.The discovery phase was performed using radiographically determined HOA cases and controls selected from the Osteoporotic Fractures in Men (MrOS) Study and the Study of Osteoporotic Fractures (SOF) (combined cases = 662).HOA cases were defined as Croft grade $\geq$ 2 or total hip replacement (THR).HOA controls were defined as Croft grade $\leq$ 1, maximum joint space narrowing (JSN) $\leq$ 1, maximum osteophytes $\leq$ 1, and no THR.SNPs were genotyped using the Illumina Omni1-Quad array and approximately 2.5 million SNPs were imputed using the HapMap reference panel.Logistic regression was performed, and MrOS and SOF results were combined using inverse variance weighted fixed effect meta-analysis.SNP associations with P-values $\leq 5 \times 10^{-8}$ were examined for replication in the Rotterdam cohorts (RSI = original cohort, RSII = second recruitment cycle), Twins UK, and Chingford cohorts.Publicly available eQTL data from HapMap CEU lymphoblastoid cell lines were used.

Results: On average, MrOS participants (100% male) were older than SOF participants (100% female) at the clinic visits when HOA was assessed (MrOS: mean$\pm$SD = 77.5$\pm$5.4 years, range = 69–97; SOF: mean$\pm$SD = 70.9$\pm$5.0 years, range = 65–91).In the discovery meta-analysis, the rs788748 A allele and the rs879966 G allele were associated with decreased odds for HOA (Table 1).The two directly genotyped SNPs were 23 kb apart and were in moderate LD (HapMap CEU r^2 = 0.54).Neither SNP remained nominally significant in conditional analysis, indicating dependence.The SNP rs788748 replicated in the RSI cohort, but not the RSII cohort or the Chingford cohort.In the Twins UK cohort, the association between the rs788748 A allele and HOA was significant and in the opposite direction relative to the discovery samples (Table 1).The SNP rs879966 did not replicate (Table 1).

Table 1. SNP association results in discovery and replication cohorts.

SNP	Effect allele (Freq)	MrOS/SOF (discovery) cases/ controls	OR (P)	RSI cases/ controls	OR (P)	RSII cases/ controls	OR (P)	Twins UK cases/ controls	OR (P)	Chingford cases/ controls	OR (P)
rs788748	A (0.49)	662/4750	0.71 (3×10^{-8})	462/3428	0.86 (0.03)	149/1430	1.02 (0.86)	73/366	1.48(0.03)	83/492	1.11 (0.54)
rs879966	G (0.39)	662/4750	0.70 (2×10^{-8})	462/3428	0.92 (0.24)	149/1430	1.12 (0.38)	73/366	1.34(0.10)	83/492	1.00 (0.99)

From eQTL data, rs788748 and rs879966 were marginally associated with IGFBP3 expression (P-value = 0.07 and 0.06, respectively), but not IGFBP1 expression (P-value = 0.74 and 0.34, respectively).SNP associations with circulating IGFBP3 levels and results from IGFBP3 knockdown experiments in the ATDC5 chondrogenesis model system will be presented.

Conclusion: Our genetic association and eQTL results provide suggestive evidence for a link between IGFBP3 and HOA, but further replication is required for the association results to be considered robust.IGFBP3 is known to be expressed in human chondrocytes and might be an attractive candidate for follow-up studies.

Genome-Wide Association Study and Gene Expression Analysis Identifies CD84 As a Predictor of Response to Etanercept Therapy in Rheumatoid Arthritis. Jing Cui[1] and International RA Consortium on Therapy (InteRACT)[2]. [1]Brigham and Women's Hospital, Boston, MA, [2]Boston, MA

Background/Purpose: There are no biomarkers that predict response to anti-TNF therapy in rheumatoid arthritis (RA).Here, we conduct a genome-wide association study (GWAS) to identify genetic variants that influence response to anti-TNF therapy.

Methods: GWAS data were aggregated on 2,743 RA patients as part of an international collaboration. Clinical data and Disease Activity Score (DAS28) were available for RA patients treated with three anti-TNF medications: etanercept (N=773), infliximab (N=894) or adalimumab (N=1,071). GWAS data were quality controlled by genotype batch, and all data were imputed to 2.5M SNPs using IMPUTE with HapMap2 CEU. Change in DAS28 (delta-DAS) was used as the primary phenotype in linear regression association tests of all samples combined and subset by anti-TNF drug.We adjusted for baseline DAS28 and three ancestry-derived principal component eigenvectors. Expression quantitative trait locus (eQTL) data for

the *CD84* locus were available for peripheral blood mononuclear cells (PBMCs, N=228). Replication samples from the Portuguese Reuma.pt registry (n=405), and the Japanese IORRA and Kyoto University Hospital registries (n=374), were genotyped using Sequenom and/or TaqMan and analyzed as in our GWAS.

Results: While no single SNP was genome-wide significant for association with delta-DAS in an analysis of all samples combined, a SNP at the *1q23/CD84* locus was highly significant in the etanercept subset of patients (rs6427528, $P=7 \times 10^{-8}$).This same SNP was not associated with delta-DAS in the infliximab or adalimumab subsets ($P>0.05$). The allele associated with a better response, which is in the 3' UTR of an immune-related gene *CD84*, is also associated with higher *CD84* gene expression in PBMCs ($P<10^{-12}$). In a subset of RA patients with gene expression data, *CD84* gene expression correlates with baseline DAS (n=210, $P=0.02$), and demonstrates a non-signficant trend toward predicting response to etanercept therapy.In a small replication study, the SNP was not associated with response to etanercept therapy among European (n=139, $P=0.4$) or Japanese (n=151, $P=0.8$) RA patients.

Conclusion: GWAS in etanercept-treated RA patients revealed a highly suggestive association with the *CD84* locus.Further, *CD84* gene expression is under genetic control and influenced by disease activity. These findings provide support that *CD84* genotypes and/or expression may serve as a useful biomarker for response to etanercept treatment in RA, although larger replication studies are required.

Association of Elevated C5a Levels, but Not the Presence of Anti-Cfh IgG Autoantibodies, with the Deletion of *CFHR3* and *CFHR1* in SLE. Jian Zhao, Seema Kamble, Yun Deng, Magdangal Erika, Daisuke Sakurai, Rongqun Li, Weiling Chen, Jennifer M. Grossman, Bevra H. Hahn and Betty P. Tsao. Division of Rheumatology, David Geffen School of Medicine, University of California Los Angeles, Los Angeles, CA

Background/Purpose: We previously reported association of the deletion of complement regulator factor H related *CFHR3* and *CFHR1* genes (*CFHR3-1Δ*), rather than *CFH* exonic SNPs, with SLE in 15,864 case-control subjects of multiple ancestries ($P=2.9\times10^{-7}$, OR=1.17). Both CFHR3 and CFHR1 suppress C5a generation, and *CFHR3-1Δ* has been associated with the presence of anti-CFH IgG autoantibodies that block CFH C-terminal binding in patients with atypical hemolytic uremic syndrome. To investigate possible functional consequences of *CFHR3-1Δ* in SLE, we tested its association with 1) the presence of anti-CFH IgG autoantibodies, and 2) elevated C5a levels.

Methods: *CFHR3-1Δ* was either directly genotyped by multiplex ligation-dependent probe amplification or deduced by its tag SNP rs6677604 (r^2=1).Levels of plasma C5a and anti-CFH IgG autoantibodies were measured by ELISA. The presence of anti-CFH IgG autoantibodies (anti-CFH+) was defined as higher levels than the mean + 3 SD of those from healthy controls carrying no deletion.

Results: Plasma anti-CFH IgG autoantibodies levels showed no difference between SLE cases and controls (Mean$\pm$SEM: 5.46$\pm$0.074 RU/ml in 75 cases vs. 5.47$\pm$0.063 RU/ml in 45 controls, $P=0.91$), no difference between men and women ($P=0.71$ in cases [9 men and 66 women]; $P=0.23$ in controls [22 men and 23 women]) and no correlation with age (r^2=0.00042 in cases [mean: 43 years old, range: 18–72], $P=0.91$; r^2=0.0010 in controls, $P=0.79$ [mean: 39, range: 20–77]). Anti-CFH+ was only identified in 4 of the 75 studied SLE cases (7%): two of them carried two copies of *CFHR3-1Δ* and the other two had zero copies, showing no association of anti-CFH+ with *CFHR3-1Δ* ($P=1.00$). Although none of the 45 controlswas classified as anti-CFH+, the presence of anti-CFH was not significantly associated with SLE ($P=0.30$) at the current sample size.

Preliminary results of plasma C5a levels were significantly higher in 15 SLE cases carrying two copies of *CFHR3-1Δ* than in 84 cases carrying one or zero copy (Mean$\pm$SEM: 5.23$\pm$0.13 ng/ml vs. 4.86$\pm$0.06 ng/ml, $P=0.018$). We observed no significant difference in plasma C5a levels between 5 controls carrying two copies of *CFHR3-1Δ* and 57 controls carrying one or zero copy (Mean$\pm$SEM: 4.57$\pm$0.29 ng/ml vs. 4.76$\pm$0.09 ng/ml, $P=0.55$), which might be due to the small sample size.

Conclusion: Our preliminary data showed that homozygous deletion of *CFHR3-1Δ*, which predisposes to SLE, was associated with elevated C5a levels in SLE cases, suggesting that this deletion might confer SLE risk by uninhibited production of C5a leading to neutrophil chemotaxis and inflammatory injuries. In contrast, the deletion was not associated with IgG

antibodies to CFH. Further investigation of these association in additional samples is ongoing.

Inverse Relation Between the *tumor Necrosis Factor* Promoter Methylation and Trascript Levels in Leukocytes From Patients with Rheumatoid Arthritis. James R. Maxwell[1], Lyndsey H. Taylor[2], Richardo A. Pachecho[2], Neil Lawrence[2], Gordon W. Duff[3], M. Dawn. Teare[2] and Anthony G. Wilson[4]. [1]University of Sheffield, Sheffield, United Kingdom, [2]University of Sheffield, United Kingdom, [3]Royal Hallamshire Hospital, Sheffield, United Kingdom, [4]Section of Musculoskeletal Sciences, University of Sheffield, Sheffield, United Kingdom

Background/Purpose: The importance of the epigenetic signature in RA is unclear but levels of methylation of CpG motifs in the *TNF* promoter are known to be important determinants of transcriptional activity.In view of the central importance of this cytokine in RA we hypothesised that methylation of the TNF gene in peripheral blood cells might differ between RA patients and controls.The primary objectives were to determine if CpG motifs in the TNF gene promoter are differentially methylated in RA compared with controls and if TNF mRNA levels correlated with DNA methylation.We also determined whether methotrexate was associated with alterations in genomic or TNF promoter DNA methylation levels.

Methods: A cross-sectional RA population (n=218) and healthy controls (n=312) was used to investigate the primary objective.A second population of RA patients starting MTX were recruited (n=33) and DNA and DAS28 scores were obtained prior to treatment and at 3 months.Methylation of seven *TNF 5'* CpG motifs (-349 to -78) and LINE-1, an assay of genomic mehtylation, in peripheral blood leucocytes were assessed by pyrosequencing and levels of TNF mRNA were measured using quantitative PCR.

Results: Levels of methylation of 4 TNF CpGs (-170, -239, -245, -304) were higher in RA compared with controls (p=7.1×10^{-5} to 1.3×10^{-10}) and TNF mRNA was 58% lower in RA cases (p=1.5×10^{-10}).In both RA and controls negative correlations of *TNF*-245 methylation with TNF mRNA levels were detected (p=0.02 and 0.04 respectively). There was no difference in LINE-1 or TNF methylation in MTX treated patients and no correlation between change in methylation with DAS28 response after 3 months.

Conclusion: Higher levels of methylation of the *TNF* promoter are present in RA leukocytes compared with controls, and levels of TNF mRNA were lower in the patients.Methylation levels of *TNF*-245 were inversely correlated with TNF mRNA levels in both groups.Treatment with MTX was not associated with changes in genomic or *TNF* methylation levels.These results suggest that methylation of the *TNF* promoter is higher in RA compared with controls and that methylation of TNF-245 is an important regulatory mark for TNF expression.

Genome Wide Association Studies of Knee Osteoarthritis in 2 Large North American Cohorts: A Meta-Analysis with 2667 Cases. Marc C. Hochberg[1], Laura Yerges-Armstrong[2], Changwan (Larry) Lu[2], Michelle S. Yau[1], Braxton D. Mitchell[2], Joanne M. Jordan[3], Youfang Liu[4], Jordan B. Renner[5], T. McSherry[6], D.M. Taverna[6], David Duggan[6], W.J. Mysiw[7] and Rebecca D. Jackson[8]. [1]University of Maryland, Baltimore, MD, [2]University of Maryland School of Medicine, Baltimore, MD, [3]University of North Carolina Thurston Arthritis Research Center, Chapel Hill, NC, [4]University of North Carolina, Chapel Hill, NC, [5]University of North Carolina at Chapel Hill Dept of Radiology, Chapel Hill, NC, [6]TGen, Pheonix, AZ, [7]Ohio State University, Columbus, [8]Ohio State University, Columbus, OH

Background/Purpose: A strong genetic contribution to knee osteoarthritis (OA) is widely recognized although few loci have been robustly associated with knee OA susceptibility. To identify genes associated with knee OA, we performed a meta-analysis of genome wide association (GWA) results from two large studies of knee OA: the Genetic Components of Knee OA (GeCKO) Study, an ancillary study from the Osteoarthritis Initiative (OAI), and the Johnston County (JoCo) Osteoarthritis Project.In addition, we attempted replication of 18 single nucleotide polymorphisms (SNPs) previously reported in the literature to be associated with hip or knee OA by the TREAT-OA Consortium, arcOGEN Study and others.

Methods: Cases with knee OA were Caucasians who had at least one knee with definite radiographic OA (Kellgren-Lawrence [KL] grade >=2) at any available visit.Controls were Caucasians who were free of definite radiographic OA in both knees (KL grade <=1) at all available study visits.In total, data from 2014 cases and 953 controls from the OAI and 653 cases and 823 controls from the JoCo Study were included in the analysis. The OAI and JoCo DNA samples were genotyped using the Illumina 2.5M and Illumina 1M genotyping chip, respectively.In both studies imputation was performed using the 1000 genomes reference panel (June 2011 release) and statistical analysis was performed assuming an additive genetic model and adjusting for participant age and sex. Fixed-effects meta-analysis was conducted using METAL.

Results: Over 5.8 million SNP variants present in both the OAI and JoCo datasets and having both high quality 1000 genomes imputation (r^2>0.3) and minor allele frequency of at least 5% were included in the meta-analysis.Ten variants had a meta-analysis P-value $< 1 \times 10^{-6}$ with Odds Ratios ranging from 1.27–1.54.The 10 variants were located in three loci: one on chromosome 11p15.4 upstream of the *TRIM21* gene (encodes for tripartite motif-containing protein 21, an intracellular antibody effector in the proteolysis pathway), and two in non-genic regions of chromosome 11p15.3and chromosome 2q35; the closest genes to the latter region being *MREG* and *FN1* (*FN1* encodes for fibronectin, a glycoprotein that binds to chondrocytes and is involved in cell adhesion and migration).Similar to previously reported findings (Osteoarthritis Cart 2012;20[Suppl 1]:S46), only the rs143383 SNP in *GDF5* (Growth and Differentiation Factor 5) was modestly associated with knee OA (P = 0.006) in the current analysis.

Conclusion: These data support the polygenic nature of the genetic contribution to knee OA. Further analyses will consist of both de novo and in silico replication in other datasets and populations.

Autoimmune Susceptibility Genes Are Regulators of Gene Expression Response to ER Stress. William E. Bernal[1], Michael P. Morley[2] and Vivian G. Cheung[3]. [1]The Children's Hospital of Philadelphia, Philadelphia, PA, [2]University of Pennsylvania, Philadelphia, PA, [3]Howard Hughes Medical Institute, Chevy Chase, MD; University of Pennsylvania, Philadelphia, PA

Background/Purpose: Endoplasmic reticulum (ER) stress is caused by excessive demands on the protein-processing capacity of the ER; inefficiencies in response to ER stress lead to human diseases such as ankylosing spondylitis (AS). ER stress has been linked to inflammatory pathways. To study the role of ER stress in disease susceptibility, we identified the genes and pathways involved in ER stress response in human cells, assessed individual variation in these pathways, and mapped DNA sequence variants that influence ER stress response.

Methods: To study ER stress response in B-cells, we exposed the cells from 131 normal unrelated individuals to tunicamycin, a chemical inducer of ER stress, and measured changes in gene expression before and following ER stress. Then, to determine the genetic basis of variation in gene expression response to ER stress, we carried out genetic mapping using B-cells from members of 15 extended families.

Results: We identified 1,523 ER stress-responsive genes which showed at least 1.5 fold changes in gene expression following ER stress.The results showed extensive individual variation in gene expression response to ER stress.For instance, TNFSF13B (BAFF/Blys), a potent activator of B cells, has a mean induction of 1.6-fold but there is a 2.4-fold difference in its level between the individuals with the lowest and highest induction of this gene.XBP1 and DDIT3 (CHOP), which encode key ER stress transcription factors, vary by 5-fold and 9-fold. From our linkage and association studies, we focused our analysis on 778 ER stress-responsive genes and identified DNA sequence variants that regulate the response of 497 of the genes, including TNFSF13B.Regulators of gene expression response to ER stress include susceptibility genes for autoimmune diseases: BLK (systemic lupus erythematosus, rheumatoid arthritis, Kawasaki disease); SVIL (multiple

sclerosis); ANTXR2, RUNX3 and ERAP1 (AS). Genes associated with neurodegenerative diseases in which ER stress is known to play a role in disease pathology–amyotrophic lateral sclerosis, Alzheimer disease, Parkinson disease–are also represented among the regulators.

Conclusion: These results allowed us to identify genes and their regulators involved in ER stress response in human B-cells. The presence of susceptibility genes for autoimmune diseases among the regulators identified in our study implicates ER stress in disease pathology. Identification of TNFSF13B as an ER stress-responsive gene in human B-cells provides further evidence of a link between ER stress and inflammation.

Zone-Specific Protein Profiles in Human Cartilage Unraveled by a Quantitative Proteomic Approach.
Patricia Fernandez-Puente[1], Lucia Lourido[2], Valentina Calamia[2], Jesus Mateos[2], Cristina Ruiz-Romero[2], Martin K. Lotz[3] and Francisco J. Blanco[2], [1]Osteoarticular and Aging Research Group. Rheumatology Division, Biomedical Research Center (INIBIC). Hospital Universitario A Coruña, As Xubias de Arriba 84, 15006, A Coruña, Spain, [2]Rheumatology Division, Proteomics Group/ProteoRed-ISCIII, INIBIC-C. Hospitalario, A Coruña, Spain, [3]Department of Molecular and Experimental Medicine, The Scripps Research Institute, La Jolla, CA

Background/Purpose: Articular cartilage consists of a single type of cells called chondrocytes, which comprise 2–5% of total tissue mass and an extracellular matrix (ECM) mainly composed of water, proteoglycans and collagens. The tissue function is dependent on the molecular composition of this ECM. Articular cartilage is characterized by a zonal architecture with unique cell phenotypes and ECM properties in the superficial, middle and deep zone. In osteoarthritis (OA), cartilage is thinned, eventually completely degraded, resulting in joint dysfunction and pain. OA is also associated with hypertrophic bone changes with osteophyte formation, subchondral bone remodeling, and, chronic inflammation of the synovial membrane. The final common pathway of cartilage destruction results from a failure of chondrocytes to maintain a homeostatic balance between matrix synthesis and degradation. There is a considerable interest pointed in the characterization of new cartilage specific OA biomarkers for diagnosis and disease progression studies in OA. The aim of this work was to identify and localize proteins in normal cartilage, and compare them to the osteoarthritic tissue in a quantitative way.

Methods: Cartilage samples were obtained from OA patients undergoing joint replacement and normal donors without history of joint disease (n=3). For the localization studies, independent normal cartilage samples (n=3) were sectioned into three layers (superficial, middle and deep). Cartilage proteins were extracted, quantified, digested with trypsin and differentially labelled with iTRAQ isobaric tags. The peptide mixture was separated by two-dimensional LC coupled to MALDI-TOF/TOF mass spectrometry. Identification and relative quantification of the proteins were performed using ProteinPilot 3.0 software.

Results: We identified 220 different proteins in normal articular cartilage. An increased abundance of type VI collagen and small proteoglycans (mimecan, lumican or PRG4) was detected in the superficial layer of cartilage. Several proteins involved in cell adhesion processes were also increased in this layer (gelsolin, vitronectin, tenascins). The middle layer was characterized by a high presence of type II, V, IX and XXVIII collagens, cartilage intermediate layer proteins (CILPs), COMP, vitrin and decorin. Finally, the deep layer exhibited an increased abundance of type I and XI collagens, aggrecan and bone-related proteins (bone sialoprotein 2, osteomodulin, and bone morphogenetic protein 3). Comparison of this normal cartilage proteome with that from OA tissue led to the identification of 281 proteins: 23 were increased in the pathologic tissue (including aggrecan, COMP, complement factors or thrombospondin 1), whereas 36 were decreased in OA cartilage, such as type I, II and VI collagens, proteoglycans (biglycan, PRG4), tenascins or actin.

Conclusion: In summary, more than 300 different human articular cartilage proteins have been mapped according to their presence in the three different tissue layers. 59 of them were altered in OA cartilage when compared to normal tissue. This information would be of high relevance in the search of tissue-specific OA biomarkers.

989

Genome-Wide Analysis Reveals a Recessive Association of *ERAP1* Variants with Behçet's Disease and Epistasis Between *ERAP1* and *HLA-B*51*.
Elaine F. Remmers[1], Yohei Kirino[1], George Bertsias[1], Yoshiaki Ishigatsubo[2], Yoonhee Kim[3], Michael J. Ombrello[1], Ilknur Tugal-Tutkun[4], Emire Seyahi[5], Yilmaz Ozyazgan[5], F. Sevgi Sacli[5], Burak Erer[4], Zeliha Emrence[6], Atilla Cakar[6], Neslihan Abaci[6], Duran Ustek[6], Colleen Satorius[1], Mitsuhiro Takeno[2], Ahmet Gül[4] and Daniel L. Kastner[1]. [1]National Human Genome Research Institute, National Institutes of Health, Bethesda, MD, [2]Yokohama City University Graduate School of Medicine, Yokohama, Japan, [3]National Human Genome Research Institute, National Institutes of Health, Baltimore, MD, [4]Istanbul Faculty of Medicine, Istanbul University, Istanbul, Turkey, [5]Cerrahpasa Faculty of Medicine, Istanbul University, Istanbul, Turkey, [6]Institute of Experimental Medicine, Istanbul University, Istanbul, Turkey

Background/Purpose: We recently performed a genome-wide association study in 1215 patients with Behçet's disease (BD) and 1278 controls from Turkey and found disease-associated variants within the class I region of the *MHC*, and in the *IL10* and *IL23R* loci. However, the combined effects of these loci account for less than 10% of the estimated disease heritability, suggesting other loci are yet to be identified.

Methods: To limit disease heterogeneity, we performed an analysis of the subset of patients with uveitis. In this subset we expanded the association analysis to include 3 genetic models, additive, dominant, and recessive, correcting the threshold for genome-wide significance for the 3 models examined. Confirmatory studies were conducted in our combined GWAS and replication sets of 2017 BD cases and 1875 controls, and in this sample an interaction between two loci was evaluated with a logistic likelihood ratio test comparing a full model (including a multiplicative interaction term) with a reduced model (without the interaction term).

Results: A genome-wide analysis, applying a recessive model, in 420 BD patients with uveitis and 1278 controls revealed one variant located 5′ of *ERAP1*, with near genome-wide significance (rs2927615, p = 1.02×10^{-7}). This effect was not observed with an additive or dominant model. *ERAP1* encodes an endoplasmic reticulum expressed aminopeptidase that plays an important role in trimming and loading intracellular peptides for class I MHC presentation. Fine-mapping with the same samples and replication in an independent collection of 370 Turkish BD cases with uveitis and 630 controls identified two disease-associated non-synonymous variants in *ERAP1*, with the most significant combined p value for rs17482078 (R725Q) = 4.73×10^{-11}, OR = 4.56, 95%CI: 2.88–7.22). Focusing solely on the recessive model, the effect of the variant was corroborated by meta-analysis of the combined 2017 BD cases (including those with and without uveitis) and 1875 controls (p = 4.35×10^{-8}). Furthermore, we identified a genetic interaction between the BD-associated MHC class I allele, *HLA-B*51*, and *ERAP1* (p < 0.0009) in the combined Turkish GWAS and replication samples. *ERAP1* R725Q homozygosity compared with non-homozygosity was associated with an OR for BD of 3.78 (95% CI = 1.94–7.35) in *HLA-B*51* positive individuals versus an OR of 1.48 (95% CI =0.78–2.80) in *HLA-B*51* negative individuals.

Conclusion: A coding variant of *ERAP1*, encoding endoplasmic reticulum expressed amino peptidase 1, recessively confers risk for BD preferentially to individuals carrying the disease-associated *HLA-B*51* allele. Genetic similarity with two other *MHC class I* associated diseases, ankylosing spondylitis and psoriasis (shared loci include *MHC class I*, *IL23R*, *ERAP1* and the *MHC-ERAP1* interaction), suggest shared pathogenic pathways among these diseases.

990

Proteomic Shotgun Analysis of Mesenchymal Stem Cells Reveals an Altered Regulation of Proteosomal Proteins in Osteoarthritis Patients.
Jose Ramon Lamas. Hospital clinico San Carlos, Madrid, Spain

Background/Purpose: To describe proteins with a potential role in OA pathogenesis, in this study we have followed a proteomic approach based on a shotgun comparative analysis of Mesenchymal Stem Cells (MSCs) isolated from OA patients and healthy donors.

Methods: MSCs were obtained from bone marrow aspirates at the time of joint replacement surgery of three OA patients (mean age 76.7 years) and three hip fracture subjects without OA (mean age 73.3). Cells were cultured and expanded. Confluent cells at the third passage (approximately 2×10^6) were used for the experiments. After Protein extraction, solubilization and digestion, samples were subjected to a LC-MS shotgun analysis. For protein identification the MS/MS spectra were extracted using the Proteome Discoverer 1.0 software and searched against the MSIPI human database (version 091510) using the Mascot 2.1 program. GeneCodis 2.0 software was used for functional classification of differential proteins.

Results: A total of 1748 proteins were identified. The statistical analysis revealed 123 differentially expressed proteins between OA-MSCs and control MSCs with foldchange values > 2 times at the p < 0.05 level of significance, of which 76 (62%) were upregulated and 47 (38%) were downregulated in OA-MSCs as compared with control cells. Interestingly, five proteosomal proteins, pertaining to the regulation of ubiquitin-protein ligase activity biological function: PSMD2 (2.52), PSMA1 (3.36), PSMB3 (4.56), PSMA3 (7.08) and PSMA4 (13.26) were clearly upregulated.

Conclusion: Given that proteasomal-dependent degradation has a critical role in regulating activities of key osteoblastogenic transcription factors (e.g., RUNX2, ATF4) and signaling pathways (e.g., Hedgehog, BMP, Wnt/β-catenin), upregulation of proteasome subunits and increased activity in MSCs from OA patients might be related to reduced bone mass and/or poor bone tissue quality in OA patients.

MTHFR Polymorphisms in Systemic Lupus Erythematosus and Rheumatoid Arthritis: Associations with Intima Media Thickness Scores. Clio P. Mavragani[1], Maira Giannelou[2], Ioanna Papadaki[3], Eleni Antypa[4], Dimitrios Ioakeimidis[5], Haralampos M. Moutsopoulos[2] and Michael Koutsilieris[1]. [1]School of Medicine, University of Athens, Athens, Greece, Athens, Greece, [2]School of Medicine, University of Athens, Athens, Greece, [3]General Hospital of Athens "G. Gennimatas", Athens, Greece, [4]General Hospital of Athens, Greece, [5]General Hospital, Greece

Background/Purpose: Previous studies identified polymorphisms in the gene coding for the Methylenetetrahydrofolatereductase (MTHFR) enzyme as genetic contributors for cardiovascular disease in the general population. The purpose of the present study was to determine the prevalence of the MTHFR polymorphisms for either 677 or 1298 allele in patients with systemic lupus erythematosus (SLE) and rheumatoid arthritis (RA) and to investigate whether they associate with carotid and femoral intima media thickness scores and plaque formation.

Methods: 77 consecutive SLE patients, according to the American/European classification criteria, 101 RA patientsand 137 healthy controls were enrolled. All study groups were assessed for MTHFR 677CT or 1298AC genotype. Furthermore, all patients underwent ultrasound determination of intima-media thickness score (IMT) and plaque formation in the carotid and femoral arteries.Data regarding clinical, hematological, serological, immunological information and therapeutic regimens were recorded in all patients. Classical risk factors for cardiovascular disease were also assessed.

Results: The prevalence of MTHFR TT and CC genotypes in the SLE group was 25% (19 of 77 patients) for the 677 allelle and 10.5% (8 of 77 patients) for the 1298 allele, respectively. The corresponding figures for the RA group were 9% (12 of 133) and 9.8% (13 of 133) and the healthy controls 13.13% (18 of 137) and 9.48% (13 of 137), respectively. A significantly higher prevalence for the MTHFR homozygous 677TT mutation was observed in patients with SLE compared to both RA patients and healthy controls (p-values 0.004 and 0.038, respectively). No differences were detected in the prevalence of the different MTHFR genotypes between RA and healthy controls.

Among the 77 SLE patients evaluated for subclinical atherosclerosis, 25 (32.46%) had increased IMT scores (defined as >0.90mm) and 44 (57.14%) had plaque. IMT score was found positively associated with the presence of either the MTHFR 677 or 1298 homozygous mutation (p=0.026). A trend of increased IMT scores was detected in RA patients

sharing the heterozygous MTHFR 1298 AC genotype compared to the other groups.No correlation was found between the development of plaque and the presence of any MTHFR mutation in SLE and RA populations.

Conclusion: The prevalence of MTHFR homozygous mutation for 677 allele was significantly higher in SLE compared to RA and controls. Furthermore, IMT score was found positively associated to homozygocity for either MTHFR 677TT or 1298CC, suggesting the effect of genetic risk factors in the accelerated atherosclerotic disease characterizing SLE patients.

Functional Genomics of the Human ITGAM Locus. Yebin Zhou[1], Dan C. Bullard[1], Alexander Szalai[2]. Jianming Wu[3] and Jeffrey C. Edberg[4], [1]University of Alabama at Birmingham, Birmingham, AL, [2]University of alabama at birmingham, Birmingham, AL, [3]University of minnesota, St. Paul, MN, [4]Department of Medicine, University of Alabama at Birmingham, Birmingham, AL

Background/Purpose: ITGAM encodes CD11b, the α_M subunit of the Mac-1-$\alpha_M\beta_2$ integrin. Mac-1 has many functions on leukocytes including its role as an adhesion molecule and complement receptor.Genome wide association studies (GWAS) have demonstrated that a non-synonymous SNP in the ITGAM locus, rs1143679 encoding an Arg/His in the extracellular domain, is associated with SLE susceptibility. This variant is in strong linkage disequilibrium with another common non-synonymous SNP (rs1143678 encoding a Ser/Lys in the cytoplasmic domain). We have explored possible functional changes due to these ITGAM variants through analysis of expression level, activation and cell function using ex vivo approach with neutrophils from genotyped healthy donors.

Methods: Neutrophils from healthy control donors genotyped at both rs1142679 and rs1143678 were isolated for ex-vivo functional studies.The phagocytic potential of CD11b variants was probed with complement coated erythrocytes (EAC) and serum treated zymosan (STZ).The adhesion potential of ITGAM variants was assessed in a flow chamber analyzing neutrophil adhesion to both ligand (ICAM-1) and endothelial cells.Total neutrophil CD11b expression and expression of the activation dependent I-domain was assessed by flow cytometry.

Results: In 2424 healthy control donors, we confirmed strong LD between SNP rs1134678 and rs1143679 (D'=0.97, r=0.82).We assessed the functional potential of neutrophils from donors heterozygous for each SNP alone using STZ to determine complement dependent binding and phagocytosis.Variation at either SNP results in a quantitative decrease in STZ phagocytosis and that donors heterozygous for both variants had even lower phagocytosis (repeated measures ANOVA, p<0.04, n=3).Quantitative complement dependent phagocytosis was also significantly decreased in donors homozygous for the variant alleles (39% decrease for STZ, n=3 pairs, p<0.02/38% decrease for EAC, n=3 pairs, p<0.02).In a flow chamber based assay of neutrophil adherence, cells from donors homozygous for the variant alleles of rs1134678 and rs1143679 adhered significantly less than neutrophils for donors homozygous for the common alleles (adherence to ICAM-1/endothelial cells:42% decrease, n=3 pairs, p<0.002/46% decrease, n=4 pairs, p<0.001).

These functional changes in neutrophil Mac-1 function were not attributable to differences in total CD11b expression nor to difference in expression of the activation induced I-domain in donors homozygous for the common vs. variant alleles of ITGAM.

Conclusion: We demonstrate that ITGAM variants rs1143678 and rs1143679 SNP each make separate contributions to alterations in Mac-1 function on human neutrophils.These functional alterations are not caused by differences in quantitative total receptor expression or expression of the I-domain.The study of the functional consequences of allelic variants associated with disease in primary human cells is necessary to fully understand the role of disease associated genetic variants.

A Genome-Wide DNA Methylation Analysis Reveals Different Methylation Patterns in the OA Disease. Ignacio Rego-Pérez[1], Juan Fernandez-Tajes[1]. Mercedes Fernandez-Moreno[1], Maria Tamayo Novas[2], Alejandro Mosquera Rey[2], Natividad Oreiro[1], Carlos Fernandez-Lopez[1], Jose Luis Fernandez Garcia[2] and Francisco J. Blanco[1]. [1]INIBIC-Hospital Universitario A Coruña. Rheumatology Division. Genomic Group, A Coruña, Spain, [2]INIBIC-Hospital Universitario A Coruña. Genetic Deparment., A Coruña, Spain

Background/Purpose: DNA methylation is a basic mechanism involved in epigenetic regulation that affects gene transcription by the addition of a methyl group to the cytosine residue within a CpG dinucleotide to form methylated cytosine. The objective of this work is to identify and analyze the genome-wide DNA methylation profiles of human articular chondrocytes from a population-based case-control study of OA.

Methods: DNA methylation profiling was performed using the Infinium HumanMethylation27 beadchip (Illumina Inc.), which allows interrogation of 27,578 highly informative CpG loci. Previously, cartilage isolated DNA from 23 OA patients and 19 healthy controls was bisulfite-modified, using the EZ DNA methylation kit (Zymo Research) and hybridized according to the manufacturerxs instructions. DNA methylation b-values were normalized using GenomeStudio v3.0 (Illumina Inc.). Appropriate bioinformatics analyses were carried out using both R bioconductor software packages and Babelomics suite v4.2 (*babelomics.bioinfo.cipf.es*).

Results: A first approach based on an unsupervised clustering method for the most variable CpG loci (n=508) showed three distinct groups of samples called cluster 1, cluster 2 and cluster 3. Specifically, cluster 2 formed a particularly tight cluster with a characteristic DNA methylation profile (Figure 1). The analyses of the biological relevance of the differentially methylated genes in cluster 2 compared with non-cluster 2 by means of a gene set enrichment approach, showed that some of the biological processes significantly altered were those related to cellular adhesion, morphogenesis/angiogenesis and regulation of cell proliferation, all of them hypermethylated in cluster 2; on the contrary, those genes related to cytokine secretion/production as well as immune response and inflammation appeared significantly hypomethylated in cluster 2.
Figure 1. Heatmap showing the three distinct clusters. Cluster 2 shows a characteristic DNA methylation profile clearly different from the other two clusters.

Conclusion: The genome-wide methylation analysis shows a clearly distinct epigenetic profile for OA patients. The DNA methylation profile could be one of the reasons of the existence of different forms OA and could also be related to both the prevalence and progression of this disease.

Disclosure: I. Rego-Pérez, None; **J. Fernandez-Tajes**, None; **M. Fernandez-Moreno**, None; **M. Tamayo Novas**, None; **A. Mosquera Rey**, None; **N. Oreiro**, None; **C. Fernandez-Lopez**, None; **J. L. Fernandez Garcia**, None; **F. J. Blanco**, None.

The Genome-Wide Expression of Human Osteoarthritic Cartilage Shows A Differential Pattern Between Two Subgroups of OA Patients. Ignacio Rego-Perez, Juan Fernandez-Tajes. Angel Soto-Hermida, Mercedes Fernandez Moreno, Maria Eugenia Vazquez Mosquera, Natividad Oreiro, Carlos Fernandez-Lopez, Estefania Cortes Pereira, Sara Relaño-Fernandez and Francisco J. Blanco, INIBIC-Hospital Universitario A Coruña. Genomic Group. Rheumatology Division., A Coruña, Spain

Background/Purpose: Many genes, many of them still unknown, are involved in the etiology and development of OA. Today, different tools are available to try to identify some of the key genes related to the OA process. Therefore, the objective of this work is to perform a genome-wide expression assay in order to identify different expression profiles in the OA disease

Methods: Total RNA from OA cartilage samples was isolated with RNeasy Kit (Qiagen, Madrin, Spain) following manufacturerxs instructions. RNA was checked for integrity and purity with the Agilent Bioanalyzer (Agilent Technologies) and NanoDrop spectrophotometer (Thermo Scientific). 150 nanograms of total RNA were used for cDNA synthesis using the Ambion WT Expression kit (Ambion). The fragmented cDNA was hybridized against the Human Gene 1.1 ST array strip (Affymetrix) and scanned using the GeneTitan system (Affymetrix). Quality controls, normalization, pre-processing, differential gene expression and functional analyses were carried out with Bioconductor packages using R software.

Results: Human Gene 1.1 ST Array, which interrogates more than 28,000 well-annotated genes of 33,297 probes, was used for studying the genome wide expression profile of 23 OA-patients cartilage samples. A non-specific filtering was previously applied for removing those probes with non-annotation information and with low intra-array variation. An unsupervised machine learning approach revealed a group of samples highly different (Figure 1). The differential expression analysis between this cluster, comprising a total of six OA-patients, and the rest of the samples allowed for the identification of 176 differentially expressed probes with an adjusted *p value* below 0.0001. The analysis of the biological processes related to these differentially expressed genes showed that inflammation and immune processes were the main pathways found to be altered when a gene set enrichment analysis was applied.
Figure 1. Dendrogram showing the two different groups of OA patients. Cluster 2 shows a characteristic expression profile among OA patients.

Conclusion: The genome-wide expression analysis shows a clearly distinct profile for a group of OA patients. Both inflammation and immune response processes appeared to be significantly altered and revealed as key factors in the development of the OA disease.

Genetic Effects of HLA-DRB1, IL4R, and FcγRIIb On Long-Term Treatment Responses in Patients with Early Rheumatoid Arthritis: 78-Week Results of a Phase 4 Study. Alla Skapenko[1], Josef S. Smolen[2], Arthur Kavanaugh[3], Vipin Arora[4], Hartmut Kupper[5] and Hendrik Schulze-Koops[1]. [1]University of Munich, Munich, Germany, [2]Medical University of Vienna and Hietzing Hospital, Vienna, Austria, [3]UCSD School of Medicine, La Jolla, CA, [4]Abbott, Abbott Park, IL, [5]Abbott GmbH and Co. KG, Ludwigshafen, Germany

Background/Purpose: Previous analyses suggested that the HLA-DRB1 shared epitope (SE), and the IL4R V50I and the FcγRIIb I232T single nucleotide polymorphisms (SNPs) affected response to adalimumab (ADA) plus methotrexate (MTX) at 26 weeks.[1] Their effect on long-term responses is unclear. To examine 78-wk clinical responses according to 3 candidate loci: HLA-DRB1 SE, and IL4R I50V and FcγRIIb I232T SNPs.

Methods: MTX-naïve patients (pts) ≥18 yrs with RA <1 yr, active disease [DAS28(CRP)>3.2, ESR≥28 mm/hr or CRP≥1.5 mg/dL], and >1 erosion, RF+, or anti-CCP+ were randomized to ADA+MTX or placebo (PBO)+MTX for 26 wks (Period 1, P1). Pts who achieved a stable LDA target (DAS28<3.2 at wks 22 & 26) with ADA+MTX were re-randomized to continue ADA+MTX (ADA Continuation arm) or have ADA blindly withdrawn (ADA Withdrawal arm) for 52 wks (P2). Pts who achieved the stable LDA target with PBO+MTX continued blinded therapy (MTX Continuation arm). Pts who did not achieve the stable LDA target with initial combination therapy or MTX monotherapy were offered open-label (OL) ADA+MTX (OL ADA Carry On and Rescue ADA arms, respectively).

Results: Baseline demographics were similar across alleles. The **Table** shows the percentage of pts achieving DAS28<3.2 at wk 78. There were no consistent patterns for the IL4R alleles in any group. While limited by small sample sizes, pts with FcγRIIb-CC appeared to have higher responses at wk 78 among groups initially exposed to ADA+MTX during P1. The positive influence of SE was apparent at wk 78 in groups originally exposed to ADA+MTX, particularly in pts who did not achieve the stable LDA target at wks 22 & 26 but continued ADA+MTX. However, this pattern was not observed in pts who failed to achieve the target with MTX and were subsequently treated with ADA+MTX.

Table. Percentage of Pts with DAS28 <3.2 at Week 78, n/N (%), non-responder imputation

Treatment	HLA-DRB1 SE			IL4R			FcγRIIb		
	0x	1x	2x	AA	AG	GG	TT	TC	CC
ADA WITHDRAWAL	21/28 (75.0)	25/36 (69.4)	17/22 (77.3)	23/31 (74.2)	33/44 (75.0)	7/11 (63.6)	43/63 (68.3)	17/20 (85.0)	3/3 (100)
ADA CONTINUATION	16/22 (72.7)	36/45 (80.0)	18/20 (90.0)	23/31 (74.2)	33/39 (84.6)	14/17 (82.4)	54/67 (80.6)	14/18 (77.8)	2/2 (100)
OL ADA CARRY ON	29/81 (35.8)	49/113 (43.4)	18/36 (50.0)	28/68 (41.2)	49/109 (45.0)	19/53 (35.8)	87/200 (43.5)	8/29 (27.6)	1/1 (100)
MTX CONTINUATION	30/40 (75.0)	25/38 (65.8)	10/15 (66.7)	18/24 (75.0)	31/44 (70.5)	16/25 (64.0)	47/69 (68.1)	18/24 (75.0)	0/0 (0)
RESCUE ADA	59/115 (51.3)	80/148 (54.1)	19/42 (45.2)	49/93 (52.7)	83/164 (50.6)	26/48 (54.2)	117/225 (52.0)	40/76 (52.6)	1/4 (25.0)

Conclusion: Regardless of genetic background, wk 78 responses were generally higher for pts who achieved the stable LDA target at wks 22 & 26. The positive effects of HLA-DRB1 SE and FcγRIIb-CC in response to ADA+MTX previously noted at wk 26 were less apparent at wk 78, but noticeable in pts who failed to achieve the target. Further, while SE predicted clinical response to ADA+MTX, particularly when combined with IL4R alleles, it had no influence on the ability to withdraw ADA in pts who achieved LDA. These findings may indicate that genetic factors have a stronger influence on initial treatment response than on sustained disease control.

Genetic Predictors of Methotrexate Efficacy and Toxicity in Early Rheumatoid Arthritis: Results From the Treatment of Early Aggressive Rheumatoid Arthritis Trial. Stella Aslibekyan[1], Elizabeth Brown[2], Richard J. Reynolds[1], David T. Redden[1], Sarah L. Morgan[3], Joseph Baggott[1], Jin Sha[1], Larry W. Moreland[4]. James R. O'Dell[5], Jeffrey R. Curtis[6], S. Louis Bridges Jr.[7] and Donna K. Arnett[1], [1]University of Alabama at Birmingham, Birmingham, AL, [2]Univ of Alabama at Birmingham, Birmingham, AL, Birmingham, AL, [3]University of Alabama Birmingham, Birmingham, AL, [4]University of Pittsburgh, Pittsburgh, PA, [5]Univ of Nebraska Med Ctr, Omaha, NE, [6]Univ of Alabama-Birmingham, Birmingham, AL, [7]Marguerite Jones Harbert-Gene V. Ball, MD Professor of Medicine, and Director, Division of Clinical Immunology and Rheumatology, University of Alabama at Birmingham, Birmingham, AL

Background/Purpose: Methotrexate (MTX) has emerged as first-line therapy for early moderate to severe rheumatoid arthritis (RA), but individual variation in treatment efficacy and toxicity remains unexplained. We test the hypothesis that genetic markers in genes involved in drug metabolism, excretion, and transport are associated with MTX response in early RA.

Methods: Treatment of Early Aggressive Rheumatoid Arthritis Trial participants (n=471) were analyzed for 863 markers spanning 224 genes from key pharmacogenetic pathways. Multiple regression models were fit with efficacy (Disease Activity Score on 28 joints at 24 weeks) and toxicity (self-report of any side effects or infections) as outcomes, adjusted for age, sex, race, and treatment, and single markers as predictors. Penalized regression models were used to test joint associations of markers and/or covariates with the outcomes.

Results: The strongest genetic associations with efficacy were in the CHST11 gene (five markers with P <0.0024), encoding carbohydrate (chondroitin 4) sulfotransferase 11. Top markers associated with MTX toxicity were in the cytochrome p450 superfamily genes CYP20A1 and CYP39A1, solute carrier genes SLC22A2 and SLC7A7, and the mitochondrial aldehyde dehydrogenase gene ALDH2 (P<0.004). Results from the penalized regression models included only genetic markers for the toxicity outcome, while clinical covariates were stronger predictors of MTX efficacy. The selected markers explained more variance in toxicity (9%) than efficacy (4%).

Conclusion: We identified several novel and biologically relevant genetic markers associated with MTX response in early RA. These preliminary findings could inform future development of personalized therapeutic approaches.

Evidence of Novel Genetic Predictors of Methotrexate Efficacy in Rheumatoid Arthritis. Stella Aslibekyan[1], Maria I. Danila[2], Jin Sha[1], David T. Redden[1], Richard J. Reynolds[1], Elizabeth Brown[3], Laura B. Hughes[1], Molly S. Bray[1], Sarah L. Morgan[4], Larry W. Moreland[5]. James R. O'Dell[6], Jeffrey R. Curtis[2], Robert P. Kimberly[1], Lindsey A. Criswell[7], Robert M. Plenge[8], S. Louis Bridges Jr.[9] and Donna K. Arnett[1], [1]University of Alabama at Birmingham, Birmingham, AL, [2]Univ of Alabama-Birmingham, Birmingham, AL, [3]Univ of Alabama at Birmingham, Birmingham, AL, Birmingham, AL, [4]University of Alabama Birmingham, Birmingham, AL, [5]University of Pittsburgh, Pittsburgh, PA, [6]Univ of Nebraska Med Ctr, Omaha, NE, [7]University of California San Francisco, San Francisco, CA, [8]Brigham and Women's Hospital, Boston, MA, [9]Marguerite Jones Harbert-Gene V. Ball, MD Professor of Medicine, and Director, Division of Clinical Immunology and Rheumatology, University of Alabama at Birmingham, Birmingham, AL

Background/Purpose: Methotrexate (MTX), a disease-modifying anti-rheumatic drug used as first-line therapy in rheumatoid arthritis (RA), is characterized by considerable heterogeneity in individual treatment response. We tested the hypothesis that polymorphisms in RA susceptibility genes and MTX metabolism pathways are associated with MTX efficacy and toxicity.

Methods: Data from a combined population of three MTX trials (Treatment of Early Aggressive RA Trial; Immunex Early RA Trial; UAB Folic Acid Supplementation Trial, total subjects = 633) were analyzed for 3,127 genetic markers previously linked to RA risk or MTX metabolism pathways, with MTX efficacy (defined as the change joint count scores over 24 weeks of MTX therapy) and toxicity (defined as self-report of any adverse events) as outcomes. Gene-based tests were conducted to complement single marker analyses. All statistical models were adjusted for age, sex, race, and treatment as fixed effects, and for study as a random effect; the efficacy models were additionally adjusted for baseline disease activity.

Results: In the MTX efficacy models, the strongest signals were observed with variation in genes encoding efflux transporters (*ABCC1*; gene-based P= 1.4×10–4), B cell surface antigen (*CD40,* gene-based P=3.8×10–4), and immunoglobulin receptors (*FCGR2A*, *FCGR3A*; gene-based P= 1.5×10–5 and P= 1.6×10–5 respectively). Although no genetic variants reached statistical significance in the models of adverse effects associated with MTX therapy, the top hits included markers near *GFRA2* (rs12549890, P= 2.8×10–3), the *ABCA12* transporter (rs4673907, P= 4.6×10–3), and multiple SNPs in *ADK* included in the adenosine pathway.

Conclusion: This study provides preliminary identification of several novel targets relevant to MTX metabolism in RA. These findings will inform future studies aimed at developing pharmacogenetic tools to predict response to MTX therapy.

Background/Purpose: Psoriatic Arthritis (PsA) is a complex disease with a substantial genetic risk component (first-degree relative risk 55). Recently, Genomewide Association Studies (GWAS) have expanded the number of risk loci for Psoriasis (Ps) in >20 new loci.We have studied the association of Ps risk loci in PsA and purely cutaneous Ps (PsC). We have also analyzed the genetic association with several subphenotypes of clinical relevance.

Methods: Loci showing the strongest statistical evidence of association to Ps were selected (n=32). For each locus, the SNP having the highest statistical evidence was genotyped using Taqman technology in a cohort of n = 955 PsA, 1,050 PsC and 1,497 hypernormal controls of the Spanish population. According to each subphenotype variable, the genetic association was performed using the chi-square test, logistic regression or linear regression.

Results: We have replicated the association to *COG6* and *SERPINB8* loci with Ps for the first time in a Caucasian population. We have identified, for the first time, an association of PsA with variation at *IFIH1*, *DPP6* and *COG6*. Analyzing the association with other clinically relevant subphenotypes we have identified a strong association of *LCE3D* locus with the severity of cutaneous affection ($P<$ 2e-5). We have also found a significant association of *IL1RN* gene with nail disease ($P < $3e-4).

Conclusion: Our findings show that common genetic variants associated to a complex phenotype like PsV influence PsA as well as different subphenotypes of high clinical relevance.

999

Identification of New Epistatic Interactions with the *HLA* Region in the Genetic Etiology of Psoriasis and Psoriatic Arthritis. Sara Marsal[1], Juan D. Cañete[2], Jose Luis Fernandez-Sueiro[3]. Raimon Sanmarti[2], Jesus Rodriguez Moreno[4], Jordi Gratacós[5], Rubén Queiro[6], Carlos Montilla[7], Juan Carlos Torre-Alonso[8], Jose Perez Venegas[9], Santiago Muñoz-Fernández[10], Carlos M. Gonzalez[11], Daniel Roig[12], Alba Erra[13], Isabel Acosta[14], Antonio Fernández-Nebro[14], Pedro Zarco[15], Arnald Alonso[16], María América López-Lasanta[16], Raül Tortosa[16] and Antonio Julià[16], [1]Hospital Universitari Vall d'Hebron, Barcelona, Spain, [2]Hospital Clínic of Barcelona, Barcelona, Spain, [3]Complejo Hospitalario Universitario La Coruña, La Coruña, Spain, [4]Hospital Universitario de Bellvitge., Barcelona, Spain, [5]Hospital Parc Taulí, Sabadell (Barcelona), [6]Hospital Universitario Central de Asturias, Oviedo, Spain, [7]Hospital Universitario de Salamanca, Salamanca, Spain, [8]Hospital Monte Naranco, Oviedo, Spain, [9]Hospital del SAS de Jerez de La Frontera, Jerez De La Frontera, Spain, [10]Hospital Universitario Infanta Sofía, San Sebastián de los Reyes (Madrid), Spain, [11]Hospital Gregorio Maranon, Madrid, Spain, [12]Hospital Universitari de Bellvitge, Hospitalet de Llobregat-Barcelona, Spain, [13]Hospital San Rafael, Barcelona, Spain, [14]Hospital Regional Universitario Carlos Haya, Málaga, Spain, [15]Fundación Hospital Alcorcon, Alcorcon, Madrid, Spain, [16]Vall d'Hebron Hospital Research Institute, Barcelona, Spain

Background/Purpose: Psoriatic Arthritis (PsA) is a complex disease and is present in 11% in patients with Psoriasis (Ps). Recently, Genomewide Association Studies (GWAS) have expanded the number of risk loci for Ps in >20 new loci. Two of these genes, *ERAP-1* and *HLA-C*, have been shown to interact epistatically in the risk to develop Ps. We have studied the presence of new genetic interactions between Ps risk lci with the *HLA* region in Purely cutaneous Psoriasis (PsC) and PsA.

Methods: Within each Ps risk locus (n=31), the SNP having the highest statistical evidence was selected. The 31 SNPs were genotyped using Taqman technology in a cohort of n = 955 PsA, 1,050 PsC and 1,497 hypernormal controls of the Spanish population. The presence of statistically significant gene-gene interactions was performed using a logistic regression model with three parameters to determine the presence of interaction at the allelic level.

Results:: We replicated the previously described interaction of *HLA-C* and *ERAP1* in the PsC cohort but not in the PsA cohort. We identified, for the first time, a significative epistatic association between *HLA-C* and *SERPINB8*. Microarray gene expression studies on cutaneous biopsies corroborate the presence of this interaction at a functional level. In PsA, no statistically significant interactions where identified with variation at *HLA-C*. However, 6 of the studied genes showed a significant ($P<0.05$) association with *HLA-B27* positivity.

Conclusion: The present study has identified new genetic interactions associated with the risk to develop PsC and PsA. The functional study of these interactions will improve our knowledge of the biological basis of these complex diseases.

IdiPaz, Madrid, Spain, [10]Groupe Hospitalier Pellegrin, Bordeaux, France, [11]Hospital Universitario Marqués de Valdecilla. IFIMAV, Santander, Spain, [12]Institut Cochin - INSERM U1016 - CNRS (UMR 8104), Paris, France, [13]Molecular and Genetic Epidemiology Laboratory, University of Tsukuba, Tsukuba, Japan, [14]Instituto de Parasitologia y Biomedicina Lopez-Neyra (CSIC), Granada, Spain, [15]APHP, Hopital Bichat, Paris, France

Background/Purpose: *BANK1* and *BLK* belong to pleiotropic genes and recently a genetic and physical interaction between *BANK1* and *BLK* has been detected in systemic lupus erythematosus. Although *BLK* has been reproducibly identified as a RA risk factor, conflicting results have been reported regarding the contribution of *BANK1* in RA susceptibility. To ascertain the real impact of *BANK1* on RA genetic susceptibility we performed a large meta-analysis. In addition, we tested for an epistatic interaction between *BLK* and *BANK1* in RA susceptibility.

Methods: We performed a large trans-ethnic meta-analysis including data from 8,898 RA patients and 15,479 controls genotyped for *BANK1* rs10516487 and data from 3,641 RA cases and 3,710 controls genotyped for *BANK1* rs3733197. *BLK* rs13277113 and *BANK1* genotypes available from 1,901 RA patients and 1,898 ethnically matched controls coming from France, Spain and Japan were used to test for epistasis by logistic regression analysis.

Results: The meta-analysis provided evidence for an association between RA and *BANK1* rs3733197 G risk allele (OR=1.11 95% CI[1.02–1.21], P=0.012). An epistatic interaction between *BLK* rs13277113 and *BANK1* rs3733197 was detected (P_{ep}=0.037). The association between the *BANK1* rs3733197 G risk allele and RA was restricted to individuals carrying the *BLK* rs13277113 GG genotype:OR=1.21 95%CI[1.04–1.41], P=0.015

Conclusion: This study confirms *BANK1* as a RA susceptibility gene and provides for the first time, evidence for epistasis between *BLK* and *BANK1*. Our results illustrate the concept of pleiotropic epistatic interaction suggesting that BLK and BANK1 might play a role in RA pathogenesis.

ACR/ARHP Poster Session B
Biology and Pathology of Bone and Joint

CNstream2: Improved SNP and CNV Genotyping Reveals New Loci Associated with Rheumatic Diseases. Arnald Alonso, Antonio Julià, Raül Tortosa and Sara Marsal. Vall d'Hebron Hospital Research Institute, Barcelona, Spain

Background/Purpose: In Genome-Wide Association Studies (GWAS), the performance of the genotyping algorithm is crucial to identify new SNPs associated to disease risk. Recently, new methods have been developed to exploit SNP-oriented microarrays in order to genotype Copy Number Variations (CNVs), albeit with a reduced performance compared to SNPs. In this study we present CNstream2, a method for both SNP and CNV genotyping that achieves a superior accuracy compared to other established methods. In addition, we have identified several new CNV loci that are in high linkage disequilibrium (LD) with SNPs previously associated to rheumatic diseases.

Methods: CNstream2 is a substantially improved version of our previous CNstream software which achieves a superior accuracy in both SNP and CNV genotyping compared to other well-established methods (i.e. GenoSNP/GenCall for SNP genotyping and PennCNV/QuantiSNP for CNV genotyping). All these improvements have been assessed in different Illumina platforms using public microarray data from HapMap samples. SNP genotypes from the 1000 Genomes Project (1KGP) and CNV genotypes from recent studies using CNV-oriented technologies have been used as golden standards for performance comparisons. In order to show the power of CNstream2, we performed a correlation analysis between SNPs associated with rheumatic diseases reported by the GWAS catalog and the CNVs identified by CNstream2 over the same HapMap samples using HumanOmni1 data. All the CNV loci that obtained an r2>0.7 (N=16) were reported in this study.

Results: CNstream2 obtained a high performance both on SNP and CNV genotyping. When assessing SNP genotyping accuracy, CNstream2 obtained an average gain of 0.20% with respect to GenoSNP and GenCall (representing a gain of 1,000–2000 genotyped SNPs per GWAS). On the other hand, when comparing CNV calls obtained by CNstream2, PennCNV and QuantiSNP within previously characterized CNV loci, CNstream2 exceeded by an average of 20% the number of correctly captured loci compared to its competitors. The LD analysis between SNPs associated to rheumatic diseases and CNVs detected by CNstream2 revealed 16 highly correlated SNP-CNV pairs. From these, 11 pairs were located in the HLA region and were associated to several rheumatic diseases. Given the strong correlation of the CNV with the disease risk SNP, additional functional studies exploring its relevance are warranted. Outside the *HLA* region, 5 new CNVs from loci associated with rheumatological diseases were identified. From these, a previously unidentified intronic deletion in Rheumatoid Arthritis risk gene *PADI4*, showed a strong association.

Conclusion: After an exhaustive evaluation of CNstream2 performance we can conclude that this new software tool provides an unprecedented accuracy both in SNP and CNV genotyping. Using CNStream2 on publicly available data, we have identified new CNVs on loci previously associated to rheumatological diseases which could likely explain the observed disease risk association.

Microrna Expression Profiles in Peripheral Blood Mononuclear Cells of Early Onset Psoriatic Arthritis. G. Ciancio[1], Manuela Ferracin[2], Barbara Zagatti[2], Elena Saccenti[2], Valentina Bagnari[1], Ilaria Farina[1], Matteo Colina[3], Marco Seri[4], Francesco Trotta[1], Massimo Negrini[2] and Marcello Govoni[1]. [1]Rheumatology Unit-Azienda Ospedaliera-Universitaria Sant'Anna, Ferrara, Italy, [2]Laboratory for Technologies of Advanced Therapies (LTTA), University of Ferrara, Ferrara, Italy, [3]Section of Internal Medicine A.Ospedale Maggiore, Bologna, Italy, [4]Medical Genetics Unit, Bologna, Italy

Background/Purpose: Micro-RNAs (miRNAs) are small non-coding RNAs that negatively regulate gene expression. It is known that an altered miRNA expression plays an important role in cancer. A new emerging role for miRNAs has been evidenced in the pathogenesis of autoimmune diseases such as rheumatoid arthritis (RA), in which miR-146a has gained increasing relevance, psoriasis and systemic lupus erithematosus. No data about the miRNA expression profile in psoriatic arthritis (PsA) are available to date. In a preliminary study, we identified 16 miRNAs (9 up- and 7 down-regulated) differentially expressed in a sample of 13 early PsA *vs* 7 healthy controls (submitted data). Now, our main purpose is to validate the identified miRNA signature in a larger series of patients and controls.

Methods: Blood samples from 21 consecutive patients with early, active and naïve from treatment PsA (disease duration < 6 months; M:9; W:12; mean age:39,3±8,1; DAS 44: 4,12 ± 0,29; SPARCC Enthesitis Index score: 2 ± 0.5) were collected. As controls, 12 random healthy volunteers (M:4; W:8; mean age 34 ± 11) were recruited. The expression levels of 723 mature miRNAs in peripheral blood mononuclear cells (PMBC) were investigated in all patients and controls by using an Agilent miRNA microarray. Differentially expressed genes were identified by applying a two-tailed unpaired t-test (Graph-Pad).

Results: We identified 3 microRNAs (miR-21,miR-34a and miR-21*),

previously described as upregulated in PsA as significantly upregulated also in this new cohort of patients (p 0.01-0.001) compared to controls.

Conclusion: A 3-miRNA signature was identified in patients with early active PsA. The upregulated miR-21, miR-34a and miR-21* appear of great interest to understand the underlying pathogenic processes of PsA. Moreover, their expression in patients with active disease makes them attractive as potential biomarkers.

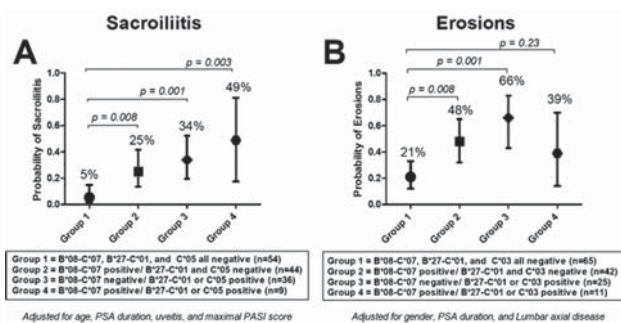
Role of Particular Class I MHC Haplotypes in Determining Different Traits within the Psoriatic Arthritis Phenotypes. Muhammad Haroon[1], Jon T. Giles[2], Robert Winchester[3] and Oliver M. FitzGerald[1]. [1]Dublin Academic Medical Center, St. Vincent's University Hospital, Dublin, Ireland, [2]Columbia University Medical Center, New York, NY, [3]Columbia University, New York, NY

Background/Purpose: A rigorously ascertained psoriatic arthritis (PsA) cohort demonstrated considerable genetic heterogeneity and provided preliminary evidence that MHC genes determine quantitative traits within the PsA phenotype with different patterns of MHC effect.

Methods: We now extend these findings by performing detailed clinical phenotyping of PsA cases to better characterize the clinical features associated with particular HLA class I alleles and their haplotypes.

Results: A total of 150 PsA patients [mean age 52 ± 12 years; 46% male; mean PsA duration$=25 \pm 12$ years; 45% with axial involvement; 25% with sacroiliitis; 41% with radiographic erosions; median PASI$=1.2$] were studied. In univariate analysis, the inheritance of B*27:05 was apparently associated with a more severe joint disease phenotype including: joint erosions, the requirement for TNF therapy and axial disease manifestations such as spine involvement and sacroiliitis that were temporally preceded by or coincident with skin disease. In striking contrast, the presence of HLA-C*06, whether on a B*57-C*06 or B*37-C*06 haplotype, was associated with a considerable delay in the development of arthritis, and conferred a reciprocal phenotype of significant negative associations with arthritis severity, including the presence of erosions, the requirement for TNF inhibitor therapy, and axial disease. B*08 and B*08-C*07 (EH8.1) were correlated with joint deformities, erosions, TNF inhibitor requirement, osteolysis, and dactylitis, developing after the appearance of psoriasis, suggesting this haplotype denotes a more severe but delayed arthritic phenotype.

Surprisingly, in contrast to the uniform association of disease susceptibility with B*27, the association with phenotypic features was not uniform across all B*27 alleles, and was mainly accounted for by the B*27-C*01 (EH27.1) haplotype and not B*27-C*02 (EH27.2), suggesting the influence of additional genetic effects on EH27.1. The predictive value of these haplotypes was confirmed by logistic regression, which after adjustment for confounders showed, for example, the probability of developing sacroiliitis was almost completely determined by the inheritance of EH27.1, EH8.1 or C*05, figure A. Similarly, the probability of developing peripheral joint erosions was strongly associated with the presence of EH27.1, EH8.1 or C*03, figure B.


Conclusion: Certain HLA alleles, and, most strikingly particular haplotypes, contribute importantly to the magnitude of traits comprising the diverse phenotypes of PsA, but this contribution does not completely parallel the role of these alleles or haplotypes in determining susceptibility.

A Unique Single Nucleotide Polymorphism in the 3' UTR of the MED29 Gene On Chromosome 19 Is Associated with the Clinical Outcome of Different Biologic Response Modifiers. Susanne Drynda, David Leesch, Marietta Gloetzner and Joern Kekow. Univ of Magdeburg, Vogelsang-Gommern, Germany

Background/Purpose: Due to the wide range of highly specific and effective biologic response modifiers that are available today for the treatment of RA it has become of great importance to identify biomarkers for the prediction of therapy outcome, supporting an individualized therapy. Most studies in this field analysed potential markers for a single biological or substance group, respectively. In this study we analysed the association of genotypes of the single nucleotide polymorphism (SNP) rs10414216 in the 3' UTR of the MED29 gene with the outcome of two biologic response modifiers, targeting different pathways.

Methods: We studied 275 RA patients treated first with the TNF-blocker etanercept (ETN) and a subgroup of 62 patients treated later in the course of the disease with a B-cell directed therapy, with rituximab (RTX). The frequency of the SNP rs10414216 MED29 C/T was analysed using a validated TaqMan™ genotyping assay containing sequence-specific primers and fluorescence-labelled allele-specific probes. Disease activity and therapy response were assessed according to the EULAR improvement criteria (http://www.das-score.nl). The primary response of the ETN therapy was assessed 3–4 months after initiation of therapy, the outcome of rituximab after 4–6 months after the first infusion of RTX.

Results: The genotype distribution of the SNP rs10414216 MED29 C/T in 275 RA patients was comparable with a cohort of non-affected controls. There were no differences in the genotype frequencies in subgroups of ACPA- positive and -negative RA patients. There was no association of genotypes with disease activity observed. The DAS28 at baseline before start of ETN or RTX treatment was comparable for all genotypes. After 3–4 months of ETN treatment the DAS28 decreased by 1.670 ± 1.377, 2.083 ± 1.348 and 2.382 ± 1.286 (mean$\pm$SD) for the C/C, C/T and T/T genotypes, respectively. The improvement of the DAS28 was significantly better for the T/T genotype compared to C/C (p$=0.003$). 58% of T/T carriers but only 27.2 % of the C/C carriers were identified as good responders to ETN. However, in RTX treated patients the carriers of the C/C genotype were identified as better responders, after 4–6 months the DAS28 decreased by 2.277 ± 1.558 for the C/C genotype compared to 1.310 ± 1.347 for the C/T genotype (p$=0,025$). 46.2% of C/C and only 27.3% of C/T carriers were good responders to RTX. The T/T carriers were underrepresented in the RTX subgroup, probably as a result of a better outcome of the TNF-blocker therapy in these patients.

Conclusion: Our data clearly indicate that a single SNP has the potential to predict the outcome to different therapeutic approaches. The functional importance of this genetic variation has not yet been characterized. However, this SNP is located in the gene region of MED29, a subunit of the mediator complex which plays a substantial role in the regulation of gene expression. Further analysis of this SNP and the respective gene locus could provide further insight into the mechanisms which determine the outcome of different targeted therapies.

1005

The Identification of Pathway Markers in Behcet's Disease Using Genomewide Association Data From Two Different Populations. Burcu Bakir-Gungor[1], Elaine Remmers[2], Daniel L. Kastner[3], Akira Meguro[4], Nobuhisa Mizuki[4], Ahmet Gul[5] and Osman Ugur Sezerman[6]. [1]Bahcesehir University, Istanbul, Turkey, [2]National Institutes of Health, National Human Genome Research Institute, Bethesda, MD, [3]National Human Genome Research Institute, National Institutes of Health, Bethesda, MD, [4]Yokohama City University Graduate School of Medicine, Yokohama, Japan, [5]Istanbul University, Istanbul Faculty of Medicine, Istanbul, Turkey, [6]Sabancı University, Istanbul, Turkey

Background/Purpose: Behcet's disease (BD) is a multi-system inflammatory disease, characterized by recurrent exacerbations affecting several organs including orogenital mucosa, eyes and skin. Two recent genome-wide association study (GWAS) of BD in Turkish and Japanese populations both confirmed the strong association of MHC Class I region and identified two non-HLA common genetic variations with a mild effect on BD. In complex

diseases such as BD, multiple factors [e.g. single nucleotide polymorphisms (SNPs), miRNAs, metabolic and epigenetic factors] may target different sets of genes in the same pathway crippling its function and thus causing the disease development. In this regard, we hypothesized that the pathways critical to the mechanisms underlying BD will be conserved within and across populations.

Methods: To identify these disease-associated pathways, we previously developed a novel methodology that combines nominally significant evidence of genetic association with current knowledge of biochemical pathways, protein-protein interaction networks, and functional information of selected SNPs. Using this methodology, we herein searched for the disease related pathways on two BD GWAS in Turkish and Japanese case-control cohorts by using the list of SNPs providing a P value <0,05.

Results: Even though there were a few significantly conserved SNPs/genes within and between populations, five of the top ten affected pathways were found to be significant in both populations. The probability of random occurrence of such an event is 5.13E-36. These shared pathways were Notch signaling pathway, focal adhesion, Jak-STAT signaling pathway, long-term potentiation and pathways in cancer. Considering some differences in the clinical manifestations such as more frequent involvement of major vessels in Turkish patients, we observed some correlating rankings in the pathways. The complement and coagulation cascades pathway was identified in 5th and 33rd rankings with P=2.47E-20, P=2.6E-12 in Turkish and Japanese populations, respectively.

Conclusion: By applying our method on two BD GWAS dataset, here we have shown that while the total number of genome-wide significant genetic associations is limited, identification of the shared pathways between the Turkish and the Japanese populations may help further explaining the general mechanisms of BD pathogenesis. Even though each individual has a unique combination of factors involved in disease development mechanism, most of the targeted pathways that need to be altered by these factors are expected to be conserved. The pathways that are identified by population specific GWAS need to be examined to gain a more comprehensive understanding of BD pathogenesis and their potential to be used as biomarkers and/or drug targets.

Dynamic Gene Expression of Wnt Signaling Pathway During Osteogenic Stimulation *in Vitro* of Osteoarthritis Mesenchymal Stem Cells. A. Peralta-Sastre[1], M. Hernandez-Molinero[2], P. Tornero-Esteban[2], E. Villa-fuertes[2], B. Fernandez-Gutierrez[3] and Jose Ramon Lamas[4]. [1]UGC de Reumatología, Hospital Clínico San Carlos, Instituto de Investigación Sanitaria del Hospital Clínico San Carlos (IdISSC), Madrid, Spain., [2]Hospital Clinico San Carlos, Madrid, Spain, [3]Department of Rheumatology, Hospital Clinico San Carlos, Madrid, Spain, [4]Hospital clinico San Carlos, Madrid, Spain

Background/Purpose: The role of Wnt signalling in Mesenchymal Stem Cell (MSC) fate is still unclarified. Both, canonical and non-canonical pathways have been implicated in differentiation and proliferation resulting from specific Wnt ligands, receptors, inhibitors and downstream molecules responsible for the signalling and/or the developmental commitment. Although osteogenesis is a well-studied process, molecular details remain unknown. Te aim of the study was to delineate the changes in gene expression of Wnt related occurring during osteogenesis in OA and control patients.

Methods: MSCs were obtained from bone marrow aspirates at the time of joint replacement surgery of five OA patients (mean 76 years) and three control subjects without OA signs (mean 80 years). Cells were cultured and expanded under osteogenic stimuli. Confluent cells in passage 6 were collected at days 1, 10 and 21. RNA was purified and retrotranscribed prior quantitative PCR analysis. Simultaneous gene expression of 84 Wnt related genes was analysed using the Human Wnt PCR Array PAHS-043A, from SABiosciences according. The resulting expression raw data was analyzed using the SABiosciences web-based PCR Array Data Analysis tool. ΔΔCt values relative to the *RPL13A* housekeeping gene were used to calculate the expression changes. Two-fold changes with p<0.05 were considered significative.

Results: MSCs from OA patients undergoing osteogenesis progressively increases the number of downregulated genes related to the Wnt signaling. While at basal conditions only two genes were downregulated, at days 10 and 21, twelve and sixteen genes were downregulated respectively. Among downregulated genes, some encode for essential proteins participating both in canonical and non-canonical Wnt pathway and including several ligands, co-rreceptors, inhibitors, kinases and transcription factors.

Conclusion: Our data demosnstrate a clear alteration during osteogenesis of MSCs biology from OA patients. We hypothesized that a possible cause of OA may lie in these intrinsic alterations of MSCs preventing proper differentiation into fully functional adult tissues.

High Resolution Peripheral Quantitative CT Detects Marked Differences in Metacarpal Head and Shaft and Ultra-Ultra-Distal Radius Bone Volumetric Density and Microstructure in Early Rheumatoid Arthritis. Lynne M. Feehan[1], Helen R. Buie[2], Linda C. Li[1], Kamran Shojania[3], Cheryl Barnabe[2] and Heather A. McKay[3]. [1]Arthritis Research Centre of Canada and University of British Columbia, Vancouver, BC, [2]University of Calgary, Calgary, AB, [3]University of British Columbia, Vancouver, BC

Background/Purpose: Despite improvements in clinical management of rheumatoid arthritis (RA), many with early disease are still at high risk for developing periarticular erosions and osteopenia, as well as, generalized systemic bone loss. It is essential to develop new approaches to assess changes in bone microstructure in people with early RA **before** permanent macro structural bone damage occurs. High Resolution Peripheral Quantitative CT (HR-pQCT) [XtremeCT, Scanco Medical AG] provides a solution; it is a novel imaging system that images bone microstructure at the thickness of a human hair. The purpose of this study was to determine if HR-pQCT could identify and characterize early volumetric density or microstructural differences in people with early RA relative to controls.

Methods: Thirty individuals with early RA and 30 age and gender matched controls consented to participate. Five regions of interest (ROI) of the dominant side were imaged with HR-pQCT (82 μm, 60 kVp, 900 μA, 100 ms): ultra-ultra-distal radius (UUDr) [9 mm, starting 3 mm proximal to the medial tip distal radius]; metacarpal heads (MH) of the 2nd and 3rd digits [18 mm, starting 2 mm distal to tip of most distal 2nd or 3rd MH]; and metacarpal shafts (MS) of the 2nd and 3rd digits [9 mm, starting 4.5 mm distal to 3rd MS mid-shaft].

Standard manufacturer protocols were used for segmentation of the bone from the soft tissue. Cortical and trabecular regions were extracted using direct transformation methods with modified boundary conditions for the MH. Primary outcome variables included: 1) whole, trabecular and cortical region apparent volumetric bone density (vBMD) and bone volume fraction (BV/TV), 2) trabecular region structural model index (SMI), 3) cortical region thickness (CtTh) and material vBMD, and 4) MS marrow space diameter (MSd). Paired Student T-test statistical analyses were used to compare all variables.

Results: *Participants:* Both groups = Sex (Females 24, Males 6); age (mean 53 years, range 21 to 73). RA group = 73% Rheumatoid Factor &/or anti-CCP positive; mean 8 (SD 5) months since diagnosis and 13 (SD8) months since symptom onset and a Health Assessment Questionairre - Disability Index mean of 0.6 (SD 0.6). *Imaging:* HR-pQCT identified marked differences in whole, trabecular and cortical bone volumetric density and microstructure in the periarticular UUDr and MH regions, as well as, the extra-articular MS regions between RA subjects and controls. All density and microstructural outcome variables were lower in early RA participants with the exception of UUDr and MH trabecular bone SMI and MSd, which were higher (Table 1).

Table 1. Comparison of Volumetric Density and Microstructural Outcomes for UUD, MH3 and MS2 ROIs

Ultra-Ultra-Distal Radius ROI (n=54, 27 Pairs)		RA [Mean (SD)]	Non-RA [Mean (SD)]	Difference (%)
Whole Bone	Apparent vBMD (mgHA/cm^3)	262.26 (53.27)	281.52 (44.41)	-7%
Trabecular Region	* Apparent vBMD (mgHA/cm^3)	167.30 (34.74)	187.70 (36.26)	**-11%**
Cortical Region	Apparent vBMD (mgHA/cm^3)	760.25 (93.2)	785.52 (74.9)	-3%
	aterial vBMD (mgHA/cm^3)	942.28 (41.83)	949.81 (35.29)	-0.8%
Whole Bone	Bone Volume Fraction - BV/TV (%)	36.70 (4.9)	38.33 (4.5)	-6%
Trabecular Region	* Bone Volume Fraction - BV/TV (%)	26.88 (0.9)	29.39 (0.9)	**-9%**
	* Structural Model Index -SMI	1.87 (0.38)	1.60 (0.37)	17%
Cortical Region	Bone Volume Fraction - BV/TV (%)	90.49 (5.3)	91.47 (5.3)	-1%
	Thickness - CtTh (mm)	0.56 (0.14)	0.58 (0.11)	-1%
3rd Metacarpal Head ROI (n=54, 27 Pairs)		RA [Mean (SD)]	Non-RA [Mean (SD)]	Difference (%)
Whole Bone	* Apparent vBMD (mgHA/cm^3)	290.28 (47.16)	316.96 (40.72)	**-9%**
Trabecular Region	* Apparent vBMD (mgHA/cm^3)	241.78 (31.32)	262.56 (33.02)	**-8%**
Cortical Region	* Apparent vBMD (mgHA/cm^3)	542.42 (73.31)	592.91 (72.49)	**-8%**
	* Material vBMD (mgHA/cm^3)	817.34 (72.49)	843.87 (45.04)	**-3%**
Whole Bone	* Bone Volume Fraction - BV/TV (%)	42.32 (4.6)	44.91 (3.7)	**-7%**
Trabecular Region	* Bone Volume Fraction - BV/TV (%)	35.74 (4.4)	37.99 (3.2)	**-6%**
	* Structural Model Index -SMI	0.88 (0.45)	0.60 (0.42)	47%
Cortical Bone	* Bone Volume Fraction - BV/TV (%)	42.32 (4.6)	44.91 (3.7)	**-7%**
	* Thickness - CtTh (mm)	0.35 (0.09)	0.39 (0.07)	**-13%**
2nd Metacarpal Shaft ROI (n=52, 26 Pairs)		RA [Mean (SD)]	Non-RA [Mean (SD)]	Difference (%)
Cortical Bone	* Apparent vBMD (mgHA/cm^3)	1033.79 (34.57)	1050.48 (21.78)	**-2%**
	* Material vBMD (mgHA/cm^3)	1079.82 (27.78)	1091.87 (18.30)	**-1%**
Whole Bone	* Apparent vBMD (mgHA/cm^3)	796.84 (112.32)	843.17 (79.35)	**-5%**
Cortical Region	* Bone Volume Fraction - BV/TV (%)	97.96 (1.2)	98.48 (0.61)	**-1%**
	* Thickness - CtTh (mm)	1.93 (0.36)	2.08 (0.29)	**-7%**
Whole Bone	* Bone Volume Fraction - BV/TV (%)	72.68 (9.7)	76.63 (6.9)	**-5%**
	Marrow Space Diameter = MSd (mm)	2.79 (0.61)	2.67 (0.51)	4%

Bold Difference (%) & * = p < 0.05 (Paired T-Test, no adjustment for multiple comparisons). NOTE: MH2 and MS3 similar results, not shown

Conclusion: HR-pQCT is a promising new imaging technology that can identify and quantify very early changes in hand and distal forearm bone volumetric density and microstructure in people with early RA. Participants in this study will be evaluated again at 1 year.

Segmentation and Quantification of Bone Erosions in the Hands of Patients with Rheumatoid Arthritis Using High Resolution Computed Tomography. Dominique Toepfer[1], Stephanie Finzel[1], Oleg Museyko[1], Klaus Engelke[1] and Georg A. Schett[2]. [1]University of Erlangen-Nuremberg, Erlangen, Germany, [2]Department of Internal Medicine III and Institute for Clinical Immunology, University of Erlangen-Nuremberg, Erlangen, Germany

Background/Purpose: Bone erosions are important for diagnosis and monitoring of disease activity in RA. However, semi-quantitative scoring schemes may be inadequate for a true 3D quantification of size and shape. Recently high-resolution peripheral quantitative CT (HR-pQCT) with an isotropic spatial resolution of about 120μm has been used for a semiquantitative assessment of erosion volume in the metacarpophalangeal (MCP) joints. Here we developed a highly automated 3D analysis technique to more accurately quantify volume, shape and surface of erosions and to increase precision.

Methods: In the MCP joints of the second to forth digit of 18 patients 80 slices distally and 242 slices proximally to the surface of the third metacarpal head were scanned (XtremeCT, Scanco Switzerland; isotropic voxel size 82μm). Erosions were quantified as follows: After segmenting the periosteal surface the user identified each erosion by manually placing a seed point. The erosions were then automatically segmented by a 3D level-set algorithm (Fig. 1a) with the option of operator corrections. Erosion volume (Vol), surface area (SA), and sphericity (SP), a parameter describing the shape deviation from a perfect sphere, were determined. In addition manual measurements were carried out. Here the erosion volume was approximated by a half-ellipsoid constructed from the surface area of the cortical break and the maximum erosion depth perpendicular to it (Fig. 1b). In order to compare both methods the lengths measurements obtained from the manual technique were also determined during the automated 3D analysis.
Figure 1. a) Metacarpal bone with periosteal segmentation and segmented erosion. b) Manual measurement of cortical break and maximum depth.

Results: 32 erosions were assessed in the 18 datasets with a mean/min/max Vol of 9.66mm$\geq$/0.37mm$\geq$/54.7mm$\geq$ (automated 3D analysis). Inter-operator precision errors (3 operators, root mean squares coefficients of variation (RMSCV)/RMS standard deviation (RMSSD)) were 7.8%/0.8 mm$\geq$, 10.4%/3.8 mm^2 and 4.9%/0.02 for Vol, SA and SP, respectively. Excluding 18 erosions, in which operator interactions were performed, decreased the errors by about a factor of 3. Correlation between the manual analysis and the length measurements obtained from the automated 3D analysis was r = 0.87, however, correlation with the Vol obtained from the full 3D analysis was r = 0.39, indicating that a simplistic approximation of erosion volume may not capture the full shape information.

Conclusion: We developed a new precise full 3D characterization of bone erosions that may help improving the assessment of disease activity and treatment efficacy. Precision errors depend on the degree of user interaction that may be necessary to correct the automated segmentation, which is more frequent in erosions with large cortical breaks. Manual measurements are less impacted by image quality, such as motion artifacts; however, the approximation of erosion volume by a half-ellipsoid underestimates the true erosion volume. The clinical evaluation of this method is currently being performed.

A New Approach for Detecting Progressive Joint Damage Using 3D Imaging From High-Resolution Peripheral Quantitative Computed Tomography: Measuring Reproducibility. Cheryl Barnabe, Helen R. Buie, Michelle Kan, Susan G. Barr, Liam Martin and Steven K. Boyd. University of Calgary, Calgary, AB

Background/Purpose: Joint space narrowing is an important feature of progressive joint damage and functional impairment in rheumatoid arthritis (RA). Methodology to provide longitudinal and sensitive 3D measurements of joint space width have not yet been developed for research or clinical applications. High-resolution peripheral quantitative computed tomography (HR-pQCT) (Scanco Medical AG, Switzerland) has recently become available to accurately and reproducibly measure bone microstructure at a nominal isotropic voxel dimension of 82 μm. Given the ability of HR-pQCT to detect bone margins with high precision, we developed a methodology to measure the 3D metacarpophalangeal (MCP) joint space width. This work determines the reproducibility of the scan protocol with hand repositioning for application for early detection and longitudinal monitoring of RA.

Methods: Two repeated HR-pQCT scans of the 2nd and 3rd MCP joints of ten subjects with early RA (70% female, mean age 45 years) withrepositioning between scans were obtained. The periosteal edges of the metacarpal head

and proximal phalanx base were detected and segmented, and from these images the joint space width and distribution of joint space thickness were measured using a custom analysis implemented for the HR-pQCT based on direct measurements from the high resolution image data.

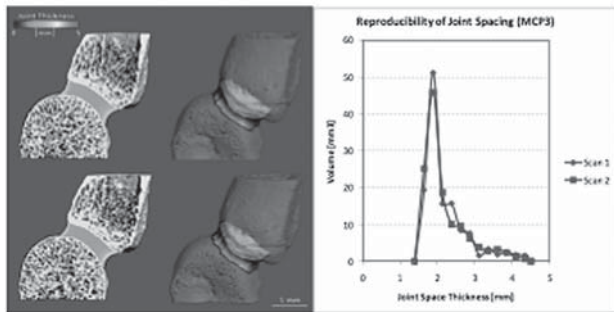
Results: In this population, the mean joint space width of the 2nd MCP was 1.82 mm (SD 0.20) and of the 3rd MCP 1.84 mm (SD 0.23). Reproducibility with repositioning was excellent, with overlapping filtered histograms and a root square mean coefficient of variance of 4.8%.


Figure 1. Cross-sectional views (left) and three-dimensional views (middle) of the third metacarpal joint for repeat scans showing consistent repositioning and highly reproducible joint space distribution measurements (right).

Conclusion: We have established a highly reproducible methodology for evaluating the joint space width, applied here to the MCP joints. Currently, we combine this assessment with measures of joint erosions and periarticular bone density. Together, these measures from HR-pQCT show great promise for a new approach for early RA detection, and monitoring of disease activity and/or treatment.

Bone Loss Before Clinical Onset of Rheumatoid Arthritis o Subjects with Anti-Citrullinated Protein Antibodies. Stephanie Finzel[1], Veronika Lang[2], Arnd Kleyer[1], Juergen Rech[1], Bernhard Manger[1], Elizabeth Araujo[1], Axel J. Hueber[1], Ulrike Harre[3] and Georg Schett[3]. [1]University of Erlangen-Nuremberg, Erlangen, Germany, [2]University of Erlangen-Nuremberg, Germany, [3]Institute for Clinical Immunology, University of Erlangen-Nuremberg, Erlangen, Germany

Background/Purpose: Anti-citrullinated protein antibodies (ACPA) are a major risk factor for rapid disease progression in rheumatoid arthritis (RA). We have recently shown that ACPA directly induce bone loss by stimulating osteoclast differentiation (Harre et al, J Clin Invest 2012;122:1791). As ACPA precede the clinical onset of RA we hypothesized that ACPA positive healthy individuals may shows skeletal changes.

Methods: performed a comparative micro computed tomography analysis of the bone microstructure in the metacarpophalangeal joints (MCPJ) of ACPA positive and -negative healthy individuals without signs of arthritis.

Results: ACPA positive (N= 10) and -negative (N= 10) healthy individuals were not different in age (48.2 ± 4.1 vs. 51.4 ± 3.8 years, p = 0.57) and gender (each 8 females and 2 males). Bone minaral density was significantly reduced in ACPA-positive individuals (mean ± SEM: 280 ± 11 mg/ccm) as compared to controls (327 ± 6 mg/ccm). Bone loss was based on cortical bone changes with significant (p = 0.044) reduction in cortical thickness in the ACPA-positive group (mean ± SEM: 0.22 ± 0.03 mm) as compared to controls (0.32 ± 0.03 mm).

Conclusion: Structural bone damage starts before the clinical onset of arthritis in subjects with ACPA. These findings revise the concept of bone damage as an exclusive consequence of synovitis in ACPA positive individuals.

Structural Damage Is Reduced by Early Achievement of Clinical Remission. Paul Emery[1], Vibeke Strand[2], Andrew S. Koenig[3], Ronald Pedersen[3] and Eustratios Bananis[3]. [1]Leeds Musculoskeletal Biomedical Research Unit, Leeds, United Kingdom, [2]Stanford University, Portola Valley, CA, [3]Pfizer Inc., Collegeville, PA

Background/Purpose: The importance of early, intensive treatment of rheumatoid arthritis (RA) to decrease disease activity and prevent structural damage is established.[1] The objective of this analysis was to examine the relationship between disease activity measured by CDAI and DAS28 at week 24, and inhibition of radiographic progression by mean mTSS change from baseline at year 2 in patients treated with etanercept (ETN) + methotrexate (MTX) or MTX monotherapy.

Methods: Randomized subjects from TEMPO (moderate-severe RA, 6.6 years mean disease duration) and COMET (moderate-severe RA, 9 months mean disease duration) who received ETN 50 mg weekly + MTX or MTX alone for 2 years with available X-rays were included in this analysis. Stratified and multivariate regression analyses (observed data) were performed to determine the relationship between variables.

Results: There were a total of 182 patients in COMET and 296 in TEMPO included in this analysis. Patients receiving ETN + MTX had less radiographic progression after 2 years of treatment than MTX monotherapy, independent of disease activity at week 24. In COMET, the percentage of patients achieving CDAI and DAS28 remission in the ETN + MTX group were 17.0% and 46.5% vs 8.8% and 27.7% in the MTX group, respectively. Results were similar in TEMPO with 18.6% and 35.5% of patients in ETN + MTX group and 6.4% and 20.2% in the MTX group achieving remission. Mean change (SD) in annualized mTSS were lower in patients who achieved remission at week 24 compared with those with low disease activity or non-responders, which were significant (P<0.05) in the ETN + MTX group (Table). In the ETN + MTX groups, the majority of patients who achieved CDAI or DAS28 remission were non-progressors by mTSS change scores ≤0.5 (TEMPO 100% and 86.9%; COMET 87.5% and 87.0%) with similar observations in the MTX group (TEMPO 100% and 72.0%; COMET 71.4% and 78.3%).

Table 1. Descriptive Statistics for mTSS by Week 36 Clinical Disease Response Category

Week 36 Response	n	ETN + MTX mTSS Baseline, Units Mean (Median)	Final Time Point,† Units Mean (Median)	Progression Rate, Units/Yr Mean (95% CI)
CDAI Remission (≤2.8)	195	36.5 (14.5)*	36.6 (14.5)*	0.1 (−0.1, 0.4)*
CDAI LDA (>2.8 ≤10)	415	39.3 (17.5)	39.7 (19.5)	0.4 (0.2, 0.6)
CDAI NR (>10)	94	44.4 (22.3)	45.0 (22.3)	0.6 (−0.3, 1.4)
DAS28 Remission (≤2.6)	487	37.9 (16.5)	38.2 (18.0)	0.3 (0.2, 0.5)*
DAS28 LDA (>2.6≤3.2)	135	41.9 (19.4)	42.1 (19.5)	0.2 (−0.1, 0.6)
DAS28 NR (>3.2)	82	42.6 (16.0)	43.3 (17.0)	0.7 (−0.2, 1.6)

*P < 0.05, Kruskal Walis test for differences in distributions. †Final time point defined as the sum of baseline and progression rate. DAS28 = 28-joint Disease Activity Score; CDAI = Clinical Disease Activity Index; LDA = low disease activity; NR = no response.

Conclusion: Inhibition of radiographic progression was more robust with ETN + MTX therapy compared with MTX, regardless of week 24 disease activity. Overall, patients who achieved remission at week 24 had less radiographic progression at year 2 than those with LDA or NR, and less progression with remission defined by CDAI than DAS28. These results may be the first to indicate that achievement of clinical remission within 6 months may predict longer term inhibition of structural damage.

Radiographic Deformity of the Foot Is Starting From the Early Stage of Rheumatoid Arthritis. Kenji Mamoto, Tatsuya Koike, Tadashi Okano, Atsuko Kamiyama, Yuko Sugioka, Masahiro Tada and Hiroaki Nakamura. Osaka City University Graduate School of Medicine, Osaka, Japan

Background/Purpose: Foot deformities frequently arise in patients with rheumatoid arthritis (RA). It might cause gait dysfunction and lead to disability. However, the precise mechanism of progression of foot deformity is still unclear.

The aim of this study is to clarify the relationship between disease progression and the deformity of feet in patients with RA.

Methods: The prospective cohort TOMORROW (TOtal Management Of Risk factors in Rheumatoid arthritis patients to lOWer morbidity and mortality; clinical trial registration number, UMIN000003876) study was started in 2010. We examined antero-posterior and lateral radiographs obtained from 416 weight-bearing feet of 208 patients with RA from this cohort. The stage of articular destruction was classified from the hand radiographs based on Steinbrocker's classification. We measured the hallux valgus angle (HVA), the intermetatarsal angle between the first and second metatarsals (M1M2) and the first and fifth metatarsals (M1M5) on antero-posterior radiographs, and calcaneal pitch (CP) on lateral radiographs. Each deformity was defined as hallux valgus: HVA>15 degree, spread foot: M1M5>30 degree and flat foot:CP<20 degree.

Results: We finally analyzed 387 feet of 196 patients excluding those that had been surgically treated. The mean age and mean disease duration were 58.2 years old and 12.7 years, respectively. Steinbrocker's stages 1, 2, 3 and 4 were identified 39, 48, 44 and 65 patients, respectively (Table 1). We identified any of hallux valgus, spread foot and flat foot in Steinbrocker's stage 1. Moreover HVA and CP had progressed according to the progression of stage and disease duration. However, M1M2 and M1M5 had been progressed from the early stage. These findings indicate that foot deformities started from the early stage of RA and progressed with advancing stages.

Table 1. Development of foot deformities in patients with rheumatoid arthritis according to Steinbrocker's stage.

Steinbrocker's stage	1 (n = 39)	2 (n = 48)	3 (n = 44)	4 (n = 65)
Disease duration (y)	6.9	7.6	14.5	21.8
DAS28-ESR	2.8	3.2	3.8	3.9
HVA (°)	15.6	18.9	17.4	24.9
M1/M2 angle (°)	9.5	10.5	9.7	9.4
M1/M5 angle (°)	29.5	29.4	30.3	29.2
Calcaneal pitch (°)	19.3	18.2	16.9	15.5
Hallux valgus (%)	47.4	59.4	50.6	63.5
Spread foot (%)	41.6	40.6	44.8	42.1
Flat foot (%)	52.6	58.3	67.8	73.8

Conclusion: Foot deformities started from an early stage of RA, and correlated with disease stage and duration in patients with RA. This result suggests that the disease activity may be underestimated without the assessment of feet in routine clinical care. It is necessary to consider joint destruction and deformity of the foot from the early stage of RA.

The Influence of Vertebral Fractures On the Functional Disability of Patients with Rheumatoid Arthritis. Soo-Kyung Cho[1], Joo-Hyun Lee[2], Min-Kyung Han[3], Seunghun Lee[4], Ji Young Kim[4], Jeong Ah Ryu[4], Yun Young Choi[4], Sang-Cheol Bae[5] and Yoon-Kyoung Sung[5]. [1]Hanyang University Hospital for Rheumatic Diseases, Seoul, South Korea, [2]Ilsan Paik Hospital, Inje University, Goyang, South Korea, [3]Hanyang University Hospital for Rheumatic Disease, Seoul, South Korea, [4]Hanyang University College of Medicine, Seoul, South Korea, [5]Hanyang University Hospital for Rheumatic Diseases, Clinical Research Center for Rheumatoid Arthritis (CRCRA), Seoul, South Korea

Background/Purpose: Rheumatoid arthritis (RA) is a chronic, painful, and disabling disease associated with reduced health-related quality of life (HRQOL) compared to the general population. Higher levels of comorbidity can make the physical disability of RA patients even worse. Osteoporosis leading to bone fracture is one of the main co-morbidities of RA, and approximately one-third of women with RA report a fracture within 5 years of follow-up. Few studies have examined the influence of vertebral fracture (VF) on the outcome of patients with RA. The aim of the present study was to compare functional disability between RA patients with and without VF.

Methods: All female RA patients aged 50 years or older who visited our hospital for periodic examination between April 2011 and August 2011 were asked to participate in this study. Of these 169 patients, 100 were consecutively enrolled after excluding 69 patients who either did not wish to participate or recently had a routine examination for osteoporosis. Participants completed questionnaires via interview regarding demographic and lifestyle characteristics. Functional disability as a primary outcome was evaluated with the Health Assessment Questionnaire Disability Index (HAQ-DI). Each participant underwent thoracolumbar radiography, and the results were evaluated by two radiologists. We used multivariable-adjusted logistic regression analysis to test for associations between functional disability and the presence of VF, the severity of VF, and the number of VFs.

Results: Among the 100 RA patients, 47 had at least one VF, but 34 of these patients were unaware that they had experienced a fracture. The presence of two or more VFs (OR 3.0, CI 1.18.1) and moderate or severe VF (OR 3.4, CI 1.39.0) were related to disability in univariate analyses, but these effects were no longer significant after adjusting for age, disease duration, current steroid use, disease activity, and no previous history of VF. Among those RA patients with higher disease activity (n=51), the presence of VF (OR 5.1, CI 1.221.7) and moderate or severe VF (OR 7.1, CI 1.339.4) were associated with disability.

Table 1. Factors influencing functional disability in patients with RA (n=100)

	Unadjusted analysis	Adjusted analysis
Age 50-60	1	
61-70	2.3 (0.9~5.8)	
71 ≤	2.0 (0.7~6.1)	
Disease duration (years) 10 ≤	1.8 (0.7~4.3)	
BMI Normal or low (≤22.9)	1	
Over weight (23.0~24.9)	1.3 (0.5~3.2)	
Obesity (25.0<)	0.9 (0.3~2.4)	
Current steroid use	1.3 (0.6~2.8)	
DAS28 Remission and low (<3.2)	1	1
Moderate and high (≥3.2)	4.7 (2.0~10.9)	5.4 (2.2~13.2)
No previous history of VF	0.7 (0.2~1.8)	0.4 (0.1~1.3)
Presence of VF	2.2 (1.0~4.9)	
Number of VFs 0	1	
1	1.6 (0.6~4.4)	
≥ 2	**3.0 (1.1~8.1)**	
Severity of VF None	1	
Mild	1.3 (0.5~3.8)	
Moderate or severe	**3.4 (1.3~9.0)**	

Table 2. Influence of vertebral fracture on disability in RA patients with moderate or high disease activity

Regression model	Details of VF	OR (95% CI) Moderate or high disease activity (n=51)
Model 1	Presence of VF	5.1 (1.2~21.7)
Model 2	Number of VFs 0	1
	1	3.2 (0.5~23.2)
	2≤	4.8 (0.9~24.7)
Model 3	Severity of VF Normal	1
	Mild	3.3 (0.6~18.6)
	Moderate or sever	7.1 (1.3~39.4)

Conclusion: Many patients with RA have occult VF. Among RA patients with higher disease activity, the presence and severity of VF may affect functional disability.

Trimmed Analyses, a New Approach to the Analysis of Sharp Score Data in the Assessment of Progression in Patients with Rheumatoid Arthritis. Robert B. M. Landewé[1] Désirée van der Heijde[2], Carol Connell[3], John Bradley[3], David Gruben[3] and Michael Brown[3]. [1]Academic Medical Center/University of Amsterdam & Atrium Medical Center, Amsterdam, Netherlands, [2]Leiden University Medical Center, Leiden, Netherlands, [3]Pfizer Inc., Groton, CT

Background/Purpose: Tofacitinib is a novel oral Janus kinase inhibitor being investigated as a targeted immunomodulator and disease-modifying therapy for RA. In the Phase 3 ORAL Scan study [NCT00847613], progression in radiographic scores (mean change from baseline [BL] in modified Total Sharp Scores [mTSS] at Month 6) was a primary analysis using an Analysis of Covariance (ANCOVA). ANCOVA demonstrated statistically significant inhibition in structural damage progression for tofacitinib 10 mg but not 5 mg twice daily (BID) doses, compared with placebo (PBO).[1] There has been a general trend towards less PBO progression in recent radiographic studies;[2] the PBO period is generally shorter (≤3 months) and most patients receiving PBO are rescued. It is therefore important to confirm that efficacy detected in a primary analysis is robust. Rank analysis of ORAL Scan data demonstrated borderline evidence of inhibition by both doses. Rank analyses are used to show results are not driven primarily through extreme values, as ranking down weights extreme values

relative to ANCOVA, but analyses of ranks do not yield intuitively interpretable values representing the magnitude of damage inhibition. A conceptual bridge between rank analyses and ANCOVA is the trimmed-analysis approach, where extreme values are systematically removed from the data set.

Methods: In this analysis, mTSS data were trimmed in 1% increments up to 10%, eg 2% trimming deletes observations <1st percentile and >99th percentile. In the ORAL Scan study this resulted in approximately 2–3 observations symmetrically removed per group per 1% trimming. ANCOVA was then applied to each resulting trimmed set (0% was the primary analysis).

Results: At 1% trimming, nominal statistical significance was achieved for both tofacitinib doses (CI less than 0) and was maintained with further trimming (Figure). As expected, the mean difference from PBO diminished slightly with trimming, but was more than compensated for by reductions in variability.
Figure.

Trimmed data = % Data Excluded

Conclusion: In ORAL Scan, significance of inhibition of structural damage was demonstrated for both tofacitinib doses after just 1% trimming, indicating that significance in the primary analysis was not dependent on extreme data. Trimmed analyses give improved insight into the influence of extreme values and should be considered as one of the sensitivity analyses of choice for structural data.

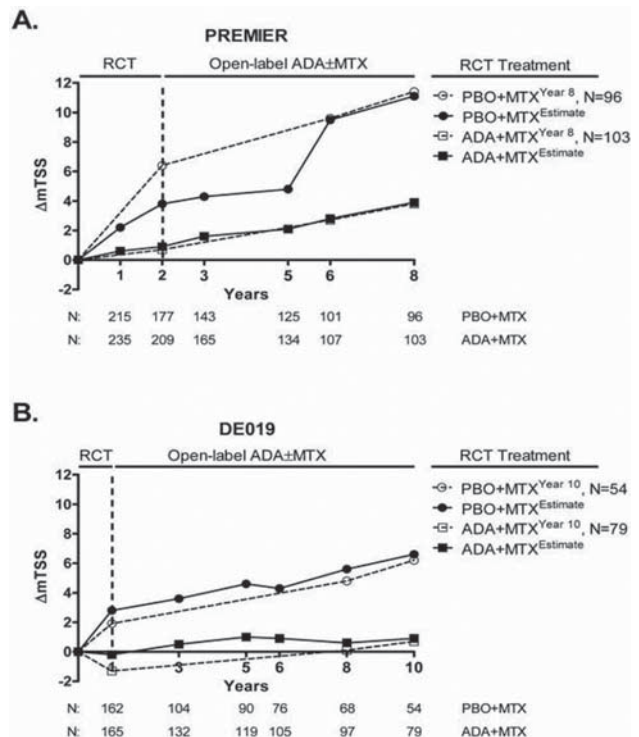
Analysis of Integrated Radiographic Data for Two Long-Term, Open-Label Extension Studies of Adalimumab. Désirée van der Heijde[1], Robert Landewé[2], Edward C. Keystone[3], Ferdinand C. Breedveld[1], Shufang Liu[4] and Neelufar Mozaffarian[4] [1]Leiden University Medical Center, Leiden, Netherlands, [2]Academic Medical Center, Amsterdam, Netherlands, [3]University of Toronto, Toronto, ON, [4]Abbott, Abbott Park, IL

Background/Purpose: The assessment of radiographic data from long-term studies in patients (pts) with rheumatoid arthritis (RA) poses a significant challenge, given the potential involvement of multiple readers who typically evaluate films from only a subset of the available time points, often re-scoring previously read images. This analysis describes an integration approach to evaluate the complete set of radiographic scores assessed over several years (yrs) from long-term studies of adalimumab (ADA).

Methods: Data from 2 large, multicenter, phase 3, randomized, placebo (PBO)-controlled trials of ADA were analyzed: PREMIER (MTX-naïve pts, early RA[1]), had a 2-yr double-blind (DB) period followed by an ongoing 8-yr open-label extension (OLE); DE019 (MTX-inadequate responders, longstanding RA[2]), had a 1-yr DB period followed by a completed 9-yr OLE. Pts received OL ADA±MTX in both OLEs. This post hoc analysis evaluated radiographic data based on randomization to the original PBO+MTX and standard dose ADA+MTX arms through 8 yrs of treatment in PREMIER and 10 yrs in DE019. Radiographic progression was assessed using the change in modified total Sharp score (ΔmTSS) from baseline (BL). Radiographs were assessed at Yrs 2, 3, 5, and 8 (PREMIER) and Yrs 1, 2, 3, 5, 6, 8, and 10 (DE019). At each assessment yr, radiographs from BL and selected prior yrs were re-read. A mixed effect model was used to evaluate the repeated measurements at different time points within different assessment yrs in the integrated analysis. ΔmTSS at each time point was estimated by least square mean and summarized alongside the most recent assessment yr of PREMIER (Yr 8, which included repeat reads for BL, and Yrs 2 and 6) and DE019 (Yr 10, which included repeat reads for BL, and Yrs 1 and 8).

Results: Radiographic data from 452 pts in PREMIER (215, PBO+MTX; 237, ADA+MTX) and 327 pts in DE019 (162, PBO+MTX; 165, ADA+MTX) with BL and ≥1 post-BL radiograph were identified. Radiographic progression was most pronounced in pts receiving PBO+MTX during the DB periods, but progression slowed dramatically upon switch to OL ADA±MTX therapy in both trials (**Figure**). Following up to 8 yrs of treatment, pts in PREMIER experienced ΔmTSS estimates of 11.1 (PBO+MTX) and 3.9 (ADA+MTX) units; pts in DE019 experienced estimates of 6.6 (PBO+MTX) and 0.9 (ADA+MTX) units through up to 10 yrs of treatment. The estimated curves in each of the studies revealed subtle changes in progression rates not seen in their respective most recent assessment yr.


Conclusion: Longitudinal, data integration analyses factoring in mTSS from all available assessments enabled a robust estimate of total radiographic progression in 2 long-term studies of ADA±MTX. Moreover, the present analysis confirmed the radiographic efficacy of long-term therapy with ADA±MTX.

The Effect of Evaluation Variability At the Unit of Measurement On the Reliability of Omeract Ramris and Van Der Heijde-Modified Sharp Score. Ruben Tavares[1], Naveen Parasu[2], Karen Finlay[2], Erik Jurriaans[2], Hao Wu[1], Karen A. Beattie[1], Maggie Larche[1], Lawrence E. Hart[3], William G. Bensen[4], Raja S. Bobba[1], Alfred A. Cividino[1], Colin E. Webber[5], Jean-Eric Tarride[6] and Jonathan D. Adachi[7]. [1]McMaster University, Hamilton, ON, [2]Hamilton Health Sciences, Hamilton, [3]St. Joseph's Health Care, Hamilton, ON, [4]St. Joseph's Hospital and McMaster University, Hamilton, ON, Hamilton, ON, [5]Hamilton Health Sciences, Hamilton, ON, [6]Programs for Assessment of Technology in Health (PATH) Research Institute, Hamilton, ON, [7]Charlton Medical Centre, Hamilton, ON

Background/Purpose: The Outcome Measures in Rheumatology (OMERACT) Rheumatoid Arthritis Magnetic Resonance Imaging Score (RAMRIS) and van der Heijde-modified Sharp score (vdHSS) are recognized semi-quantitative measures for the evaluation of rheumatoid arthritis (RA) disease progression on magnetic resonance imaging (MRI) and radiography (X-ray), respectively. The smallest detectable difference (SDD) is used to quantify the reliability between ratings of status scores in scale units. To date, the SDD has been evaluated at the overall or component feature score levels of analysis thereby ignoring variability at the unit of measurement. The objective of this study was to determine the reliability of RAMRIS and vdHSS at the unit of measurement across four radiologists and to compare it to the conventional approach.

Methods: A paired, cross-sectional study of RA patients with varying symptom duration (mean 6.8 years (SD 6.4) for MRI, 7.6 years (SD 7.3) for X-ray) was conducted. 19 MR image sets of metacarpophalangeal joints (MCP) 2–5 and 9 X-ray image sets of both hands, wrists, and forefeet were each independently evaluated by 4 radiologists using RAMRIS and vdHSS, respectively. Shrout and Fleiss fixed and random effects intra-class correlation coefficients (fICC and rICC, respectively), and SDD were calculated for overall and component feature scores, as well as at the unit of measurement.

Results: At the unit of measurement, the RAMRIS erosion, edema, and synovitis fICC were 0.71, 0.56, and 0.41, respectively. The corresponding SDD values (rounded to scale unit) for erosion, edema, and synovitis were 2, 1 and 2. Overall and component feature score reliability measures were dependent on the anatomy compared. For single MCP 2–5 joint sets (i.e. per hands), the fICC for the overall RAMRIS and component feature subscore for erosion, edema, and synovitis were 0.66, 0.55, 0.60, and 0.39. The corresponding SDD values were 11, 7, 4, and 5. For X-ray, erosion and joint space narrowing (JSN) fICC at the unit of measurement were 0.61 and 0.69, and the associated SDD values were both 2. For the hands, wrists and feet, the overall and component feature scores for erosion and JSN were 0.69, 0.60, and 0.85. The corresponding SDD values were 39, 34, and 11.

Conclusion: The conventional approach to the calculation of reliability for overall or component feature scores fails to account for variability at the unit of measurement. In order for reliability of composite measure scores to be valid, the assumption is made that the SDD at the unit of measurement is less than the scale unit. The study findings suggest that this prerequisite assumption may be false. The validity of literature evidence for the reliability of diagnostic imaging and composite measures in general is therefore questionable.

Bye Bye Biopsy: Diffusion Tensor and Dynamic Contrast Enhance Magnetic Resonance Imaging Parameters Reflect Molecular Events of Inflammation in the Synovium. Vikas Agarwal[1], Rishi Awasthi[2], Deepak Tripathi[3], Vinita Agrawal[3], Ram Kishore Singh Rathore[4], Kusum Sharma[5], CM Pandey[3] and Rakesh K. Gupta[3]. [1]Sanjay Gandhi Post Graduate Institute of Medical Sciences, Lucknow, Lucknow, India, [2]Sanjay Gandhi Post Graduate Institute of Medical Sciences, Lucknow, India, Lucknow, India, [3]Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow, Lucknow, India, [4]Indian Institute of Technology, Kanpur, India, [5]Postgraduate Institute of Medical Education and Research, Chandigarh, India

Background/Purpose: Chronic synovial inflammation is characterized by accumulation of inflammatory cells and increased vascularity. Synovial histology remains the most definitive way to delineate the severity of inflammation. Herein we hypothesize that Diffusion tensor imaging (DTI) derived metrics may delineate the aggregation of the inflammatory cells. Dynamic contrast enhanced (DCE) imaging may provide information regarding vascularity in the inflamed synovium. Combination of these may provide information about the ongoing inflammation.

Methods: Patients with chronic knee arthritis underwent conventional, DTI and DCE MRI (3T) followed by arthroscopic synovial biopsy. Masks of synovial regions that enhanced on post contrast T1-weighted imaging were created using an automated segmentation algorithm. Created masks were used to segment the inflamed synovium to extract various DCE and DTI metrics. Synovium was subjected to histopathology, immunohistochemistry (IHC), culture and PCR.

Results: There were 65 patients (45 male) with mean age 39 years [range 18–76] and mean disease duration 29 months [range 4–192]. Fifteen patients had tuberculosis and rest had; undifferentiated spondyloarthropathy (n=14), chronic monoarthritis (n=11), chronic undifferentiated monoarthritis (n=10), rheumatoid arthritis (n=6), osteoarthritis (n=3), ankylosing spondylitis (n=2), reactive arthritis (n=2) and juvenile idiopathic arthritis and leprosy one each.

The mean values of various DTI and DCE and IHC parameters are presented in (Table-1). Amongst the DTI parameters, FA significantly correlated with all the inflammatory cells infiltrating into the synovium (Table-2) and various proinflammatory cytokines. FA was the best predictor of infiltrating T cells, B cells, plasma cells, macrophages, adhesion molecule and proinflammatory cytokines. DCE parameters significantly correlated with CD34 and blood volume was the best predictor of CD34.

Table 1. Mean values of DTI, DCE, IHC markers

DTI indices	Mean ±SD
FA	0.22 ± 0.031

Background/Purpose: Instruments designed to determine the clinical relevance of bone erosions captured by magnetic resonance imaging (MRI) in rheumatoid arthritis (RA) patients have been set-back by inconsistency in both intra and inter-rater reliability. The developed *Early Erosions in Rheumatoid Arthritis* (EERA) software holds promise for increasing reliability across readers by quantifying RA patient erosions in a semi-automated fashion using an amalgamation of conventional Region Growing and Level-Set Segmentation algorithms. The principle aim of this study was to determine intra and inter-rater reliability when applying EERA software to the quantification of erosions in the metacarpal phalanges (MCPs) of RA patients.

Methods: Two readers, R1 and R2, trained to use EERA software, but otherwise inexperienced with conventional quantification techniques, evaluated erosions captured by MRI in the second through fifth MCPs of 50 patients diagnosed with RA under the American College of Rheumatology 1987 revised definition. A 1T magnet, 100mm diameter cylindrical transmit and receive coil, and a 3D spoiled gradient echo sequence were used in acquiring the images. Images were evaluated by each reader twice with a 72 hour wait period between runs. Intra and inter-rater reliabilities for the total volume measures between the two readers and two runs was assessed via intra-class correlations, ICC(2,1), with 95% confidence intervals. For each run, volume differences between readers were graphed against R2's volume measures in Bland-Altman difference plots so as to visually capture the degree to which scores varied.

Results: Of the 50 participants recruited for the study, 16 were male and 34 were female. Study subjects had a mean age of 57 (SD=11.5)yr, a mean weight of 78 (SD=15.6)kg, and a mean height of 169 (SD=13.9)cm. Readers identified 64 ± 1 erosions in the patients: 15 of these occurred in second MCP, 33 ± 1 in the third MCP, 12 ± 1 in the fourth MCP, and 4 in the fifth MCP. Mean erosion size, as determined by R1 during the first and second runs, were 87.1 (SD=118.9)mm³ and 88.1 (SD=121.2)mm³ respectively. R2's measures had a mean erosion volume of 90.7 (SD=130.1)mm³ for the first run and 103.2 (SD=151.0)mm³ for the second run. For both runs, agreement between readers was better for smaller sized erosions decreasing appreciably beyond 100mm³ (See Figure 1. Run 2 results are not shown but are available upon request). The intra-rater reliability had an ICC value of 0.956 with the 95% confidence interval ranging from 0.935 to 0.970. Between R1 and R2, the inter-rater reliability had an ICC value of 0.921 with a 95% confidence interval from 0.886 to 0.946.
Figure 1. Run 1 Reader Measured Erosion Volume Differences Plotted against R2's Measures

Conclusion: Results obtained suggest that EERA software can be applied to acquire MCP erosion volume measures in a reliable manner.

Visualization of Cartilage in High-Resolution Magnetic Resonance Imaging Is a New Imaging Biomarker for the Quantification of Joint Damage in Rheumatoid Arthritis. Barbara Herz[1], Stephanie Finzel[1], Andreas Albrecht[1], Juergen Rech[1], Matthias Englbrecht[1], Goetz Welsch[2] and Georg Schett[3]. [1]University of Erlangen-Nuremberg, Erlangen, Germany, [2]Department of Traumatic Surgery, University Clinic of Erlangen-Nuremberg, Erlangen, Germany, Erlangen, Germany, [3]Institute for Clinical Immunology, University of Erlangen-Nuremberg, Erlangen, Germany

Background/Purpose: Recent achievements in Magnetic Resonance Imaging (MRI) have been the gradient-echo-based T1-delayed gadolinium-enhanced MRI of cartilage (dGEMRIC) focussing on the detection of proteoglycan content in cartilage; moreover, the multi-echo and spin-echo T2-mapping has been developed for the assessment of cartilage hydration and collagen microstructure. Current MRI-studies suggest a link between dGEMRIC and T2-mapping and early changes of cartilage in inflammatory diseases. However, their diagnostic value in inflammatory diseases has not yet been fully clarified..To investigate the relation between morphological and biochemical alterations in the cartilage of patients with Rheumatoid Arthritis (RA) by high-resolution 3Tesla-MRI.

Methods: 29 RA-patients received a 3Tesla-MRI scan of the 2nd and 3rd metacarpophalangeal (MCP) joint of the dominant hand. T2-mapping and dGEMRIC were performed with 2 small-diameter surface coils designed for high-resolution imaging of cartilage (0.26×0.26×105mm voxel size; Verio Siemens Healthcare, Erlangen, Germany). T2 and T1 relaxation times were obtained via a region-of-interest (ROI) evaluation. MCP heads and bases were scored semiquantitatively for synovitis, bone marrow edema (BME) and bone erosion (BE) using the RA MRI scoring (RAMRIS) system; joint space and cartilage thickness were measured perpendicular to the joint plane in all 3 joint regions (fig. 1a).

Results: Inter- and intraobserver agreement was good (details see fig. 1b). For correlation analysis mean values of real and total joint spaces (RJS, TJS), RAMRIS-subscores, and ROIs of dGEMRIC- and T2-evaluations were used; image 1a shows details of source data acquisition, image 1c data of correlation analysis. Interestingly, early changes of cartilage such as BME and synovitis in RAMRIS as compared to dGEMRIC were correlated negative (p=0.029; p=0.003); likewise, BME and synovitis showed positive correlation (p=0.013; p=0.015) in T2. In contrast, periarticular changes occurring later in the course of the disease such as BE did not correlate with dGEMRIC (p=0.704) and weakly with T2 (p=0.026). All joint space subanalyses of MCP3 despite RJS correlated with dGEMRIC and T2 mainly in medial region (TJS p=0.017; TCT p=0.020; CT p=0.018). Additionally, in dGEMRIC MCP2 and RJS correlated in ulnar side (p=0.001).
Figure 1a: Details of cartilage and joint space analysis. Image 1 shows details of ROI-evaluation in MCP2 and 3, image 2 Total Cartilage Thickness (TCT, left), Cartilage Thickness (CT, right) proximally and distally, image 3 shows Total Joint Space (TJS, left) and Real Joint Space (RJS, right).

Figure 1b: Details of Intra- and Interobserver Reliability; ranges of r-values are shown.

Figure 1c: Details of Correlation analysis; P-values are shown. nd = not done; ns = not significant

	Dorsal Medial	Dorsal Lateral	Plantar Medial	Plantar Lateral
1st Proximal Phalanx	7	3	5	7
1st Metatarsal	6	4	13	19
2nd Proximal Phalanx	0	1	5	8
2nd Metatarsal	6	5	9	6
3rd Proximal Phalanx	1	1	6	6
3rd Metatarsal	3	4	10	8
4th Proximal Phalanx	1	1	6	6
4th Metatarsal	6	3	12	6
5th Proximal Phalanx	2	4	9	5
5th Metatarsal	10	11	14	14
Total	42	37	89	75

Conclusion: High-resolution MRI using dGEMRIC and T2-mapping enables meticulous detection of very early inflammatory changes in cartilage which are known to precede RA-typical periarticular bone damage. This is important both for early discovery of those damages, adequate therapy decisions and therapy monitoring; moreover, it may also have an impact on the development of anti-inflammatory drugs in the future. Additional studies on mechanical influences on cartilage are needed to further evaluate the mechanisms of joint space alterations.

Location of Erosions At the Metatarsophalangeal Joints in Patients with Rheumatoid Arthritis. Heidi J. Siddle[1], Richard J. Hodgson[2], Andrew J. Grainger[3], Anthony C. Redmond[4], Richard J. Wakefield[4] and Philip S. Helliwell[5]. [1]University of Leeds, Leeds, United Kingdom, [2]NIHR Leeds Musculoskeletal Biomedical Research Unit, Leeds, United Kingdom, [3]Leeds Teaching Hospitals NHS Trust and NIHR Leeds Musculoskeletal Biomedical Research Unit, Leeds, United Kingdom, [4]University of Leeds and NIHR Leeds Musculoskeletal Biomedical Research Unit, Leeds, United Kingdom, [5]NIHR Leeds Biomedical Research Unit, University of Leeds and Leeds Teaching Hospitals NHS Trust, Leeds, United Kingdom

Background/Purpose: The forefoot is described as the most common site of symptoms in the foot and ankle of patients with rheumatoid arthritis (RA). Pressure under the forefoot area is significantly increased in patients with RA compared to normal subjects and forefoot peak pressures have been reported to correlate with pain, damage and higher erosion scores at the MTP joints. Damage to plantar structures such as the capsule and plantar plate of the MTP joints in patients with RA is associated with bone erosion, suggesting altered biomechanics or mechanical effects due to capsule or plantar plate abnormalities may cause bone changes. While a tendency towards a lateral distribution has been noted in the hands, the location of erosions at the MTP joints has not been previously reported in patients with RA. This exploratory study hypothesised that the majority of erosions at the MTP joints in patients with RA are on the plantar aspect, contributing to pain, damage and increased pressure.

Methods: In 24 patients with RA the more symptomatic forefoot was imaged using 3Tesla MRI. T1 weighted sagittal and short axis post gadolinium sequences were acquired through the MTP joints. Images were scored for bone erosion in the distal and proximal part of the MTP joints using the RAMRIS system. The base of the proximal phalanx and the head of the metatarsal were divided into quadrants to determine the location of erosions in dorsal-medial, dorsal lateral, plantar medial and plantar lateral regions.

Results: Seventeen females and seven males with a mean age of 55.5 years, disease duration 10.6 years (range 0.6 – 36) and self reported foot pain measured by 100mm visual analogue scale (VAS) of 43.4 (SD 27.9) took part in the study. Eighteen patients were rheumatoid factor positive, the mean (SD) DAS44 (CRP) and DAS44 (ESR) were 2.5 (0.8) and 2.6 (0.9) respectively. The location of erosions at the MTP joints in patients with RA is shown in the table below. The majority of erosions are reported on the plantar aspect of the MTP joints.

Conclusion: This is the first study to report the location of erosions at the MTP joints in patients with RA and forefoot pain. The results confirm the hypothesis of this exploratory study; erosions were more commonly reported on the plantar aspect of the distal and proximal parts of the MTP joints, often in sites not readily imaged using standard ultrasound protocols. Further work is required to determine the relationship between forefoot pain, deformity and raised plantar pressures with the location of erosions at the MTP joints in patients with RA. Furthermore, these study findings highlight the need to image the dorsal and plantar aspect of the MTP joint when using ultrasound alone to detect erosions in RA.

Magnetic Resonance Imaging in Follow-up of Clinical Remission in Juvenile Idiopathic Arthritis. Mira van Veenendaal[1], Robert Hemke[2], Marjolein I. Bos[1], Mario Maas[2], Marion A. J. Van Rossum[1] and Taco W. Kuijpers[1]. [1]Emma Children's Hospital/Academic Medical Center (AMC), Amsterdam, Netherlands, [2]Academic Medical Center (AMC), Amsterdam, Netherlands

Background/Purpose: Despite clinical remission, a substantial proportion of Juvenile Idiopathic Arthritis (JIA) patients will flare after a period of inactive disease. MRI has proven to depict subclinical inflammation as reflected by synovial hypertrophy, and may therefore be useful to identify patients at risk for flaring during follow-up.

The purpose of this study, focussing on the main target joint, was to use MRI in JIA patients in clinical remission, and to identify inflammatory changes as compared to clinical status over time.

Methods: In this prospective study, 16 patients with JIA (median age 11.8 years [IQR, 10.5–14.5], median disease duration 3.2 years [IQR, 1.8–5.6]) in clinical remission (fulfilling the Pediatric Rheumatology International Trials Organization (PRINTO) preliminary criteria for clinical remission) werestudied with MRI at 2 consecutive time points (median interval 16.1 months [IQR 14.4–17.1]) and assessed for clinical relapse. Initial clinical remission was achieved in 14 patients on medication (CRM) (median duration inactive disease 11.0 months [IQR 7.2–13.7]) and in 2 patients off medication (CR) (median duration inactive disease 28.7 months [IQR 15.7–28.7]). Contrast-enhanced MRI of the formerly most involved knee was performed to evaluate the degree of synovial hypertrophy, using the validated Juvenile Arthritis MRI Scoring (JAMRIS) (synovial hypertrophy score; <2 mm=0, 2–4 mm=1 and >4 mm=2, at 8 knee regions).

Results: The first MRI showed signs of subclinical synovitis in 8 patients (50 %) and no synovitis in 8 patients. The second MRI in follow-up demonstrated an increased score of synovial hypertrophy as compared to the first MRI in the 6 patients with relapse of arthritis. In contrast, all patients with sustained clinical remission showed either stable (6 patients) or improved (4 patients) scores of synovial hypertrophy. CRP and erythrocyte sedimentation rate were not increased at both MRI time points.

Conclusion: A large degree of JIA patients who satisfy the PRINTO remission criteria with normal findings on clinical and laboratory assessment had MRI based synovitis in this study, suggestive of ongoing disease activity. Increase of synovial hypertrophy over time was related to disease flaring, whereas stable or further reduction of synovial hypertrophy was associated with sustained clinical remission. Serial MRI allows for adequate follow-up of underlying disease even when clinically silent.

Imaging of Ankle Joints by MRI in Murine Models of Inflammatory Arthritis. Shawn M. Rose[1], Harris R. Perlman[1], Emily Alex Waters[2] and Thomas Meade[2]. [1]Northwestern University, Chicago, IL, [2]Northwestern University, Evanston, IL

Background/Purpose: One of the fundamental shortcomings in the field of experimental rheumatology is the inability to non-invasively monitor the development of inflammatory arthritis longitudinally. Magnetic resonance imaging (MRI) overcomes this limitation, by allowing for detailed examination of anatomical structures as well as the assessment of joint and soft tissue inflammation. Here, we have utilized cutting-edge MRI technologies to image ankle joints in control (C57BL/6) and arthritic (K/BxN serum transfer-induced arthritis (STIA) and K/BxA^{g7}) mice over time. Further, the MRI data was validated against both clinical, histological, and in vivo imaging system (IVIS) assessments of inflammatory arthritis.

Methods: C57BL/6 mice were injected with PBS (controls) or 100 mL of K/BxN serum at day 0. Mice were scored clinically and imaged via IVIS and MRI at days 0, 3, 7, 15, and 21 after arthritis induction. MRI imaging was also performed on ankle joints from 10- and 21-week-old K/BxA^{g7} mice. Arthritis severity was assessed by measurement of ankle width and clinical score. Decalcified ankle joint specimens were sectioned and stained with hematoxylin and eosin for histological analysis. Luminescence acquisition was performed using an IVIS Spectrum System 10 minutes after intraperitoneal injection of 100 mL (200 mg/kg) of XenoLight Rediject Inflammation Probe. Radiance signal intensity from normalized gated analyses of forepaw and hindpaw joints was quantified utilizing Living Image software. Ankle joint MRI was performed on a 9.4T Bruker Biospec MRI system. Two high-resolution 3D images were acquired; a gradient echo pulse sequence (FLASH) to evaluate bone and a spin echo sequence (MSME) to evaluate inflammation (long T2 signal volume). Amira software was used to perform MRI long T2 signal analyses and bone reconstructions. Graphpad Prism software was used for ANOVA and linear regression analyses with statistical significance established at $p < 0.05$.

Results: Arthritic STIA animals demonstrated increased clinical, histological, IVIS, and MRI measures of disease severity compared to controls. Peak arthritis intensity occurred at day 7 and complete resolution of inflammation was observed by day 21. Following induction of arthritis, the majority of increased long T2 signal and volume expansion of ankle joints occurred in a juxtaarticular rather than intrarticular fashion. Ankle joint bone destruction in K/BxA^{g7} mice was readily detectible via MRI as early as age 10 weeks. Linear regression analyses demonstrated a strong correlation between clinical score and paw joint radiance intensity by IVIS ($R^2 = 0.54$, $p < 0.0001$). There was also a statistically significant relationship between ankle joint width and volume of long T2 signal by MRI ($R^2 = 0.57$, $p < 0.0001$).

Conclusion: MRI is an optimal technology for anatomic localization of articular and soft tissue changes during the development and resolution of inflammatory arthritis. Future studies may combine MRI imaging with various in vivo labeling agents to investigate joint disease in a cell-type specific fashion.

Scoring Radiographic Progression in Axial Spa: Should We Use the Modified Stoke in Ankylosing Spondylitis Spine Score or the Radiographic Ankylosing Spondylitis Spinal Score? Sofia Ramiro[1], A.M. Van Tubergen[2], Carmen Stolwijk[2], Robert Landewé[3] and Désirée van der Heijde[4]. [1]Academic Medical Center, University of Amsterdam, The Netherlands and Hospital Garcia de Orta, Almada, Portugal, [2]Maastricht University Medical Center, Maastricht, Netherlands, [3]Academic Medical Center, University of Amsterdam and Atrium Medical Center, Heerlen, Netherlands, [4]Leiden University Medical Center, Leiden, Netherlands

Background/Purpose: Radiographic damage is one of the core outcomes in axial SpA and it is usually assessed with the modified Stoke Ankylosing Spondylitis (AS) Spine Score (mSASSS). The recently proposed Radiographic AS Spinal Score (RASSS)[1] includes an assessment of the lower thoracic vertebrae, under the hypothesis that most progression occurred in these segments. We aimed to compare the mSASSS and RASSS with regard to efficiency and added value.

Methods: Two-yearly spinal radiographs from patients followed in the Outcome in AS International Study (OASIS) were used. Two readers independently scored the x-rays, and averaged scores per vertebral corner (VC) were used. Only radiographs with ≤3 missing VCs per segment (cervical and lumbar, the latter with 4 thoracic VCs included as described for the RASSS) were included, so that both scores could be calculated. Status- and 2-year progression scores of both scoring methods were compared, first in terms of their availability. To assess the potential additional value of including the thoracic segment in the score, the relative contribution (in %) to the 2-year total RASSS progression of each spinal segment (cervical, thoracic and lumbar) was determined, and compared to the expected contribution, assuming a balanced segmental progression and proportional to the number of sites (12 cervical VCs, 4 thoracic VCs and 12 lumbar VCs).

Results: The mSASSS could be scored in a total of 809 radiographs. The RASSS could be calculated in 78% of these radiographs. In 58% of those, the RASSS was calculated based on 1 or 2 present thoracic VC scores (of the 4 possible thoracic VC scores), and the remaining 2–3 had to be imputed because they were missing (these imputed VCs were therefore uninformative). There were 520 two-year mSASSS interval progression scores available, and in 63% of them a 2-year RASSS interval progression score could be determined.

Of all the radiographs in which both scores could be determined (n=629), the mean (SD) status- score was 15.5 (17.9) units for the mSASSS and 18.0 (20.9) units for the RASSS. The mean (SD) 2-year interval progression scores (in 330 two-year intervals) were 2.0 (3.6) for the mSASSS and 2.4 (4.4) for the RASSS. Exclusive progression of the thoracic segment occurred in only 5% of the cases. There were no significant differences between the observed and expected contributions of the thoracic segment to progression (Table), whilst progression was more frequently than expected observed in the cervical spine, and less frequently in the lumbar spine.

Table. MRI scores at baseline, week 6 and week 28/end of study

	Relative contribution to total RASSS progression (in %)		
	Expected	Observed	*P*-value for the difference
Cervical segment (12 VCs)	43	55	0.09
Lumbar segment (12 VCs)	43	29	0.04
Thoracic segment (4 VCs)	14	16	0.70
Total (28 VCs)	100	100	

Conclusion: The determination of a RASSS for status or progression of radiographic abnormalities in the spine is frequently impossible or strongly influenced by non-contributory imputation. In comparison to the conventional mSASSS method, the contribution of thoracic VCs in the RASSS-method is negligible, and does not justify the additional scoring efforts.

What Constitutes the Characteristic Fat Lesion On MRI of the Sacroiliac Joints in Early Spondyloarthritis? Ulrich Weber[1], Susanne Juhl Pedersen[2], Veronika Zubler[1], Kaspar Rufibach[3], Stanley Chan[4], Robert GW Lambert[4], Mikkel Ostergaard[5] and Walter P. Maksymowych[4]. [1]Balgrist University Hospital, Zurich, Switzerland, [2]Copenhagen University Hospital Glostrup, Copenhagen, Denmark, [3]University of Zurich, Zurich, Switzerland, [4]University of Alberta, Edmonton, AB, [5]Copenhagen University Hospital at Glostrup, Glostrup, Denmark

Background/Purpose: It is well known that fat infiltration (FI) of bone marrow may be observed on T1-weighted MRI in the sacroiliac joints (SIJ) of healthy individuals and patients with mechanical back pain and with spondyloarthritis (SpA). But it is unclear whether the MRI features of FI allow characterization of FI as pathological rather than physiological. Moreover, it is unclear if this might have diagnostic utility in early SpA. We aimed to assess which MRI features of fat contribute to diagnostic utility of SIJ MRI in 2 inception cohorts of early SpA.

Methods: Cohort A comprised 69 consecutive patients ≤50 years referred from rheumatology and primary care practices for assessment of clinically suspected SpA, cohort B comprised 88 consecutive patients ≤50 years with acute anterior uveitis and back pain. They were classified according to clinical examination and pelvic X-ray as having non-radiographic axial SpA (nr-axSpA) (n=20 and 31 for cohorts A and B, respectively), ankylosing spondylitis (AS) (n=10 and 24), or mechanical back pain (MBP) (n=39 and 33). Cohort A also comprised 20 healthy volunteers (HV). SIJ MRI were assessed independently in random order by 4 blinded readers for the following morphological features of FI: distinct border around the region of FI, homogeneity of the T1-weighted signal, proximity to subchondral bone, and association with other SIJ lesions (bone marrow edema (BME), erosion (ER)).

Results: In cohort A and B, FI in ≥2 SIJ quadrants was recorded by any 2 readers in AS in 90% and 100%, in nr-axSpA in 45% and 48%, in MBP in 36% and 24%, respectively, and in HV in 10%. Inter-reader agreement for FI expressed as intraclass correlation coefficient over all 4 readers was 0.59 and 0.75 for cohort A and B.

Diagnostic utility (mean of 4 readers for cohort A/B) of SIJ FI in nr-axSpA vs MBP patients

Feature	Sensitivity	Specificity	Positive LR	Negative LR
FI per se	0.44/0.42	0.73/0.78	1.62/1.91	0.77/0.74
FI with distinct border	0.21/0.21	0.97/0.90	8.29/2.13	0.81/0.88
Homogeneous FI	0.20/0.26	0.97/0.93	6.24/3.78	0.83/0.80
Subchondral FI	0.36/0.35	0.85/0.83	2.36/2.04	0.75/0.78
FI with any 2 features	0.24/0.30	0.97/0.92	9.26/3.58	0.78/0.77
FI+BME	0.19/0.18	0.99/0.92	14.63/2.13	0.82/0.90
FI+ER	0.21/0.24	0.99/0.93	33.15/3.55	0.79/0.81

BME: Bone marrow edema. ER: Erosion. FI: Fat infiltration. LR: Likelihood ratio. FI with any 2 features: ≥2 features out of FI with distinct border/ Homogeneous FI/Subchondral FI

Conclusion: SIJ FI characterized by a distinct border or homogeneity on MRI had substantial diagnostic utility in early SpA. FI in combination with BME or ER also showed high diagnostic utility.

Spinal Inflammation in the Absence of SI Joint Inflammation On MRI in Patients with Active Non-Radiographic Axial Spondyloarthritis. Désirée van der Heijde[1], Joachim Sieper[2], Walter P. Maksymowych[3], Matthew A. Brown[4], Suchitrita S. Rathmann[5] and Aileen L. Pangan[5]. [1]Leiden University Medical Center, Leiden, Netherlands, [2]Charité Universitätesmedizin Berlin, Berlin, Germany, [3]University of Alberta, Edmonton, AB, [4]University of Queensland Diamantina Insititute, Brisbane, Australia, [5]Abbott Laboratories, Abbott Park, IL

Background/Purpose: The imaging arm of the ASAS axial spondyloarthritis (SpA) criteria requires the presence of sacroiliitis on MRI or radiographs. In patients (pts) with non-radiographic axial SpA (nr-axSpA), there may be inflammation along the spine in the absence of sacroiliac joint (SIJ) inflammation on MRI. This analysis evaluated the existence of spinal inflammation on MRI at baseline (BL) in nr-axSpA pts with and without inflammation in the SIJs on MRI.

Methods: ABILITY-1 is an ongoing multicenter, randomized, controlled trial of adalimumab vs. placebo in pts with nr-axSpA classified using the ASAS axial SpA criteria, who had an inadequate response, intolerance to, or contraindication for NSAIDs. MRI of the SIJ and spine performed at BL were centrally scored using the SPARCC method (6-DVU method for the spine) by 2 independent readers blinded to the treatment codes. Mean scores of the readers were used. SPARCC score ≥2 for either the SIJ or spine was used as the operational definition of positive MRI evidence of inflammation. For these analyses, all pts were combined, independent of randomization.

Results: Mean symptom duration of the study population (N=185) was 10 yrs. At BL, 48% of pts were reported by the local investigator to have past or present MRI evidence of sacroiliitis as required by the ASAS axial SpA criteria. Of pts with available BL SPARCC scores, 40% had a BL SIJ score ≥2 and 52% had a BL spine score ≥2. Of the pts with BL SPARCC SIJ score <2, 49% had evidence of spinal inflammation (BL SPARCC spine score

≥2). Comparison of BL disease characteristics based on BL spine and SIJ scores <2 vs. ≥2 were generally comparable except for a greater proportion of males among those with spine and SIJ scores ≥2, and younger age and shorter symptom duration among those with spine and SIJ scores <2. The cumulative probability plot (figure) shows a similar distribution of SPARCC spine scores regardless of presence or absence of SIJ inflammation on MRI. The most frequently involved DVUs with bone marrow edema were in the lower thoracic and lumbar spine.
Figure.

Conclusion: Assessment by experienced readers shows that spinal inflammation on MRI may be observed in half of nr-axSpA pts without SIJ inflammation on MRI. MRI of both sites might be of value when evaluating pts with nr-axSpA. These data in pts with long-standing disease need to be confirmed in pts with shorter disease duration.

Psoriatic Arthritis and Spondyloarthritis: Inflammation Assessed by "Head to Toe" Wholebody Magnetic Resonance Imaging—A Comparison with Clinical Joint Examination. René Panduro Poggenborg[1], Susanne Juhl Pedersen[2], Iris Eshed[3], Inge Juul Sørensen[2], Ole Rintek Madsen[4], J.M. Møller[5] and Mikkel Østergaard[6]. [1]Copenhagen University Hospital in Glostrup, Copenhagen, Denmark, [2]Glostrup Hospital, Copenhagen, Denmark, [3]Sheba Medical Center, Tel Hashomer, Israel, [4]Copenhagen University Hospital in Gentofte, Copenhagen, Denmark, [5]Copenhagen University Hospital in Herlev, Copenhagen, Denmark, [6]Copenhagen University Hospital Glostrup, Glostrup, Denmark

Background/Purpose: Psoriatic arthritis (PsA) and spondyloarthritis (SpA) is associated with a varied pattern of axial and peripheral inflammation. Wholebody magnetic resonance imaging (WBMRI) is a new imaging modality where patients are scanned from head to toe in one single examination. The purpose was to explore the potential of WBMRI for detecting peripheral and axial inflammation.

Methods: Patients with clinically active peripheral PsA (Moll and Wright, n=19) or axial SpA (ESSG, n=19) and healthy subjects (HS, n=12) were included. T_1-weighted pre/post-contrast and STIR sequences were performed on a 3 tesla MRI unit. Synovitis and bone marrow oedema (BME) were evaluated at sites included in the 78-tender joint count (TJC). Axially, BME was evaluated dichotomously in each discovertebral unit (DVU) of the spine, and in each quadrant of the sacroiliac joints (SIJ).

Results: Characteristics median (range): PsA/SpA/HS age 49(23–79)/ 42(26–61)/32(20–61) yrs. PsA/SpA disease duration: 4 (0–34)/17 (5–48) yrs; 78-TJC: 11(3–65)/3(0–17), 76-swollen joint count (SJC): 5 (0–20)/ 1(0–5), and BASDAI score 45(9–85)/55(2–93) mm.

WBMRI assessment was done in 3800 joints included in the TJC, and

synovitis/BME were detected in 593 (16%)/207 (5%) joints, synovitis/BME was absent in 1929 (51%)/1860 (49%) joints, and 1278 (34%)/1733 (54%) joints were not possible to evaluate. Evaluation was most frequently possible in the hip joints (188 joints (94%)), knees (186 (93%)), and the spine (in overall 94% of DVUs). In contrast, no temperomandibular joints, and only 17 (8%) of elbows could be evaluated.

In PsA, synovitis was found most frequently in carpometacarpal (CMC) (19 joints (61%)) and shoulder (18 (53%)) joints. In SpA, synovitis was found most frequently in 1st metatarsophalangeal joints (21 (67%)), and shoulders (17 (50%)).

In patients, the best agreement between WBMRI synovitis and clinical swelling was found at the right hand proximal interphalangeal (PIP) (kappa: 0.65), left hand 3rd distal interphalangeal joint (0.63), and the right hand 3rd PIP joints (0.62). The best agreement between WBMRI synovitis and tenderness was found at left foot 2nd and 3rd PIP (0.78; 0.47), and right hand 2nd PIP (0.70) joints.

In PsA, we found a significant correlation between SJC-28 and BME assessed in 28 and 78 joints (Spearman's rho: 0.54, P<0.05; 0.69, P<0.005). WBMRI synovitis did not correlate significantly with clinical joint examination. Scores of BME assessed in 78 joints were significantly higher in PsA/SpA compared to HS (Mann-Whitney, P<0.05).

BME in the spine was detected in PsA/SpA in median 2 (0–6)/1 (0–11) DVU, respectively, and BME in the SIJ was detected in 0 (0–2)/0 (0–8) quadrants, respectively. Sum scores of BME detected in spine and SIJ were for PsA: 2 (0–7) and SpA: 4 (0–11), which were significantly higher than in HS (1 (0–4)) (P<0.05).

Conclusion: Wholebody MRI scores of axial and peripheral bone marrow oedema are significantly higher in clinically active PsA and SpA patients than in healthy subjects. In PsA, we found a significant correlation between number of joints with BME and SJC, whereas TJC did not correlate. WBMRI is a promising imaging modality, as it allows simultaneous visualisation of inflammation in peripheral and axial joints.

Frequency of MRI-Detected Hip Osteoarthritis Features in Persons with Chronic Hip Pain and the Diagnostic Performance of Radiography Using MRI As the Reference. Li Xu[1], Daichi Hayashi[1], Ali Guermazi[1], David J. Hunter[2], Anton Winterstein[3], Ling Li[4], Klaus Bohndorf[3] and Frank Roemer[3]. [1]Boston University School of Medicine, Boston, MA, [2]University of Sydney, Sydney, Australia, [3]Klinikum Augsburg, Augsburg, Germany, [4]New England Baptist Hospital, Boston, MA

Background/Purpose: Conventional radiography has been the standard imaging tool to diagnose and grade the severity of hip OA. However, radiography cannot visualize the bone marrow, cartilage and articular soft tissues that are relevant for clinical manifestation and structural progression of disease. The Hip Osteoarthritis MRI Scoring System (HOAMS) was recently developed to enable MRI-based whole-organ semiquantitative assessment of the hip. Frequency distribution of OA-associated features in the various anatomical subregions of the hip has not been described before. Further, the diagnostic performance of radiography to detect these abnormalities is unknown. Our aim was to describe the frequency of MRI-detected features of hip OA (cartilage damage, subchondral cysts, osteophytes and attrition) in various subregions of the hip joint and to evaluate the diagnostic performance of radiography for detection of these features using MRI as the reference.

Methods: 52 consecutive patients with chronic hip pain (mean age ±SD 63.5±9.5 years; 54% women) without inflammatory arthritis or recent trauma were imaged by 1.5T MRI. Of these, 44 subjects (85%) underwent weight-bearing antero-posterior pelvic radiography. For MRI assessment, the hip joint was subdivided into the following subregions (modified HOAMS system): latero-superior, centro-medial, anterior and posterior. According to HOAMS, cartilage was graded 0 to 4 based on extent (depth and area) of surface damage. Subchondral cysts and osteophytes were graded 0–3 and 0–4, respectively based on size. Bone attrition was noted as absent or present in the latero-superior subregion only. Presence of radiographic joint space narrowing (JSN) was compared to MRI-assessed cartilage damage. Sensitivity and specificity of radiography for diagnosing each feature (presence or

absence) were calculated using MRI as the reference standard, and the AUC was calculated from the ROC curve for each feature.

Results: 21 of 44 subjects had radiographic OA. Frequency of diffuse cartilage damage (for n=44) (HOAMS grade 3–4) in the latero-superior, centro-medial, anterior and posterior subregions was 58%, 58%, 35% and 33%, respectively. Frequency of subchondral cysts (grade≥1) and osteophytes (grade≥1) was 31% and 64% in the latero-superior, 12% and 77% in the centro-medial, 27% and 15% in the anterior, 8% and 35% in the posterior subregions, respectively. Frequency of bone attrition in the latero-superior subregion was 17%. Sensitivity, specificity and AUC of radiography to detect MRI assessed cartilage damage were 64%, 88% and 0.76 for JSN, 84%, 71% and 0.78 for osteophytes, 44%, 89% and 0.67 for subchondral cyst, and 78%, 86% and 0.82 for attrition.

Conclusion: In this cohort of subjects with hip pain diffuse cartilage damage and osteophytes were more frequent in the latero-superior and centro-medial subregions, while subchondral cysts were more frequent in the latero-superior and anterior subregions. Radiography offers acceptable diagnostic performance for attrition, diffuse cartilage damage (in the form of joint space narrowing) and osteophytes, but shows low sensitivity in detecting acetabular subchondral cysts a finding explained by the projectional drawbacks of radiography.

Semi-Quantitative Assessment of Bone Marrow Edema and Synovitis-Effusion in Osteoarthritis with the Knee Inflammation MRI Scoring System: A Target Lesion Based Methodology. Walter P. Maksymowych[1], Ulrich Weber[2], Marcus Pianta[3] and Robert GW Lambert[1]. [1]University of Alberta, Edmonton, AB, [2]Balgrist University Hospital, Zurich, Switzerland, [3]University of Alberta, AB

Background/Purpose: Current MRI scoring methods for assessment of bone marrow lesions (BML) in the knee of patients with osteoarthritis rely on a complex subdivision of the knee into 15 subregions and then a further estimation of the proportion of subregion with BML[1]. Scoring of synovitis-effusion (S-E) is based on a restricted grading scheme assessing the whole joint (0= none, 3 = large) which limits responsiveness. We aimed to develop and conduct preliminary validation of an MRI method for direct semi-quantitative assessment of BML and S-E, that focuses on detection of change (Knee Inflammation MRI Scoring System (KIMRISS)).

Methods: Assessment of BML is based on assessment of coronal and sagittal images for medial/lateral knee compartments and axial/sagittal images for patella-femoral compartment using a fluid-sensitive MRI sequence (STIR, T2 FatSat). Size of a BML lesion is defined according to the largest continuous increase in signal assessed in all dimensions and number of slices in which the increased signal can be detected (small = <1cm in all dimensions on 2 slices; moderate = >1cm but NOT >2 cm in ≥2 dimensions; large = >2cm in ≥ 2 dimensions). A weighting is applied to change in BML size (1.5× and 2× for moderate and large lesions, respectively). Size of S-E is assessed in each of 4 compartments (medial and lateral patellar recess, suprapatellar, semimembranosus bursa) according to a 0–4 grading scheme and a weighting is applied for change in S-E size (1.5× and 2× for grade 3 and 4 lesions, respectively). MRI scans were performed on the knee joints of 15 patients enrolled into an open label trial of an anti-TNF agent in subjects with persistent pain due to knee osteoarthritis and clinical evidence of effusion who had failed conventional therapy. Scans were performed at baseline and 12 weeks and independently reviewed by 3 readers blinded to timepoint. Reliability of change scores was assessed by intraclass correlation coefficient (ICC) and responsiveness by standardized response mean (SRM). We assessed correlations with WOMAC pain, patient global, and target joint clinical effusion score.

Results: Reliability of detection of change in KIMRISS BML (ICC for 3 reader pairs = 0.71. 0.73. 0.75), KIMRISS S-E (ICC for 3 reader pairs = 0.78, 0.82, 0.86), and Total KIMRISS (ICC for 3 reader pairs = 0.77, 0.81, 0.89) was very good with substantial responsiveness after 12 weeks of treatment (Table). Improvement in Total KIMRISS score was observed in 12 patients although change in either the Total KIMRISS or KIMRISS BML did not significantly correlate with change in WOMAC pain or patient global. KIMRISS S-E did not correlate with target joint effusion score.

	ICC (3 readers)	SRM
KIMRISS BML	0.73	0.82
KIMRISS Synovitis-Effusion	0.82	0.70
KIMRISS Total	0.81	0.88

Conclusion: The KIMRISS methodology for MRI-based semi-quantitative assessment of acute lesions in knee joints is responsive and is capable of reliably detecting change. It merits further validation in inflammatory knee joint disorders.

1029

Frequency of Mediopatellar Plica in Persons with Chronic Knee Pain and Its Cross-Sectional Association with Patellofemoral Cartilage Damage and Bone Marrow Lesions: Data From the Joints On Glucosamine Study.

Li Xu[1], Daichi Hayashi[1], Ali Guermazi[1], C. Kent Kwoh[2], Michael J. Hannon[3], Mohamed Jarraya[1], Carolyn E. Moore[4], John M. Jakicic[5], Stephanie M. Green[6] and Frank Roemer[7]. [1]Boston University School of Medicine, Boston, MA, [2]University of Pittsburgh and VA Healthcare System, Pittsburgh, PA, [3]University of Pittsburgh School of Medicine, Pittsburgh, PA, [4]Texas Women's University, Houston, TX, [5]University of Pittsburgh, PA, [6]University of Pittsburgh, Pittsburgh, PA, [7]Klinikum Augsburg, Augsburg, Germany

Background/Purpose: Osteoarthritis (OA) commonly occurs in the patellofemoral joint (PFJ) and knee pain in subjects with knee OA often emanates from the PFJ rather than the tibiofemoral joint (TFJ). Despite this, research into risk factors and mechanisms for PFJ OA is limited compared to that of the TFJ. Mediopatellar plica (MPP) is often observed in conjunction with patello-femoral structural damage and plica syndrome is a common cause of knee pain. However, it is unclear if MPP is an independent risk factor for structural PFJ damage or if MPP is an incidental finding of questionable relevance. Our aim was to describe the frequency of different types of MPP in a cohort of subjects with knee pain and to assess the cross-sectional association of MPP with cartilage damage and bone marrow lesions (BMLs) in the PFJ.

Methods: 177 subjects aged 35–65 with chronic, frequent knee pain were included. 3T MRI of both knees was performed and a total of 342 knees were included. MPP was scored as Types A, B, and C according to a grading system modified from the Sakakibara arthroscopic classification, which takes into account the relative size of the plica in relation to the osteochondral junction of the anterior medial trochlea. Using the Whole Organ Magnetic Resonance Imaging Score (WORMS) system, cartilage (graded 0 to 6) and BMLs (graded 0 to 3) were semiquantitatively assessed for the medial patella, medial trochlea, lateral patella, and lateral trochlea. In addition Hoffa-synovitis and effusion-synovitis were scored from 0 to 3. Anatomical measurements of the PFJ that are potential risk factors for cartilage loss included the patellar length ratio (PLR), lateral patellar tilt angle (LPTA), bisect offset (BO), and sulcus angle (SA) on MR images. The frequencies of each type of MPP were recorded. Further, presence of MPP (any type) and its cross-sectional association with cartilage damage (defined as WORMS score ≥ 2) and BMLs (defined as WORMS score ≥ 1) in the PFJ was assessed using logistic regression. Adjustment was made for age, gender, body mass index (BMI), PLR, LPTA, BO, SA, and Hoffa- and effusion-synovitis.

Results: The mean age of subjects was 52 (SD±6) years, 95 (53.7%) were men, 160 (90.4%) were white and 144 (81.4%) had a BMI ≥ 25. Altogether 163 (47.7%) knees exhibited MPP (76 knees (22.2%) were Type A, 69 knees (20.2%) were Type B, and 18 knees (5.3%) were Type C). Significant cross-sectional associations between MPP and cartilage damage were observed for the medial patella (adjusted odds ratio (aOR) 2.12, 95% CI 1.23–3.64), but not for the medial trochlea or the lateral PFJ. No associations were found for MPP and presence of BMLs in the medial and lateral patellofemoral compartments.

Conclusion: Type A and B plicae were common while type C plicae were less common. The presence of MPP is cross-sectionally associated with medial patellar cartilage damage. No increased risk was observed for presence of MPP and cartilage damage at the medial trochlea or the lateral compartment. No associations were found between MPP and BMLs in any of the PF subregions. The latter finding might be explained by different loading conditions in the PFJ in comparison to the TFJ.

1030

Frequency and Fluctuation of Susceptibility Artifacts in the Tibio-Femoral Joint Space in Painful Knees On 3T MRI and Association with Meniscal Tears, Radiographic Joint Space Narrowing and Calcifications.

Daichi Hayashi[1], Mohamed Jarraya[1], Ali Guermazi[1], C. Kent Kwoh[2], Michael J. Hannon[3], Carolyn E. Moore[4], John M. Jakicic[5], Stephanie M. Green[6] and Frank Roemer[7]. [1]Boston University School of Medicine, Boston, MA, [2]Univ of Pittsburgh, Pittsburgh, PA, [3]University of Pittsburgh School of Medicine, Pittsburgh, PA, [4]Texas Women's University, Houston, TX, [5]University of Pittsburgh, PA, [6]University of Pittsburgh, Pittsburgh, PA, [7]Klinikum Augsburg, Augsburg, Germany

Background/Purpose: Linear or punctate hypointensities are commonly seen on gradient echo (GRE) sequences in the tibiofemoral joint (TFJ) space of osteoarthritic joints. These magnetic susceptibility artifacts (SAs) are thought to represent vacuum phenomenon, a common radiologic finding in OA joints and vertebral disks. They appear adjacent to the cartilage or menisci and cartilage assessment may be impaired due to signal loss or be misinterpreted as a lesion. Aim was to assess the frequency of SAs in the TFJ space on dual-echo steady state (DESS, a GRE sequence very sensitive to magnetic susceptibility) and on intermediate-weighted (IW) fat-suppressed (fs) sequence, and assess associations with intraarticular calcifications and joint space narrowing (JSN) on X-ray (XR), and with MRI-detected meniscal damage in the TFJ.

Methods: 346 knees of 177 subjects aged 35–65 with knee pain were included. 3T MRI was performed at baseline and at 6-month follow-up (f/u). Baseline anteroposterior knee XR were read for JSN according to the OARSI atlas and linear/punctate calcifications within the TFJ were recorded as present or absent. The WORMS system was used to assess meniscal damage on MRI, and the presence of any damage (grade ≥ 1) was recorded at baseline. Linear/punctate hypointensities representing SAs in the TFJ space were assessed on coronal DESS and IW fs sequences. Readings were done blinded and in a random order. XR, DESS and IW images were each read on separate reading sessions >2 weeks apart. κ statistics were applied to assess concordance between findings on the baseline DESS and IW fs or XR.

Results: Subjects had a mean age of 52 (SD±6) years, BMI of 29±4, and 95 (54%) were men. Baseline Kellgren-Lawrence (KL) grades (for worst knee) were: KL 0– 37 (21%) knees; KL 1– 14 (8%) knees; KL 2– 26 (15%) knees; KL 3– 81 (46%) knees; KL 4– 19 (11%). On XR, 44 (13%) and 9 (3%) knees had medial and lateral JSN, respectively; and 7 (2%) and 14 (4%) knees had calcifications in the medial and lateral TFJ space, respectively. On MRI, 126 (36%) knees had medial and 31 (9%) knees had lateral meniscal damage. In the medial TFJ, 13 and 4 knees showed SAs at baseline on DESS and IW fs, respectively. On DESS, 6 of 13 knees had persistent SA at f/u and 6 knees had incident SA at f/u. In the lateral TFJ, 5 and 1 knees showed SAs at baseline on DESS and IW fs, respectively. On DESS, 2 of 5 knees had persistent SAs at f/u and 1 new SA was noted at f/u. In the medial TFJ, compared to knees without SAs on DESS, knees with SAs on DESS were more likely to have medial meniscal damage (9/13, 69% vs. 117/333, 35%, p=0.017) and medial JSN (5/13, 38%, vs. 39/333, 60%, p=0.016). Agreement on presence/absence of SAs between DESS and IW was κ=0.46 (95%CI 0.17–0.75) and that between SAs on DESS and calcifications on XR was κ=0.18 (-0.06 – 0.42) in the medial TFJ. We could not calculate p-values or κ in the lateral TFJ due to a very small number of SAs.

Conclusion: SAs on GRE sequence in the TFJ were seen in <5% of knees in this cohort. SAs are more frequently seen in knees with medial meniscal tears and medial JSN, which suggests an association with more advanced OA-related joint damage. SAs on MRI rarely correspond to XR-detected calcifications and commonly show longitudinal changes, which support the theory that these represent vacuum phenomenon.

High Degree of Symmetricity of MRI-Detected Articular Tissue Damage in Subjects with Knee Pain: A within-Person Analysis From the JOG Study. Frank Roemer[1], C. Kent Kwoh[2], Michael J. Hannon[3], Robert M. Boudreau[4], Stephanie M. Green[4], John M. Jakicic[5], Carolyn E. Moore[6] and Ali Guermazi[7]. [1]Klinikum Augsburg, Augsburg, Germany, [2]University of Pittsburgh and VA Healthcare System, Pittsburgh, PA, [3]University of Pittsburgh School of Medicine, Pittsburgh, PA, [4]University of Pittsburgh, Pittsburgh, PA, [5]University of Pittsburgh, PA, [6]Texas Women's University, Houston, TX, [7]Boston University School of Medicine, Boston, MA

Background/Purpose: Several risk factors for osteoarthritis (OA) have been described to be associated with an increased risk for incident radiographic OA, on a local (joint) or systemic (person) level. While radiography depicts articular changes only late in the disease process, magnetic resonance imaging (MRI) is capable of visualizing tissue pathology at a much earlier stage. Most MRI-based studies have used a one knee per person approach and thus data on bilaterality of OA features is sparse. Study aim was to describe symmetricity of MRI-detected OA features in a cohort with knee pain.

Methods: 169 subjects aged 35–65 with chronic, frequent knee pain were included in the Joint in Glucosamine (JOG) study. 3T MRI of both knees was performed using the same pulse sequence protocol as in the Osteoarthritis Initiative (OAI). Knees were semiquantitatively assessed according to the WORMS system by one expert MSK radiologist. Cartilage damage and bone marrow lesions (BMLs) were read in five plates (medial/lateral femur, medial lateral tibia, patella, femoral trochlea) while meniscal damage was read in three medial and three lateral subregions. Chi[2] tests were used to compare the proportion of people with unilateral tissue pathology to the proportion what would be expected if the two knees were independent. For this analysis, all MRI features were divided into present (score≥1) and absent (score=0). We further used linear weighted (w) kappa statistics to describe agreement between knees for cartilage damage and BMLs in the same articular plates using the full WORMS scores (0–4 for cartilage and 0–3 for BML).

Results: 52.1 % of participants were men, mean age was 51.2 (±6.2) years old, mean BMI was 29.0 (± 4.1). The worst Kellgren/Lawrence (KL) grades in either knee were: K/L 0: 37 (21.9%) knees, K/L 1: 14 (8.3%) knees, K/L 2: 26 (15.4%) knees, K/L 3: 78 (46.2%) knees K/L 4: 14 (8.3). All plates showed a significant lower degree of unilaterality for any cartilage damage (ranging between 15.5% and 32.0%) than expected (ranging between 27.1% and 50.2%). For any BMLs the degree of unilaterality was lower for the patella, trochlea, medial tibia, and medial femur; for any meniscal damage the degree of unilaterality was lower for all medial meniscal subregions but not lateral. All plates showed higher overall % agreement (range 82.6–94.7%) than expected (range 73.0–93.1%) for cartilage damage and BMLs. Moderate agreement (defined as w-kappa 0.4–0.6) was observed for patellar and trochlear cartilage damage (0.59 and 0.54) and patellar (0.41) BMLs.

Table 1. Expected and exact overall % agreement and w kappa for different articular plates

Plate (Worst grade in plate)	Exact % agreement	Expected % agreement	Weighted kappa	Standard Error
Cartilage				
Patella	88.99%	73.00%	0.59	0.054
Femoral Trochlea	91.12%	80.73%	0.54	0.058
Medial Femur	86.09%	79.55%	0.32	0.055
Lateral Femur	89.94%	85.28%	0.32	0.069
Medial tibia	86.39%	79.27%	0.34	0.057
Lateral Tibia	90.53%	85.25%	0.36	0.059
BMLs				
Patella	82.64%	70.64%	0.41	0.058
Femoral Trochlea	83.63%	75.11%	0.34	0.059
Medial Femur	86.39%	81.54%	0.27	0.060
Lateral Femur	94.67%	93.08%	0.23	0.060
Medial tibia	87.50%	83.55%	0.24	0.061
Lateral Tibia	90.53%	89.80%	0.07	0.061

Table 2. Expected and exact overall % agreement and kappa for different articular subregions in descending order by kappa

Subregions ranked by descending order of w kappa value (4 highest shown)	Exact % agreement	Expected % agreement	Non-weighted kappa	Standard Error
Cartilage				
1. Lateral patella	84.52%	51.70%	0.68	0.077
2. Lateral fem. ant.	84.02%	61.63%	0.58	0.076
3. Medial tib. central	82.25%	62.05%	0.53	0.077
4. Medial patella	77.38%	52.56%	0.52	0.077
BMLs				
1. Lat. femur post.	96.45%	92.05%	0.55	0.076
2. Lateral patella	74.56%	58.99%	0.38	0.077
3. Medial fem central	79.29%	70.21%	0.30	0.075
4. Lateral fem. ant.	78.11%	68.89%	0.30	0.077

Conclusion: A higher degree of symmetricity of articular tissue damage than expected by chance was observed in this cohort of subjects with knee pain. These findings support the hypothesis that OA is a multifactorial disease triggered by risk factors on an individual joint level but also by person-based risk factors that predispose joints not only to radiographic OA but also to articular tissue damage commonly associated with OA.

Medial Meniscal Root Tears and the Association with Meniscal Extrusion, Prevalent Cartilage Damage and Longitudinal Cartilage Loss: The MOST Study. Mohamed Jarraya[1], David T. Feslon[1], Daichi Hayashi[1], Frank Roemer[2], Yuqing Zhang[1], Jingbo Niu[1], Michel Crema[1], Martin Englund[3], John A. Lynch[4], Michael C. Nevitt[5], James Torner[6], C.E. Lewis[7] and Ali Guermazi[1]. [1]Boston University, Boston, MA, [2]Klinikum Augsburg, Augsburg, Germany, [3]Lund University, Lund, Sweden, [4]University of California at San Francisco, San Francisco, CA, [5]University of California-San Francisco, San Francisco, CA, [6]University of Iowa, Iowa City, IA, [7]University of Alabama at Birmingham, Birmingham City, AL

Background/Purpose: The meniscal root is a ligamentous structure that anchors the posterior horn of the meniscus to the tibial plateau. The association of isolated meniscal root tears with progression of osteoarthritis or cartilage loss has not been examined. Aim of the study was to assess the cross-sectional association of medial meniscal root tears with prevalent medial tibiofemoral cartilage damage and medial meniscal extrusion in subjects with radiographic osteoarthritis. We further wished to assess if isolated medial meniscal root tears increase the risk of incident and progressive cartilage damage in the medial tibiofemoral compartment at 30-month follow up.

Methods: The Multicenter Osteoarthritis (MOST) Study is a longitudinal observational study of subjects with or at risk for knee osteoarthritis. Knees were randomly selected from subjects with radiographic OA at baseline and read for presence of absence of root tear ($\kappa=1$ for intrareader agreement). Cartilage damage was graded from 0 to 6 in each of the 5 medial tibiofemoral subregions according to WORMS scoring system. Prevalent cartilage damage was defined as any score ≥2 in at least one subregion. Longitudinal progression of cartilage damage was studied for 548 patients who had follow up MRIs read, and was defined as at least within grade or more increase in at least one subregion including incident cartilage damage. Meniscal extrusion was recorded as present or absent. Isolated meniscal root tear was defined as the presence of a root tear without any additional meniscal damage (WORMS1–4). Knees were divided into 3 groups: knees with an isolated medial meniscal root tear (i.e., exposed group), those without root tears but with other meniscal damage (i.e., referent group A); and knees without root tear or meniscal damage (i.e., referent group B). In the longitudinal analysis, we calculated relative risk (RR) of cartilage worsening comparing the exposed group and the group A with the group B.

Results: Of 594 knees included in the cross-sectional analysis (64.1% women, mean age 62.8 +/− 7.9, mean BMI 30.9 +/−5.2), 37 knees were in the exposed group, 293 in referent group A and 264 in referent group B. Exposed knees showed higher prevalence of meniscal extrusion than referent group B (91.9% vs. 60.7%, p<0.0001). Prevalence of cartilage damage was

also higher in the exposed group than in group B (97.3% vs 63.7%, p<0.0001) but not group A (97.3% vs 95.2%, p=0.057). Of 548 knees included in the longitudinal analysis, 33 knees were in the exposed group, 270 in group A, and 245 in group B. The adjusted RRs of cartilage loss in the exposed group and the group A were 2.04 (95%CI 1.19 – 3.49) and 1.84 (95% CI 1.32 - 2.58), respectively, when compared with group B.

Conclusion: Knees with isolated medial meniscal root tears exhibit a higher prevalence of ipsicompartimental extrusion when compared to knees without meniscal damage. Isolated meniscal root tears increase the risk of ipsicompartmental cartilage loss longitudinally.

Reliability and Responsiveness of Two Methods for Assessment of Magnetic Resonance Imaging Abnormalities in Hip Osteoarthritis in a Placebo-Controlled Trial of Intra-Articular Steroid Injection. Walter P. Maksymowych[1], Jolanda Cibere[2], Ulrich Weber[3], Jacob Jaremko[1], Damien Loeuille[4], Veronika Zubler[3], Frank Roemer[5], Eric C. Sayre[6] and Robert GW Lambert[1]. [1]University of Alberta, Edmonton, AB, [2]Arthritis Research Ctr of CA, Vancouver, BC, [3]Balgrist University Hospital, Zurich, Switzerland, [4]CHU Brabois, Vandoeuvre les Nancy, France, [5]Klinikum Augsburg, Augsburg, Germany, [6]Arthritis Research Centre of Canada, Vancouver, BC

Background/Purpose: Inflammation in osteoarthritis (OA) is the basis for the use of steroid injection therapy which has demonstrated efficacy for symptoms of hip OA in a randomized placebo-controlled trial[1]. Both synovitis and bone marrow lesions (BML) have been associated with pain in OA and can be detected on MRI. Two scoring methods have been developed which assess synovitis-effusion but score BML using different approaches: 1) the Hip Inflammation MRI Scoring System (HIMRISS) assesses BML using consecutive images in the coronal plane and a dichotomous (yes/no) scoring method; 2) the Hip Osteoarthritis MRI Scoring System (HOAMS) is a whole joint scoring system which assesses BML according to volume of region affected on both coronal and sagittal scans. We aimed to determine the reliability and responsiveness of both methods for detecting change in these MRI lesions and associations with clinical changes in patients receiving steroid injection therapy.

Methods: Six readers (3 radiologists, 3 rheumatologists) assessed MRI scans of hip joints from 18 patients enrolled into a randomized double-blinded placebo-controlled trial of intra-articular steroid treatment for hip OA. Scans were performed at baseline and the primary endpoint at 8 weeks. Coronal STIR sequences of the hip joints were evaluated. For HIMRISS, the sum of femoral BML scores (0–65), acetabular BML scores (0–35), effusion score (0–30) and total score was calculated based on femoral and acetabular subregion readings. In HOAMS, BML (0–3) and synovitis (0–2), were assessed in femoral and acetabular subregions and summed scores for all subregions were calculated for BML (0–45) and synovitis (0–8). Reliability of change scores was assessed using intra-class correlation coefficient (ICC), responsiveness by standardized response mean (SRM) and Guyatt's effect size (ES). We assessed associations with WOMAC pain subscale in the same patients and a second cohort of 27 patients with early OA by regression analysis.

Results: Inter-observer reliability of change scores was very good to excellent for femoral BML, and good to very good for synovitis-effusion and acetabular BML despite limited training. Reliability was comparable between radiologists and rheumatologists. Responsiveness and discrimination was moderate to high for synovitis-effusion. Significant associations were noted between BML or synovitis scores and pain scores for baseline values (p ≤ 0.001 in combined N=45) but not change values (N=18). The association with pain was particularly evident in patients with early OA (N=27) with the HIMRISS synovitis-effusion (p = 0.001) and HOAMS synovitis (p = 0.005) scores.

	ICC (change)	ICC (Rheumatologist)	ICC (Radiologist)	SRM	Guyatt's ES
Total HIMRISS	0.77	0.76	0.82	0.16	0.33
Femoral BML HIMRISS	0.81	0.80	0.82	0.03	0.08
Acetabular BML HIMRISS	0.49	0.52	0.54	0.14	0.19
Synovitis-effusion HIMRISS	0.35	0.48	0.36	0.55	0.69
HOAMS BML	0.71	0.73	0.71	0.18	0.29
HOAMS Synovitis	0.58	0.58	0.69	0.44	0.95

Conclusion: Change in BML and synovitis on MRI is reliably detected using both HOAMS and HIMRISS but only synovitis scores are responsive to treatment. Association with pain is primarily evident in early OA and with scores for synovitis-effusion.

Changing Osteoarthritis Treatment Assessment Paradigms: Subchondral Bone Is a More Responsive Measure of Progression Than the Current Radiographic Standard. Michael A. Bowes[1], Christopher B. Wolstenholme[1], Devan Hopkinson[1], Graham R. Vincent[1] and Philip G. Conaghan[2]. [1]Imorphics Ltd, Manchester, United Kingdom, [2]University of Leeds, Leeds, United Kingdom

Background/Purpose: Radiographic joint space width (JSW) assessment, a surrogate for cartilage assessment, is the standard for structure modification trials of osteoarthritis (OA). However the subchondral bone is integral to OA progression and modern image analysis techniques allow accurate, automated identification of bone in MR images. The objective of this study was a comparison of the sensitivity of 3D bone area measures in MR images with minimum medial JSW in radiographs in all subjects in the Osteoarthritis Initiative dataset with definite medial OA over a 2 year period, representative of a typical OA clinical trial.

Methods: 828 subjects with medial OA and MR images at baseline, 12 and 24 months, and available radiograph scoring were selected from the Osteoarthritis Initiative dataset; medial OA was defined as KL≥2 and presence of medial osteophytes. Femur, tibia and patella bones were automatically segmented from MRIs using active appearance models[1]. Anatomical areas were automatically identified within the model[2] and were measured at each time-point. All regions of the articulating surface of the femur, tibia and patella were included in the analysis. Minimum medial joint space width (minMJSW) was provided by the OAI, using a semi-automated software method[3]. Sensitivity of both methods to change was assessed using the standardised response mean (mean/SD of change).

Results: Mean age (SD) of the case group was 62 years (8.8); BMI 29.7(4.8); KL 2.55(0.65); 35% females. MinMJSW showed significant change at 12 and 24 months with SRM values of −0.16 and −0.33. Change in bone area was significant in all regions for all time-points, except the lateral femur at 12 months (see Figure 1). Medial femur compartments provided the greatest sensitivity to change, with SRM values typically twice those of minMJSW. Tibial compartments and the notch of the femur also showed higher SRM figures than minMJSW, while patellar compartments had comparable SRMs to the radiographic measure. Only the lateral femoral compartments had lower SRMs than the minMJSW method.

Figure 1. Sensitivity of bone area to change, compared with minMJSW measures on 828 subjects.

	Mean Change		SRM	
	Year 1	Year 2	Year 1	Year 2
Minimum median JSW	−0.1 (0.04)	−0.23 (0.05)	−0.16	−0.33
MF	0.52 (0.09)	1 (0.12)	0.39	0.57
TrFMed	0.55 (0.1)	1.1 (0.12)	0.39	0.63
LF	0.1 (0.12)*	0.17 (0.16)	0.05	0.07
TrFLat	0.1 (0.09)	0.35 (0.1)	0.07	0.23
Notch	0.44 (0.1)	0.73 (0.11)	0.31	0.45
MT	0.45 (0.1)	0.87 (0.12)	0.31	0.48
LT	0.34 (0.1)	0.69 (0.12)	0.23	0.38
MP	0.34 (0.16)	0.91 (0.2)	0.15	0.31
LP	0.33 (0.16)	0.95 (0.19)	0.14	0.34

JSW values are in mm, bone area change in % change in bone area from baseline (95% confidence limits). All changes were highly significant except* which was not significant

Conclusion: Change in bone area was more sensitive than the minMJSW method in a number of knee compartments, particularly in the medial femur

and tibia. Measurement of bone change provided a more responsive tool for monitoring OA progression in a cohort selected for typical OA trial characteristics.

Characterisation of New Bone Formation in Gout: A Quantitative Site-by-Site Analysis Using Plain Radiography and Computed Tomography. Nicola Dalbeth[1], Aaron Milligan[2], Barnaby Clark[2], Fiona M. McQueen[1] and Anthony Doyle[1]. [1]University of Auckland, Auckland, New Zealand, [2]Department of Radiology, Auckland District Health Board, Auckland, New Zealand

Background/Purpose: Radiographic descriptions of gout have noted the tendency to hypertrophic bone changes. The aim of this study was to characterise the features of new bone formation (NBF) in gout, and to determine the relationship between NBF and other radiographic features of disease, particularly erosion and tophus.

Methods: Paired plain radiographs (XR) and computed tomography (CT) scans of 798 individual hand and wrist joints from 20 patients with gout were analyzed. Following a structured review of a separate set of images, films were scored for the presence of the following features of NBF: spur, osteophyte, periosteal NBF, ankylosis and sclerosis (Figure). Sites for NBF scoring were those included in the gout-modified Sharp-van der Heijde method for erosion scoring. The relationship between NBF and other imaging features of gout (erosion and tophus) was analysed.
Figure. Examples of the features of new bone formation (NBF) observed by plain radiography and computed tomography in patients with gout. A. Spur. B. Osteophyte. C. Periosteal NBF. D. Ankylosis. E. Sclerosis. Top panel shows plain radiographic images and lower panel shows CT images.

Results: The most frequent forms of NBF were bone sclerosis (28.6% of all assessed joints using CT) and osteophyte (30.5%). Spur and periosteal NBF were less common (17.8% and 6.0% respectively), and ankylosis was rare (0.6%). On both XR and CT, joints with bone erosion were more likely to have NBF; for XR, odds ratios (OR) 64.9 for spur, 64.9 for osteophyte, 119.8 for periosteal NBF, 30.1 for ankylosis and 101.1 for sclerosis (p for all <0.0001); and for CT, OR 45.1 for spur, 3.3 for osteophyte, 16.6 for periosteal NBF, 26.6 for ankylosis and 32.3 for sclerosis (p for all <0.01). Similarly, on CT, joints with intraosseous tophus were more likely to have NBF; OR 48.4 for spur, 3.3 for osteophyte, 14.5 for periosteal NBF, 35.1 for ankylosis and 39.1 for sclerosis (p for all <0.001).

Conclusion: This detailed quantitative analysis has demonstrated that NBF occurs more frequently in joints affected by other features of gout. This work suggests a connection between bone loss, tophus, and formation of new bone during the process of joint remodelling in gout.

The Prevalence of Chondrocalcinosis of the Acromioclavicular Joint On Chest Radiographs and correlation with Calcium Pyrophosphate Dihydrate Crystal Deposition Disease. Konstantinos M. Parperis, Guillermo F. Carrera, Keith E. Baynes, Alan P. Mautz, Melissa S. DuBois, Ross M. Cerniglia and Lawrence M. Ryan. Medical College of Wisconsin, Milwaukee, WI

Background/Purpose: Digital imaging combined with picture archiving and communication system (PACS) access allows detailed image retrieval and magnification. Calcium pyrophosphate dihydrate (CPPD) crystals preferentially deposit in fibrocartilages, the cartilage of the acromioclavicular (AC) joint being one such structure. We sought to determine if careful examination of the AC joints on magnified PACS imaging of routine chest films would be useful in identifying chondrocalcinosis (CC).

Methods: Retrospective radiographic readings and chart reviews involving all 1920 patients aged 50 or more who had routine outpatient chest radiographs over a 4 month period were performed. CC was identified as linear or punctate cartilage calcifications. Knee radiographs were available for comparison in 489 patients. Medical records were reviewed to abstract demographics, chest film reports, and diagnoses.

Results: AC joint CC was identified in 1.1% (21/1920) of consecutive chest films. Patients with AC joint CC were 75 ($\pm$ 11.6 S.D.) years of age versus 65 ($\pm$10.5 S.D.) in those without CC (p<0.0002, Wilcoxon rank sum). There was no significant gender difference in the prevalence of AC CC. 489 patients had knee films. 6 of these patients had AC joint CC and of these 5 also had knee CC (83%). Of the 483 without AC joint CC 62 (12%) had knee CC (p=0.002 Fischer's exact). Of the patients with AC joint CC only 14% had a diagnosis of CPPD recorded on the chart and none had AC joint calcification noted on the official radiology report. Patients with AC joint CC were more likely to have a recorded history of CPPD crystal disease than those without AC joint CC (14% versus 1%, p=0.0017 Fischer's exact).

Conclusion: By using digital imaging and PACS software magnification, AC joint CC is discernible on routine chest films. The prevalence of AC joint CC increases with age and is usually an indicator of associated knee CC. AC joint CC is most often overlooked by radiologists reading routine chest images. Rheumatologists (and radiologists) should consider scrutiny of available chest films for AC joint CC. A finding of AC joint CC should heighten suspicion of pseudogout or secondary osteoarthritis in appropriate clinical settings. And AC joint CC in a young patient should alert the clinician to the possibility of an associated metabolic condition. Moreover, such scrutiny is without cost other than less than a minute of time.

Magnetic Resonance Imaging (MRI) Assessment of Inflammatory Myopathy: Quantitative Fat-Corrected Muscle T2 and Conventional T2 Measurement Versus Standard MRI and Clinical Metrics. Lawrence Yao[1], Adrienne L. Yip[2], Sepehr Mesdaghinia[3], Ashkan Shademan[3], Joseph A. Shrader[1], Anna V. Jansen[2], Frederick W. Miller[2] and Lisa G. Rider[2]. [1]Clinical Center, NIH, Bethesda, MD, [2]NIEHS, NIH, Bethesda, MD, [3]NIEHS, NIH, Bethesda

Background/Purpose: Active muscle disease in patients with idiopathic inflammatory myopathies (IIM) is characterized by prolonged muscle T2 relaxation on MRI. We examined the utility of MR T2 maps, and a method of correcting these maps for varying fat content, as quantitative, semi-automated alternatives to conventional MRI in the evaluation of IIM. MRI measures were also validated against other myositis metrics.

Methods: Forty-four IIM patients (8 dermatomyositis [DM], 13 polymyositis [PM], 22 juvenile DM, 1 juvenile PM) underwent MRI of the thighs at 1.5 Tesla and extensive clinical testing, including assessment of Physician Global Activity (PGA), muscle strength by isometric dynamometry (QMT), functional assessment by Childhood Myositis Assessment Scale (CMAS) and Childhood Health Assessment Questionnaire (CHAQ), and the Myositis Damage Index (MDI). Follow-up imaging was also performed 11 months later in 20 patients after therapy. MRI included a Carr-Purcell-Meiboom-Gill sequence and a Dixon-based

fat water separation sequence, for generation of T2, fat fraction (FF), and fat-corrected T2 (fc-T2) maps, and Short Tau Inversion Recovery (STIR) and T1 spin echo (SE) sequences for standard visual assessment. Muscle edema and damage were visually scored on STIR and T1 SE images, respectively, using a semi-quantitative rating system that incorporates anatomic extent and severity of findings. T2, fc-T2, and fat fraction (FF) values were tabulated for the thigh muscles of each patient with an automated segmentation algorithm.

Results: STIR scores correlated significantly with mean T2 and mean fc-T2 values (Spearman $r_s = 0.65$ and 0.61, $p< 0.001$), while T1 damage scores correlated with mean FF ($r_s = 0.67$, $p< 0.001$). Baseline mean T2, mean fc-T2, and visual STIR scores correlated significantly with the CMAS ($r_s = -0.50$, -0.36, -0.55, respectively, $p<0.05$) and CHAQ ($r_s = 0.46$, 0.35, 0.43 respectively, $p< 0.05$), and with QMT ($r_s = -0.49$, -0.52, -0.48, respectively, $p<0.05$). MDI muscle damage scores correlated significantly with visual T1 damage scores ($r_s = 0.72$, $p<0.001$) and mean FF measurements ($r_s = 0.67$, $p<0.001$). For 20 patients evaluated after a change in therapy, standardized response means for visual STIR, mean fc-T2, and mean T2 scores were -0.52, -0.31, -0.12, respectively. The change in PGA assessment correlated with changes in STIR ($r_s = 0.74$, $p<0.01$) and mean fc-T2 scores ($r_s = 0.46$, $p<0.05$). However, changes in STIR scores and mean fc-T2 values were discordant with outcomes, based on 20% improvement in PGA, in 5 and 6 of 20 patients, respectively.

Conclusion: Semi-automated survey of quantitative thigh muscle T2, FF, and fc-T2 MRI maps have good content validity with visual scoring of clinical MRI. These quantitative MRI measures have good construct validity with other measures of myositis disease activity and damage, particularly muscle measures. While fc-T2 appears to be more responsive than conventional T2, fc-T2 and T2 are less responsive than visual STIR scores. Additionally, both visual and quantitative MR analysis of thigh muscles exhibited limited agreement with global disease improvement after therapy, as reflected by the PGA assessment.

Assessment of Aortic Stiffness by Cardiac Magnetic Resonance Imaging in Systemic Autoimmune Rheumatic Diseases. Galia Karp[1], Arik Wolak[2], Nina Baram[3], Victor Novack[4], Philip Rosen[3], Yael Perl[5], Talia Wolak[6], Ilan Shelef[3] and Mahmoud Abu-Shakra[7]. [1]Department of Medicine, Soroka Medical Centre and Ben Gurion University, Beer-Sheva, Israel, [2]Dept. of Cardiology, Cardiac MRI unit, Soroka University Medical Center, and Ben Gurion University, Beer-Sheva, Israel, [3]Radiology division, Soroka University Medical Center and Ben Gurion University, [4]Department of Medicine, Clinical Research center, Soroka University Medical Center and Ben Gurion University, [5]Clinical Research center, Soroka University Medical Center and Ben Gurion University, [6]Department of Medicine and Hypertension unit, Soroka University Medical Center and Ben-Gurion University, [7]Department of Medicine and Rheumatology, Soroka Medical Centre and Ben Gurion University, Beer-Sheva, Israel

Background/Purpose: Systemic Lupus Erythematosus (SLE) and rheumatoid arthritis (RA) are known to cause premature arterial aging and early atherosclerosis hence leading to increased stiffness of the large arteries. Recently, Cardiac MRI (CMRI) was introduced as a new technique for assessment of aortic stiffness by measuring the Pulse Wave Velocity (PWV). Therefore, we aimed to assess aortic stiffness by CMRI in RA and SLE patients.

Methods: We prospectively recruited 25 RA female patients, 26 SLE female patients and adjusted controls that matched each patient for age, comorbidities (hypertension, diabetes mellitus, dyslipidemia) and smoking status. Clinical and laboratory data were gathered. CMRI was performed using a 1.5T scanner and included phase contrast images of the ascending and descending aorta. Dedicated cardiovascular analysis software was used to measure the flow at the level of the ascending and the descending aorta. The distance between these 2 levels was obtained and PWV was calculated accordingly

Results: The mean age of RA patients and their healthy control group was 51.83 ± 15.14 and 51.33 ± 14.47 respectively. Systolic Blood pressure was higher amongst RA patients, 132.61 ± 15.16 mmHg versus 121.72 ± 20.55 mmHg for controls ($p=0.02$). PWV was higher among the RA group;

9.11 ± 3.96 for RA and 7.79 ± 2.98 for the control group ($p=0.13$). SLE patients were younger than RA patients, averaging 41.31 ± 13.51. SLE patients were heavier and had larger waist circumference than their controls. Their Framingham score was slightly lower than their paired controls. PWV was higher than their paired controls, 6.67 ± 2.39 vs. 6.03 ± 2.23 ($p=0.02$), thus reaching statistical significance. We further found positive correlation between SLE disease activity and PWV ($p=0.02$). This correlation was not found among RA patients.

Conclusion: PWV is higher amongst SLE patients, as opposed to healthy controls ($p=0.02$). In addition PWV is positively correlated with SLE disease activity ($p=0.02$). Amongst RA patients, PWV was higher as opposed to paired controls, but this failed to achieve statistical significance. Our data raise the hypothesis that amongst SLE patients, who are known to have significantly higher levels of atherosclerosis, PWV may serve a marker for cardiovascular morbidity.

Cardiac Involvement in Systemic Sclerosis: The Added Value of Magnetic Resonance Imaging. Luna Gargani[1], Alessandro Pingitore[2], Daniele De Marchi[2], Serena Guiducci[3], Giancarlo Todiere[2], Silvia Bellando Randone[3], Cosimo Bruni[3], Marica Doveri[4], Laura Bazzichi[4], Stefano Bombardieri[4], Massimo Lombardi[2], Eugenio Picano[1] and Marco Matucci Cerinic[3]. [1]Institute of Clinical Physiology, National Research Council, Pisa, Italy, [2]Gabriele Monasterio Foundation, CNR-Regione Toscana, Pisa, Italy, [3]Department of Biomedicine, Division of Rheumatology AOUC, Excellence Centre for Research, Florence, Italy, [4]Rheumatology Unit, University of Pisa, Pisa, Italy

Background/Purpose: Cardiac involvement in systemic sclerosis (SSc) affects the prognosis of the disease. Myocardial fibrosis is the pathological hallmark of this complication and has been reported in 50-80% of cases in necropsy. Echocardiography is the routine imaging tool to easily detect cardiac involvement, but it is not accurate to detect myocardial fibrosis. Delayed gadolinium enhancement (DE) cardiovascular magnetic resonance (CMR) is the gold-standard for myocardial fibrosis assessment. The aim of the present study was to evaluate the added value of DE-CMR to echocolorDoppler in SSc patients.

Methods: After a thorough clinical characterization, 171 SSc patients (age=52 ± 14, 91% females, 22% diffuse form) underwent, on the same day, a comprehensive echocardiogram, including tissue Doppler imaging (TDI), and a DE-CMR.

Results: Echocardiography showed normal systolic function (ejection fraction>50%) and wall motion score index (=1) in 100% of patients, whereas DE-CMR showed a pattern of non-ischaemic myocardial fibrosis in 12/53 (23%) patients. In 2/53 patients (4%), T2-weighted CMR showed myocardial oedema, that resolved after steroid therapy. No clinical parameter (age, duration of disease, limited or cutaneous form, Scl-70 positivity, Rodnan skin score, activity score) was an independent predictor of the presence of myocardial fibrosis.

Conclusion: Subclinical cardiac involvement is relatively frequent in SSc and is not necessarily related to duration of disease or other clinical characteristics. CMR can detect different patterns of reversible (by T2-weighted) and irreversible (by DE) cardiac involvement (see figure), not detectable by echocardiography.

Normal   Myocardial fibrosis   Myocardial oedema

irreversible   reversible

Combined High-Resolution Single Photon Emission Computed Tomography and Magnetic Resonance Imaging for Therapy Monitoring in Rheumatoid Arthritis. Philipp Sewerin[1], Christian Buchbender[1], Katalin Mattes-György[1], Falk Miese[1], Hans-Jörg Wittsack[1], Christof Specker[2], Gerald Antoch[1], Matthias Schneider[3], Axel Scherer[1] and Ben Ostendorf[1]. [1]Heinrich-Heine-University, Düsseldorf, Germany, [2]Hospital Essen Sued, Essem, Germany, [3]Heinrich-Heine-University, Duesseldorf, Germany

Background/Purpose: To evaluate whether combined multi-pinhole single photon emission computed tomography (MPH-SPECT) with technetium-99m-labelled disphosphonates (Tc99m-DPD) and magnetic resonance imaging (MRI) detect changes in inflammation in early rheumatoid arthritis (ERA) patients under methotrexat (MTX) therapy and to investigate the relation between Tc99m-DPD uptake and the development of erosion.

Methods: MPH-SPECT and MRI of metacarpophalangeal joints (MCP) have been prospectively performed in 10 consecutive ERA patients (8 female, 2 male; 49 ± 13 years [mean $\pm$ SD]), range: 24–68) prior to and 6 months after initiation of MTX. The Tc99m-DPD uptake was measured using a region of analysis. The course of synovitis, bone marrow edema (BME) and erosions were scored according to the Rheumatoid Arthritis MRI Score (RAMRIS) criteria.

Results: The frequency of increased Tc99m-DPD uptake, synovitis and BME decreased under MTX therapy; but the number of bone erosions increased. Joints with progressive and newly developed erosions on follow-up had a higher baseline Tc99m-DPD uptake (2.64 ± 1.23 vs. 1.43 ± 0.91) ($p < 0.001$). Joints with persistent synovitis did not show higher Tc99m-DPD uptake values (1.56 ± 1.27 vs. 1.47 ± 0.75) ($p=0.74$). There was no correlation between persistence of synovitis and the development of erosions ($Fc= 0.3$, $p= 0.12$).

Conclusion: Persistence of synovitis seems to be independent from Tc99m-DPD uptake and the development of erosions, while early increased bone metabolism is found in MCP joints which show erosive progression under MTX therapy. Hybrid MPH-SPECT and MRI might thus provide valuable additional information for individual risk-stratified therapeutic decisions.

Whole-Body Magnetic Resonance Imaging - A New Diagnostic Tool in the Assessment of Activity in Juvenile Dermatomyositis Patients? Tania Monteiro de Castro[1], Henrique Lederman[1], Maria Teresa Terreri[1], Wanda I. Caldana[1], Edmar Zanoteli[2] and Maria Odete Hilario[1]. [1]Federal University of São Paulo, São Paulo, Brazil, [2]University of São Paulo, São Paulo, Brazil

Background/Purpose: Juvenile dermatomyositis (JDM) is a rare autoimmune disorder, but remains the most commonly chronic inflammatory myopathy among children. A redefinition of the diagnostic criteria is currently underway and is likely to lead to non-invasive exams such as magnetic resonance (MR) imaging, in place of electromyography and muscle biopsy in the diagnosis of the disease. Our goal was to demonstrate the benefit of whole-body MR imaging as a diagnostic tool in the detection of muscle inflammatory activity in JDM and to correlate these findings with clinical evaluation including muscle strength, laboratorial exams, nailfold capillaroscopy and muscle biopsy.

Methods: Thirty-three patients aged 6–19 years (median age, 12.1 years), 22 girls with a diagnose of JDM according to Bohan & Peter criteria were evaluated at any point during their illness course using clinical examination, muscle enzymes determination, muscle strength tests such as Childhood Myositis Assessment Scale (CMAS) and Manual Muscle Testing (MMT), nailfold capillaroscopy and short tau inversion recovery (STIR) whole-body MR imaging. JDM activity was evaluated by Disease Activity Score (DAS). An open muscle biopsy was performed in deltoids or biceps braquialis if muscle disease activity was detected on MR exam.

Results: Whole-body scanning gave a complete assessment of all muscles groups and disease activity was detected in STIR MR imaging in four (12.1%) patients confirmed by muscle biopsy. All four patients had elevation of at least one muscle enzyme and the nailfold capillaroscopy showed scleroderma (SD) pattern in these patients. CMAS, MMT and DAS means were 25.7, 32.3 and 9 respectively in patients with altered MR, and 48.1, 77 and 2.35 respectively in patients whose MR were normal. Twenty-nine patients had inactive disease (24 with medication and five without medication). Nailfold capillaroscopy was normal in 16 patients and with SD pattern in nine patients (not done in four patients). Muscle strength tests (CMAS and MMT) were normal in 16 out of 29 patients (MMT not done in four patients).

Conclusion: Whole-body MR allows us to evaluate the extent and symmetry of muscle disease and inflammatory activity in a single exam by revealing muscles groups not seen with standard protocols. Nailfold capillaroscopy is an important additional exam to assess disease activity. Muscle strength tests are important to evaluate not only the disease in the acute phase, but the accumulated effect over the same time.

Psoriatic Arthritis Patients Assessed by Dynamic Contrast-Enhanced MRI in High Disease Versus Minimal Disease Activity State - a Cross-Sectional Study Correlating Conventional MRI and Clinical Composite Measures. René Panduro Poggenborg[1], Pernille Bøyesen[2], Charlotte Wiell[3], Susanne Juhl Pedersen[4], Inge Juul Sørensen[5], Ole Rintek Madsen[6], Ole Slot[1], Jakob M. Møller[7], Mikael Boesen[8], Henning Bliddal[9], Olga Kubassova[10] and Mikkel Østergaard[11]. [1]Copenhagen University Hospital in Glostrup, Copenhagen, Denmark, [2]Diakonhjemmet Hospital, Olso, Norway, [3]Copenhagen University Hospital in Gentofte, Copenhagen, Denmark, [4]Copenhagen University Hospital Glostrup, Copenhagen, Denmark, [5]Glostrup Hospital, Copenhagen, Denmark, [6]DANBIO, On behalf of Depts of Rheumatology, North, South, Central, Zealand and Capital Region, Copenhagen, Denmark, [7]Copenhagen University Hospital in Herlev, Copenhagen, Denmark, [8]Copenhagen University Hospital at Frederiksberg, Copenhagen, Denmark, [9]Copenhagen University Hospital at Frederiksberg, Frederiksberg, Denmark, [10]Image Analysis Ltd., Leeds, United Kingdom, [11]Glostrup Hospital, Glostrup, Denmark

Background/Purpose: Dynamic contrast-enhanced (DCE) magnetic resonance imaging (MRI) has been validated in rheumatoid arthritis for measuring inflammation, but has rarely been studied in psoriatic arthritis (PsA).

The purpose was to investigate whether DCE-MRI can discriminate PsA patients with high disease activity from minimal disease activity (MDA)(1), and to correlate DCE-MRI findings with conventional MRI and clinical measures.

Methods: PsA patients fulfilling CASPAR criteria were eligible in this investigator-initiated study of patients with either high disease activity (group 1) or MDA (group 2). Inclusion criteria were for group 1: swollen joint count (SJC)$\geq$6, tender joints count (TJC)$\geq$6, hand involvement and clinical indication for initiation of anti-TNF therapy, and for group 2: hand involvement within 1 year, long-term treatment with adalimumab 40 mg eow, and fulfilling criteria for MDA (at least 5 out of 7: TJC$\leq$1; SJC'1; body surface area$\leq$3%; PtGA$\leq$20; pain$\leq$15; HAQ$\leq$0.5; 13-enthesitis$\leq$1). DAS28 and the new Disease Activity index for PSoriatic Arthritis (DAPSA)(2) score (sum of SCJ, TJC, PtGA, pain and CRP) was calculated. The validated PsAMRIS scoring system (3) was used for analyzing conventional MRI (0.6 tesla). PsAMRIS total inflammation was calculated by adding synovitis, flexor tenosynovitis, periarticular inflammation and bone marrow oedema scores. DCE-MRI were analysed by Dynamika software (Image Analysis Ltd., Leeds, UK). Regions of interest (ROIs) were drawn around 2.-5. metacarpophalalangeal joints, excluding large blood vessels. The ROIs were used for automatic computing of the number of pixels with plateau and washout pattern (N_{p+w}), the initial rate of enhancement (IRE), and maximum enhancement (ME).

Results: Patient characteristics were: 9 males/8 females, median age 45 (25–63) years, joint/skin disease duration 8 (2–59)/15(2–59) years (no difference between groups). Clinical and imaging data are shown in the table.

	Group 1: High disease activity (n=9)	Group 2: Minimal Disease Activity (n=8)	P value
N_{p+w}	712 (13–1587)	362 (25–1316)	0.25
IRE $\times 10^3$	8 (5–33)	10 (6–14)	0.29
ME	1.20 (1.17–1.33)	1.21 (1.16–1.33)	0.92
N_{p+w}* IRE	5.4 (0.4–15.9)	2.8 (0.2–13.2)	0.44
N_{p+w}* ME	946 (16–1903)	434 (29–1608)	0.29
PsAMRIS synovitis	3 (0–5)	2 (0–5)	0.59
PsAMRIS total inflammation	16 (1–24)	7.5 (3–18)	0.19
DAS28 score	5.5 (3.9–6.4)	1.4 (1.1–2.4)	0.01
DAPSA score	64.9 (30.9–103.3)	2.4 (0.1–5.6)	0.01

Median (range). Groups compared using Krustal-Wallis test.

We found a significant correlation between the DCE-MRI parameters (N_{p+w}*IRE, N_{p+w}*ME and N_{p+w}) and PsAMRIS total inflammation (Spearman's rho: 0.53, 0.51 and 0.51; all $P<0.05$). DCE-MRI parameters were not statistically significant correlated with clinical measures, but N_{p+w}*IRE, N_{p+w}*ME and N_{p+w} were numerically lower in the MDA group.

Conclusion: DCE-MRI parameters correlated significantly with PsAMRIS total inflammation score, and showed a trend toward higher values in the high disease activity versus the MDA group. DCE-MRI is a promising method for assessing joint inflammation in PsA. However, a larger longitudinal study is needed to clarify, if DCE-MRI is superior to conventional MRI for discriminating between disease activity levels.

Assessment of Rheumatoid Arthritis Disease Activity by Power Doppler Ultrasonography: Association with Routine Clinical Indices and Its Usefulness in Detecting Remission. Hiroaki Taguchi, Kazuo Nishi, Takeo Kudo and Yutaka Okano. Kawasaki Municipal Kawasaki Hospital, Kawasaki, Japan

Background/Purpose: Power Doppler ultrasonography (PDUS) is sensitive for detecting synovitis in patients with rheumatoid arthritis (RA). We aimed to clarify the association of PDUS findings with routine clinical indices and its usefulness in detecting disease remission.

Methods: We studied 72 RA patients with mean age 62.5 years, mean disease duration 5.6 years, and 61% women. We examined 22 joints including bilateral wrists, metacarpo-phalangeal, and proximal interphalangeal joints using PDUS to evaluate the presence of inflammation with scoring from 0 to 3 according to the signal intensity of each joint, and the sum score (ranging from 0 to 66) was defined as "PDUS score". Clinical disease activity score/indices including DAS28CRP, SDAI, and CDAI were also recorded. Clinical remission was defined according to the following criteria: DAS28CRP < 2.3, SDAI ≤ 3.3, CDAI ≤ 2.8, and Boolean-based definition. Sonographic remission was defined by absence of PDUS signals.

Results: Mean values ± SD of DAS28CRP, SDAI, and CDAI were 3.3±1.5, 18.8 ±15.0, and 17.3±13.5, respectively. Mean values ± SD of PDUS score was 6.2 ± 6.3 and significantly correlated with all three clinical disease activity score/indices; among them the correlation with SDAI was strongest (r=0.77, p<0.001). PDUS score was more significantly correlated with swollen joint counts (r=0.73), patient global assessment (GA) (r=0.77), or evaluator GA (r=0.85), than with tender joint counts (r=0.50) or serum CRP (r=0.61). Remission was observed in 17 (24%) patients by DAS28CRP, in 11 (15%) by SDAI, in 12 (17%) by CDAI, and in 14 (19%) by Boolean-based definition, respectively. Sonographic remission was observed in 9 (13%) patients. In 36-59% of the patients satisfying clinical remission criteria, the PDUS signals were detected indicating the presence of synovitis (Table 1). Values of DAS28CRP, SDAI, and CDAI of patients with sonographic remission were 1.3, 1.7, and 1.9, respectively.

Table 1. Distribution of patients with absence and presence of PDUS signals for patients with clinical disease remission defined by DAS28CRP, SDAI, CDAI, and Boolean-based criteria.

	n	sonographic signals absence	sonographic signals presence
DAS28CRP <2.3	17	7 (41%)	10 (59%)
SDAI ≤3.3	11	7 (64%)	4 (36%)
CDAI ≤2.8	12	7 (58%)	5 (42%)
Boolean-based criteria	14	8 (57%)	6 (43%)

Conclusion: PDUS is useful for evaluating RA disease activity, is exceedingly sensitive, and is a useful method for detecting "pure" RA disease remission.

Ultrasound Scores of Enthesitis and Dactylitis Do Not Correlate with Corresponding Clinical Findings in Psoriasis Arthritis. Rusmir Husic[1], Josef Hermann[1], Judith Gretler[2], Winfried B. Graninger[1] and Christian Dejaco[1]. [1]Medical University Graz, Graz, Austria, [2]Auenbruggerplatz 15, Graz, Austria

Background/Purpose: To compare sonography verified inflammation of entheses, tendons and joints with corresponding clinical findings in psoriasis arthritis (PsA) patients.

Methods: Prospective study of 70 consecutive PsA patients [mean age 51.1 (±SD 11.6) years, 30% female, median disease duration 7.0 (range 0–44.7) years]. Clinical and ultrasound examination was performed at 68 joints and 14 entheses (lateral epicondyle, triceps insertion, quadrizeps insertion, proximal and distal insertion of patellar ligament, Achilles tendon, plantar fascia), and clinical scores including the Disease Activity index for PSoriatic Arthritis (DAPSA), composite psoriatic disease activity index (CPDAI), dactylitis score, Leeds enthesitis index (LEI), HAQ and PASI were calculated. Sonography was performed by two rheumatologists blinded to clinical data using an ESAOTE Twice ultrasound device. Synovial hypertrophy and/or joint effusion (SH/E) as well as Power Doppler (PD) were graded at each joint from 0 to 3 in accordance with prior publications. At hands and feet we also recorded the presence of perisynovitis and tenosynovitis. For grading of enthesitis by ultrasound the MASEI and GUESS scores were used. Ultrasound signs of dactylitis were defined by the presence of synovitis plus tenosynovitis at MCP/MTP, PIP and DIP joints.

Results: The median DAPSA was 12.1 (0.1–70.2), mean CPDAI 4.8 (±2.5), median clinical Dactylitis score 0 (0–10), median LEI 0 (0–4), mean HAQ 0.73 (±0.81) and median PASI 1.0 (0–23.2). Using sonography, we found SH/E and/or PD at 12 (range 3–35) [median SH/E score 16.0 (range 3.0–56.0)] and/or 2 (0–19) [PD-score 3.0 (0–31.0)] joints, respectively. Eighteen patients (25.7%) had evidence of perisynovitis in at least one MCP joint and 20 (28.6%) patients demonstrated flexor tenosynovitis affecting at least one whole finger or toe. Median MASEI and GUESS scores were 32.5 (7.0–73.0) and 13.0 (4.0–27.0), respectively. Ultrasound signs of dactylitis were found in 5 (7.1%) patients.

DAPSA showed a moderate correlation with total SH/E (corrcoeff 0.35, p=0.003) and PD-scores (corrcoeff 0.36, p=0.002), as well as with the number of joints affected by SH/E (corrcoeff 0.24, p=0.045) and/or PD (corrcoeff 0.32, p=0.006). Total CPDAI did not correlate with SH/E, PD, enthesitis or dactilytis scores; however, within the CPDAI-joint domain we found differences concerning SH/E- and PD-scores between patients with no [n=17, median SH/E 12.0 (3.0–32.0); PD-score 1.0 (0–11.0)] and moderate [n=17, SH/E 25.0 (6.0–43.0), p=0.009; PD 5.0 (0–31.0), p=0.005] or high clinical activity [n=26, SH/E 18.5 (6.0–56.0), p=0.025; PD 5.5 (0–30.0), p=0.005). In the CPDAI enthesitis and dactilytis domains no differences were found, comparing the MASES/GUESS and ultrasound defined dactylitis, respectively between the groups. No correlation was found between clinical and sonographic dactylitis scores; or LEI (clinical) and MASEI/GUESS (sonography).

Conclusion: No association was found between sonographic and clinical assessment of enthesitis and dactylitis in PsA patients. Ultrasound verified joint inflammation moderately correlated with DAPSA and CPAI joint components.

Dynamic Contrast-Enhanced Magnetic Resonance Imaging of the Wrist in Rheumatoid Arthritis Patients Treated with Methotrexate, Intra-Articular Glucocorticoid and Adalimumab/Placebo. Mette Bjørndal Axelsen[1], Merete L. Hetland[2], Kim Hørslev-Petersen[3], Kristian Stengaard-Pedersen[4], Peter Junker[5], Jan Pødenphant[6], Jakob M. Møller[7], Henning Bliddal[8], Olga Kubassova[9], Mikael Boesen[10] and Mikkel Østergaard[1]. [1]Copenhagen University Hospital at Glostrup, Copenhagen, Denmark, [2]Copenhagen University and Glostrup Hospital, Copenhagen, Denmark, [3]University of Southern Denmark, Graasten, Denmark, [4]Arhus University Hospital, Aarhus, Denmark, [5]Odense University Hospital, Odense C, Denmark, [6]Copenhagen University at Gentofte, Hellerup, Denmark, [7]Copenhagen University Hospital in Herlev, Copenhagen, Denmark, [8]The Parker Institute, Copenhagen University Hospital at Frederiksberg, Copenhagen, Denmark, [9]Image Analysis Ltd., Leeds, United Kingdom, [10]Copenhagen University Hospital at Frederiksberg, Copenhagen, Denmark

Background/Purpose: To validate parameters of dynamic contrast-enhanced magnetic resonance imaging (DCE-MRI) in an early rheumatoid arthritis (RA)

clinical trial by comparison with clinical parameters of disease activity, and by investigating the sensitivity to change during a 2-year-follow-up.

Methods: 14 early RA patients diagnosed according to the ACR1987 criteria within 6 months of inclusion and with a DAS28 ≥3.2 (9/5 women/men, median aged 37 [range 27-69] years, disease duration 82 [42-129] days) were randomized 1:1 to treatment with methotrexate (MTX) and adalimumab or MTX and placebo. Any swollen joints were injected with triamcinolone (max 4 joints/4 ml per visit) in a 2-year-follow-up. If continuous disease activity was present, treatment was intensified. Conventional MRI and DCE-MRI of the right wrist were performed at baseline, and after 6, 12 and 24 months using a 0.6 Tesla MRI-unit. A 3-slice dynamic sequence was obtained at the time of injection of the contrast agent (Gadoteric acid 0.2 mL/kg). DCE-MRI parameters: TR 33ms, TE 4.2ms, flip angle 25°, FOV 200 mm^2, matrix 108×192, slice thickness 3 mm.

On DCE-MR images, the wrist were manually delineated using the image software Dynamika version 4.6.0 (Image analysis Ltd., Leeds, UK, www.image analysis.org) and for these regions of interest (ROI) the number of enhancing voxels (Nvoxel), the initial rate of enhancement (IRE), the maximum enhancement (ME), the IRE×Nvoxel and ME×Nvoxel were extracted by the software and compared to clinical parameters of disease activity.

Results:

Table 1. Clinical and MRI data at baseline and at follow-up visits.

	Baseline	6 months	12 months	24 months
DAS28(CRP)	4.75 (3.5–6.1)	2.2 (1.8–2.8)***	2.0 (1.7–3.9)***	2.1 (1.7–3.3)***
CRP (mg/mL)	14 (7–116)	7 (7–11)**	7 (7–47)*	7 (7–31)*
Patient's VAS pain	48 (12–82)	11 (2–37)***	22 (1–72)*	15 (0–72)***
Patient's VAS global	54 (19–98)	22 (3–45)***	24 (0–75)*	21 (0–67)***
Patient's VAS fatique	46 (9–90)	18 (2–83)^{NS}	30 (0–85)^{NS}	24.5 (0–68)*
Health Assessment Questionnaire	1.0 (0.0–1.875)	0.130 (0–1)***	0.125 (0.0–1.00)**	0.13 (0.0–1.0)**
VAS doctor	51 (15–76)	5 (0–16)***	2 (0–26)***	3 (0–33)***
Swollen Joint Count 28	3 (1–7)	0 (0–1)***	0 (0–1)	0 (0–0)
Tender Joint Count 28	5 (2–17)	0 (0–2)***	0 (0–2)	0 (0–3)
Number of Enhancing voxels (Nvoxel)	548 (0–3786)	73 (0–1763)^{NS}	181 (0–1694)^{NS}	74 (0–617)^{NS}
Maximum Enhancement (ME)	1.21 (0–1.39)	1.17 (0.00–1.32)^{NS}	1.19 (0–1.39)^{NS}	1.23 (0–1.51)^{NS}
Initial Rate of Enhancement (IRE) (%/s)	0.45 (0.0–1.20)	0.35 (0–0.9)^{NS}	0.40 (0.0–1.0)^{NS}	0.6 (0.0–1.7)^{NS}
ME×Nvoxel	666 (0–5251)	85 (0–2329)^{NS}	215 (0–2350)^{NS}	90 (0–929)^{NS}
IRE×Nvoxel (%/s)	246 (0–4543)	26 (0–1587)^{NS}	63 (0–1694)^{NS}	44 (0–1049)^{NS}

Values are presented as medians (minimum–maximum). VAS: visual analog scale. Change from baseline: Wilcoxon Signed Ranks Test, *: p<0.05, **: p<0.01, ***: p<0.005, ^{NS}: not significant.

All clinical parameters decreased during follow-up, while there were no statistically significant changes for the DCE-MRI parameters, which may reflect lack of power. Furthermore, it should be emphasized that only 3 of the examined wrist joints were clinically affected at baseline.

Conclusion: DCE-MRI is a promising outcome measure in clinical trials, but MRI at baseline must include clinically involved joints.

Automated Breast Volume Scanner (ABVS), a New Automated Ultrasonic Device, Is Useful to Examine Joint Injury in Patients with Rheumatoid Arthritis. Shin-ya Kawashiri[1], Takahisa Suzuki[1], Yoshikazu Nakashima[1], Akitomo Okada[1], Naoki Iwamoto[1], Kunihiro Ichinose[1], Mami Tamai[1], Kazuhiko Arima[2], Hideki Nakamura[2], Tomoki Origuchi[1], Masataka Uetani[1], Kiyoshi Aoyagi[1] and Atsushi Kawakami[1]. [1]Nagasaki University Graduate School of Biomedical Sciences, Nagasaki, Japan, [2]Nagasaki University, Nagasaki, Japan

Background/Purpose: Automated Breast Volume Scanner (ABVS) is an ultrasonic device to be developed for the automated scanning for mammary glands. We have tried to explore the clinical application of ABVS toward the synovial lesion in patients with rheumatoid arthritis (RA).

Methods: Ten active RA patients of mean 54 y.o., whose mean disease duration 15 months and DAS28-ESR 5.69, were recruited. Patients gave their informed consent to be subjected to the protocol that was approved by the Institutional Review Board of Nagasaki University. We have examined in total 100 metacarpophalangeal (MCP) joints as well as 20 wrist joints at dorsal sites by both ABVS (ACUSON S2000) and conventional ultrasonography (US) at the same day consecutively. ABVS was scanned in a water tank. Presence of synovial hypertrophy and bone erosion by gray-scale were examined by both methods, and the association of both methods was calculated by kappa coefficient.

Results: The scanning time of ABVS was 2 min per patient and that of conventional US was 15 min per patient, respectively. ABVS detected synovial hypertrophy in 10 MCP joints and 13 wrist joints whereas conventional US detected synovial hypertrophy in 11 MCP joints and 13 wrist joints. Kappa coefficient of synovial hypertrophy was 0.84 in MCP joints and 0.78 in wrist joints, respectively. ABVS detected bone erosion in 2 MCP joints and 5 wrist joints whereas conventional US detected bone erosion in 5 MCP joints and 6 wrist joints. Kappa coefficient of bone erosion was 0.56 in MCP joints and 0.90 in wrist joints, respectively.

Conclusion: Present data have shown a substantial agreement of ABVS with conventional US to find the synovial hypertrophy and bone erosion of wrist and finger joints in patients with RA. Since ABVS is able to scan the wrist and finger joints automatically in a short time, ABVS is a helpful new ultrasonic method to examine joint injury in patients with RA.

Evaluation of Ankle Swelling Due to Löfgren's Syndrome: A Pilot Study Using B -mode and Power Doppler Ultrasonography. Emmanuelle LeBras[1], Sandra Balser[1], Valentin S. Schäfer[1], Boris P. Ehrenstein[1], Patrick Hoffstetter[1], Martina Müller[2], Martin Fleck[1] and Wolfgang Hartung[1]. [1]Asklepios Klinikum Bad Abbach, Bad Abbach, Germany, [2]University Clinic Regensburg, Regensburg

Background/Purpose: Patients suffering from acute sarcoidosis frequently present with bilateral painfull swelling of the ankles, establishing ankle arthritis as a hallmark of Löfgren's syndrome. Standardized high resolution musculoskeletal ultrasound (MUS) including power Doppler has been utilized to further characterize the nature of the ankle swelling in patients presenting with Löfgren's syndrome.

Methods: Ankle joints of 36 consecutive patients suffering from Löfgren's syndrom were investigated by high resolution MUS using B- and power Doppler mode. Presence of effusion/synovitis and tenosynovitis has been determined, and hyperperfusion was scored in a semiquantitative fashion (grade 0–3).

Results: The majority of patients (26/36; 72,2%) did not present characteristic arthrosonographic findings of an acute arthritis (distension of the capsule and hyperperfusion). Ankle joint effusion was only observed in 9 of the 36 patients (25%). Remarkably, 88,8% of these patients had an ankle effusion grade I and only 11,1% presented an effusion grade II. Instead, an extensive subcutaneous edema indicating periarthritis was detected in 23 of 26 patients (88,4%). In addition, tenosynovitis could be visualized in 14 patients (38,8%).

Conclusion: Utilizing MUS including power Doppler, the present results clearly demonstrate that ankle swelling in patients suffering from Löfgren's syndrome is predominantely due to periarticular soft tissue swelling and tenosynovitis. In contrast, distinct articular synovitis is rare and if present only of mild degree without relevant power Doppler activity.

Tenosynovitis in Carpal Tunnel Syndrome - Prevalence and Comparison Between Ultrasonography, Surgery and Histology. David F. Ten Cate[1], Nick Glaser[1], Jolanda J. Luime[2], K.H. Lam[3], Johannes W.G. Jacobs[4], Ruud W. Selles[2], Johanna Hazes[5] and M. Bertleff[6]. [1]Erasmus Medical Center, Rotterdam, Netherlands, [2]Erasmus MC - University Medical Center, Rotterdam, Netherlands, [3]Erasmus University Medical Center, Netherlands, [4]University Medical Center Utrecht, Utrecht, Netherlands, [5]Erasmus Medical Centre Rotterdam, Rotterdam, Netherlands, [6]Xpert Clinic, Rotterdam, Netherlands

Background/Purpose: Carpal tunnel syndrome (CTS) is a common neuropathy affecting the median nerve. CTS occurs more frequently in inflammatory arthropathies, such as rheumatoid arthritis (RA). This may relate to the presence of tenosynovitis in the wrist. Patients with tenosynovitis might be better treated conservatively with a diagnostic rheumatological consultation and other non-surgical methods, such as a glucocorticoid injection. However, flexor tenosynovitis at carpal tunnel level is not always easy to detect at clinical examination, but may be detected reliably by ultrasonography (US). Our aim was to determine the presence of tensynovitis detected at US in idiopathic CTS patients referred for surgery and to compare this with the peroperative evaluation and histological findings.

Methods: The wrists of 34 consecutive idiopathic CTS patients, with an indication for carpal tunnel release, were assessed before surgery with greyscale US (GSUS) and power Doppler US (PDUS) at the volar aspect of the wrist. Flexor tenosynovitis was scored according OMERACT US definitions. During surgery, tenosynovitis was evaluated by the surgeon according to a three-grade tenosynovitis classification system. Biopsy specimens were obtained in 28 patients; tenosynovitis was scored histologically by a pathologist according to a three-grade scoring system.

Results: US Tenosynovitis was detected in 59% of the patients. Peroperative, surgical tenosynovitis was detected in 88% of the patients. The pathologist found minor tenosynovitis in 17% of the patients, while 79% showed reactive changes (Table 1). The agreement between the respective modalities is presented in tables 2 and 3.

Table 1. Prevalence of tenosynovitis

	US	Surgery	Histology
TS +	59%	46%	17%
TS +/−	N.A.	42%	79%
TS−	41%	12%	4%

- TS: Tenosynovitis
- For surgery and histology TS +/− is grade 1

Table 2. Comparison US-Surgery

US	Surgery	TS+	TS−
TS+	17	3	20
TS−	13	1	14
	30	4	34

Surgical TS: Grade 1 + grade 2. Histological TS: Grade 2 (expert opinion)

Table 3. Comparison US-Histology

US	Histology	TS+	TS−
TS+	4	12	16
TS−	1	11	15
	5	23	28

Surgical TS: Grade 1 + grade 2. Histological TS: Grade 2 (expert opinion)

Conclusion: In idiopathic CTS patients undergoing surgery, frequently tenosynovial changes are found at US and surgical evaluation, but histology did not confirm this entirely. Tenosynovitis was seen, histologically, in only a minority of all cases. However, reactive changes can be observed in a large number of cases and this could also be the basis of the surgical and ultrasonographic findings. The exact definition of tenosynovitis in these three modalities needs further investigation.

The Prevalence of the Ultrasonographic Positive Power Doppler Synovitis Is High and Predicts the Risk of Relapse and Structural Progression in Rheumatoid Arthritis in Clinical Remission: A Systematic Literature Review and Meta Analysis. Huong Nguyen[1], Adeline Ruyssen-Witrand[1], Arnaud L. Constantin[1], Violaine Foltz[2], Frédérique Gandjbakhch[2] and Alain G. Cantagrel[1]. [1]Purpan University Hospital, Toulouse, France, [2]Pitié Salpétrière Hospital, Paris, France

Background/Purpose: Ultrasonography (US) can detect synovitis in patients with rheumatoid arthritis (RA) more sensitively than clinical examination either in active disease or in remission.[1,2] There are many definitions of clinical remission, no consensus on US assessment of RA activity and the clinical implication of residual US synovitis is hotly debated.[3,4] This study is to assess the prevalence of residual US synovial hypertrophy (USGS+) and US power Doppler (PD) activity in patients in clinical remission and evaluate the predictive value of this residual synovitis in terms of relapse and structural progression.

Methods: A systematic literature search was performed in the Medline, Embase and Rheumatology meeting databases up to 28 May 2012. The prevalence of USGS+, cold synovitis (USGS+/PD-), active synovitis (USGS+/PD+) and complete remission (USGS-/PD-) were collected taking into account the definition of clinical remission, the stage of RA (early or established disease) and the US examination method. A meta-analysis assessing the risk of relapse or structural progression in patients with USGS+/PD+ compared to other patients was performed calculating the odds ratio (OR[MH]) and 95% confidence interval [95%CI] with the Mantel-Haenszel method.

Results: 18 studies including 1528 patients were included in this systematic literature review. All of the studies used the OMERACT method for US scoring. The prevalence of US GS+, USGS+/PD-, USGS+/PD+ and USGS-/PD- were 81.8 %, 40%, 43% and 15.7%, respectively. USGS+ or USGS+/PD+ prevalence was comparable between the different definitions of clinical remission (DAS44, DAS28, SDAI, ACR 1981 or ACR/EULAR 2011) and between the different US examination methods (from 5 to 44 joints assessed). The prevalence of USGS+ and USGS+/PD+ was higher in the patients with established RA in comparison to patients with early RA (respectively 87% of USGS+ compared to 64%, p<0.001 and 45% of USGS+/PD+ compared to 34%, p<0.001). According to the results of the meta-analysis performed on 4 studies[5–8] (including 178 patients) and 3 studies[5, 9, 10] (including 173 patients), the presence of USGS+/PD+ was associated with an increased risk of relapse (OR[MH][95%CI]=2.9, [1.5,5.9], p=0.002) and an increased risk of structural progression (OR[95%CI]= 12.8, [1.3, 126.8], p=0.03), respectively, over 1 to 2 years.

Conclusion: The prevalence of residual US synovitis is high in patients in clinical remission. Residual USGS+/PD+ increase the risk of relapse and structural progression in these patients.

Assessment of Validity of Magnetic Resonance Imaging Measures of Joint Inflammation and Damage in Rheumatoid Arthritis Wrist/Hand - a Systematic Literature Review. TG Woodworth[1], O. Morgacheva[2], OM Troum[3], OL Pimienta[3], P. Maranian[2], V.K. Ranganath[2] and D.E. Furst[2]. [1]Visiting Clinical Researcher, David Geffen School of Medicine, UCLA, Los Angeles, CA, [2]David Geffen School of Medicine, UCLA, Los Angeles, CA, [3]USC Keck School of Medicine, Santa Monica, CA

Background/Purpose: Limitation of x-ray joint damage is a key indicator of therapeutic efficacy in rheumatoid arthritis (RA). Although magnetic resonance imaging (MRI) is increasingly used due to its greater sensitivity vs radiographs, summary evidence validating MRI features of RA joint inflammation and damage is lacking. By systematic literature review (SLR), we examined the validity of MRI for assessment of RA wrist/hand features according to Outcome Measures in Rheumatology Clinical Trials (OMERACT) criteria.

Methods: An SLR in PubMed with Cochrane hedge was conducted using search terms: RA, AND MRI, AND specific terms i.e., synovitis, joint space narrowing (JSN), erosions or bone marrow edema (BME) AND humans AND randomized controlled trials [RCTs], clinical studies; 1970 to Aug 2011; English. Pairs of authors evaluated titles/abstracts, selecting articles for extraction according to these criteria: adults with RA, MRI of hands and/or

wrists assessing at least one of the following: synovitis, BME/osteitis, tenosynovitis, erosions, JSN; RCT, observational study, or case series ≥10 patients. To achieve ≥ 95% consistent data extraction, authors evaluated the same 5 articles, ensuring consensus on data extraction methods. Each author then extracted a proportion of the articles. Data extracted included MRI, field strength, measurement methods, and validity criteria: criterion, content, construct, reliability, responsiveness, and discrimination. Level of evidence was assessed using Cochrane Handbook criteria, adapted for imaging research.

Results: Of 575 MRI titles/abstracts, 180 met criteria with 81 having at least 1 type of validation. Although MRI measurement methods were developed using several approaches, OMERACT RA MRI scoring (RAMRIS) was determined to be the dominant method. As 43 articles utilized 1.5T, and 7 used other field strengths; only 1.5T articles were analyzed. (Table) 19 articles including 6 RCTs using 1.5T and RAMRIS were extracted seeking validation of MRI measures. The table summarizes the number of articles with data for validation. Histologic or radiographic evidence for criterion validity was extracted from 5 other articles.

Table. Validation status for measurement with 1.5T MRI images of synovitis, tenosynovitis, osteitis, erosions, joint space narrowing (JSN)—**number of articles providing data**

Type of validity	Criterion	Content	Construct (Discriminant)	Construct (Convergent)	Responsiveness to change	Intra-rater reliability	Inter-rater reliability	Summary
Definition	Extent to which measure agrees with "gold standard"	Describes joint features regardless of age, gender, RA duration, treatment	Correlation with clinical assessment of joint status	Compares correlation coefficients between scores on the same health component, as measured by two different instruments	Sensitivity to change	Same reader scores similarly (ICCs)	Two or more readers score similarly (ICCs)	# validated of 7 required validity criteria
Synovitis (RAMRIS) 1	2	12	4	1	7	6	5	7
0	1	3			1			
Tenosynovitis 1		5	1	*(a)	3	2	1	5
0	1				1			
Erosions (RAMRIS) 1	1	13		2	3	7	7	6
0	1	5	1		7			
BME/Osteitis (RAMRIS) 1	3	9	2	*(b)	5	6	5	6
0		4			2			
JSN 1		1						1

1=statistically significant validation; 0=non-significant data; ICC = intra/inter-class correlation coefficient

Conclusion: Using a rigorous PRISMA-compliant method for quality assurance and uniform article extraction in a SLR, we found that synovitis, osteitis/BME, and erosions are the best-validated features of joint inflammation and damage for RA wrist and hand. Assessment of other measurement methods, field strengths and joints requires further work.

Magnetic Resonance Imaging in Inflammatory Bowel Disease Patients with Arthralgia.

W. Stomp[1], L.K.P.M. Brakenhoff[1], F.A. van Gaalen[1], D. van der Heijde[1], H.H. Fidder[2], D.W. Hommes[3], M. Reijnierse[1] and J.L Bloem[1]. [1]Leiden University Medical Center, Leiden, Netherlands, [2]University Medical Center Utrecht, Utrecht, Netherlands, [3]University of California Los Angeles, Los Angeles, CA

Background/Purpose: Joint manifestations frequently occur in chronic inflammatory bowel diseases (IBD). Arthralgia, non-inflammatory joint pain without objective evidence of swelling or effusion, is present in 8–30% of all patients.(1–3) An underlying cause of arthralgia in IBD patients is not known and might be autoimmune related, which might express on MR as bone marrow edema. The purpose of this study is to assess whether inflammatory changes, including bone marrow edema can be detected on MRI in IBD patients with joint pain without clinical synovitis.

Methods: The most painful peripheral joint, without clinical signs of inflammation based on examination by a rheumatologist, at most 2 weeks prior to MR, was scanned in 14 IBD patients (11 Crohn's disease/3 ulcerative colitis) on a 1.5T extremity MRI. In addition the same joints were scanned in a control group of 14 IBD patients who were matched for form of IBD, disease duration, sex and age without joint complaints. MR imaging was performed according to a standard arthritis protocol including T1 and fat-suppressed T2 weighted images and T1 weigthed fat-suppressed post gadolinium sequences. MRI images were evaluated by two musculoskeletal radiologists in consensus for the presence of synovitis, tenosynovitis, bone marrow edema and erosions. The readers were blinded for all patient information.

Results: MR imaging of the MCP, PIP and/or DIP 2–5 joints of the hand was performed in 10 patients and 10 matched controls, MRI of the knee in 4 patients and 4 matched controls. A total amount of 62 painful joints were evaluated and 62 corresponding joints in the control group. Minimal synovitis was seen in one of the MCP joints in two of the arthralgia patients (3.2% of all painful joints) and in none of the control group (p=0.50). Bone marrow edema was not appreciated in the arthralgia patients, but a small amount of bone-marrow edema was seen in a MCP joint of a control (1.6% of total joints, p=1.00). Tenosynovitis and erosions were absent in both groups.

Conclusion: Subclinical inflammation on MRI was not seen more often in painful joints in arthralgia patients than in joints of controls. No anatomical substrate was found for arthralgia in IBD patients.

Systematic Review of the Association Between Magnetic Resonance Imaging and Radiographic Detection of Erosions in Rheumatoid Arthritis.

Ruben Tavares[1], Stephen R. Tytus[2], Karen A. Beattie[1], Maggie Larche[1], Naveen Parasu[3], Colin E. Webber[4], Lawrence E. Hart[5] and Jonathan D. Adachi[6]. [1]McMaster University, Hamilton, ON, [2]Northern Ontario School of Medicine, Sudbury, Qatar, [3]Hamilton Health Sciences, Hamilton, [4]Hamilton Health Sciences, Hamilton, ON, [5]St. Joseph's Health Care, Hamilton, ON, [6]Charlton Medical Centre, Hamilton, ON

Background/Purpose: In rheumatoid arthritis (RA), disparities between erosive bone lesion detection on magnetic resonance imaging (MRI) and X-ray require reconciliation. It is hypothesized that early erosions detectable on MRI increase in size with disease progression to become detectable on radiography (X-ray). The study's objectives were 1) to compare the relative diagnostic test accuracy of X-ray for MRI-detected erosions; and 2) to determine if MRI erosions develop into X-ray erosions over time.

Methods: A systematic review was conducted. Medline (Jan 1996-Apr 2011) and EMBASE (Jan 1998-Apr 2011) citation indexes were searched using the PICO strategy. RA studies with paired comparisons of erosion detection on X-ray and MRI at the joint or more precise level of analysis were included. Two reviewers independently screened the titles, abstracts and full articles to determine eligibility. Disagreements on eligibility between reviewers were mutually resolved by discussion or arbitrated by a third, independent reviewer if mutual resolution was not achieved. Cross-sectional comparisons were examined overall and then sorted by study sample symptom duration. Temporal explorations sorted data by time between initial MRI and subsequent X-ray. Study quality was evaluated using the Quality Assessment of Diagnostic Accuracy Studies (QUADAS) and reported. Cochrane Collaboration Review Manager software was used to manage and analyze the data collected.

Results: Sixteen eligible studies reporting 34 unique datasets comprising 10,953 paired observations were included. The relative diagnostic test accuracy results were heterogeneous across studies. Sensitivity results ranged from 0.00 (95% CI: 0.00–0.04) to 0.87 (95% CI: 0.60–0.98). Average sensitivity weighted by study sample size was 0.28 (95% CI: 0.28–0.29). Specificity ranged from 0.38 (95% CI: 0.14–0.68) to 1.00 (95% CI: 0.99–1.00). The weighted mean specificity was 0.97 (95%CI: 0.97-0.97). The sensitivity of X-ray for MRI erosions appeared to increase with increasing symptom duration. Sensitivity ranged from 0.07 (95% CI: 0.01–0.24) for patients with a mean symptom duration of 0.25 years, to 0.34 (95% CI: 0.20–0.51) for patients with 14 years symptom duration. Specificity decreased slightly with increasing symptom duration. Specificity ranged from approximately 0.99 (95% CI: 0.97–1.00) to 0.92 (95% CI: 0.88–0.95) for

symptom durations ranging from 0.25 to 9.5 years, respectively. Studies varied by sample symptom duration, anatomy investigated, MRI magnetic strength, definition of erosion, number of X-ray projections, use of prescribed scoring systems, number of raters, unit of analysis, and QUADAS parameters.

Conclusion: X-ray has low sensitivity and high specificity for MRI erosions. The relationship between X-ray and MRI erosion detection is dependent on symptom duration and the time interval between imaging interventions. As the time between initial MRI and follow-up X-ray increases, there is decreasing specificity of X-ray for MRI erosions. This suggests that erosive progression is not limited to joints initially detected on MRI. Sources of study heterogeneity and potential bias warrant attention in future comparative investigations.

Severe Joint Injury Assessed by Musculoskeletal Ultrasonography (MSKUS) Predicts the Presence of MRI-Proven Osteitis in Patients with Rheumatoid Arthritis. Shin-ya Kawashiri[1], Takahisa Suzuki[1], Yoshikazu Nakashima[1], Yoshiro Horai[1], Naoki Iwamoto[2], Kunihiro Ichinose[1], Kazuhiko Arima[2], Mami Tamai[2], Hideki Nakamura[2], Tomoki Origuchi[1], Kiyoshi Aoyagi[1] and Atsushi Kawakami[1]. [1]Nagasaki University Graduate School of Biomedical Sciences, Nagasaki, Japan, [2]Nagasaki University, Nagasaki, Japan

Background/Purpose: MRI-proven osteitis is known as the prognostic factor toward radiographic progression in patients with rheumatoid arthritis (RA). Musculoskeletal ultrasonography (MSKUS) is another high sensitive imaging modality to find joint injury of RA patients. We have tried to explore whether MSKUS assessment of synovial joint injury predict the presence of MRI-proven osteitis in patients with RA.

Methods: Thirty RA patients, who fulfilled 2010 RA classification criteria and are naïve to disease-modifying antirheumatic drugs (DMARDs) including biologics or glucocorticoids, are consecutively enrolled in this study from May 2010 through December 2011. Twenty-two joints from each patient including bilateral wrists and finger joints of the 1st - 5th metacarpophalangeal (MCP) joints, the 1st interpharangeal (IP) joint and the 2nd–5th proximal interpharangeal (PIP) joints were examined by both MSKUS and plain MRI. Therefore, a total of 660 joints were investigated by both methods in the present study. Power Doppler (PD) and gray scale (GS) assessment of articular synovitis by a semi-quantitative manner as well as the presence of bone erosion were examined by MSKUS. Plain MRI-proven osteitis was evaluated by RAMRI scoring (RAMRIS) technique. The Cochran-Armitage test was used to investigate a correlation of each MSKUS finding with MRI-proven osteitis.

Results: The mean disease duration, age, DAS28-ESR, prevalence of RF and anti-cyclic citrullinated peptide antibodies (ACPA) at examination were 4 months, 62 years-old, 5.06, 83.3% and 73.3%, respectively. MSKUS-proven bone erosion was found in 40 sites and MRI-proven osteitis 64 sites, respectively. A remarkable correlation of the PD grade (p < 0.0001), GS grade (p < 0.0001) and the presence of MSKUS-proven bone erosion (p < 0.0001) with the presence of osteitis was demonstrated by the Cochran-Armitage test.

Conclusion: Our present data suggest that severe joint injury assessed by MSKUS predicts the presence of MRI-proven osteitis in patients with rheumatoid arthritis.

Diffusion Tensor and Dynamic Contrast Enhanced Perfusion Imaging Metrics Discriminate Chronic Tubercular Synovitis From Chronic Inflammatory Synovitis of the Knee. Vikas Agarwal[1], Rakesh K. Gupta[2], Rishi Awasthi[2], Deepak Tripathi[2], Prativa Sahoo[3], Vinita Agrawal[2], Kusum Sharma[4], Rungmei Marak[5], Ram Kishore Singh Rathore[3] and CM Pandey[2]. [1]Sanjay Gandhi Post Graduate Institute of Medical Sciences, Lucknow, Lucknow, India, [2]Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow, Lucknow, India, [3]Indian Institute of Technology, Kanpur, India, [4]Postgraduate Institute of Medical Education and Research, Chandigarh, India, [5]Microbiology, Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow, Lucknow, India

Background/Purpose: The study was performed to quantify dynamic contrast enhanced (DCE) and diffusion tensor imaging (DTI) metrics in synovium of patients with tubercular synovitis (TS) and chronic inflammatory synovitis (CIS) with an aim to discriminate between TS and CIS.

Methods: Seventy-three patients with knee synovitis (18–75 years, 51 Male) underwent conventional, DTI and DCE-MRI. DTI and DCE data were quantified from the segmented contrast enhanced synovium. Descriptive statistics, Box-plot with Tukey's hinges were produced for all DTI (fractional anisotropy, FA and mean diffusivity, MD) and perfusion metrics (blood volume, BV; blood flow, BF and volume transfer constant, k^{trans}). The mean difference between the two groups was compared using Student's t-test for independent samples. To classify subjects into TS and CIS, two-group discriminant function analysis with stepwise inclusion of variables was performed.

Results: Out of 73 patients, 15 were detected to have TS, while rests were found to have CIS. DCE (BV, BF) and DTI metrics (FA, MD) were significantly (p<0.001) different between the two groups (TS: BV=14.35±4.21 ml/100gm, CIS:BV=4.57±2.77 ml/100gm, TS BF=155.7±29.5 ml/100gm/min, CIS BF=94.9±34.5 ml/100gm/min, TS FA=0.26±0.02, MD=1.23±0.39×10^{-3} mm^{2}sec^{-1}; CIS FA=0.20±0.02, MD=1.7±0.5×10^{-3} mm^{2}sec^{-1}). Discriminant analysis revealed BV and FA as discriminators of TS and CIS. It classified 93.3% of TS and 100% of CIS correctly. The overall model classified 98.6% cases correctly.

Conclusion: DTI and DCE-MRI metrics are able to discriminate TS from CIS. FA and BV may be used as non-invasive image biomarkers for its differentiation.

Sec61 Is Indispensable for Antigen Cross-Presentation and the Development of Lupus Nephritis: A Novel 'Self-Organized Criticality Theory' Explaining the Cause of Systemic Lupus Erythematosus (SLE). Ken Tsumiyama and Shunichi Shiozawa. Kyushu University Beppu Hospital, Beppu, Japan

Background/Purpose: We found that systemic lupus erythematosus (SLE) was induced experimentally by repeatedly immunizing the mice normally not prone to autoimmune diseases by any exogenous antigen so far examined (Tsumiyama K *et al.* PLoS One 4(12):e8382, 2009). We have then proposed a novel 'self-organized criticality theory' that explains the cause of SLE. Systemic autoimmunity, or SLE, necessarily takes place when host's immune system is overstimulated by repeated exposure to antigen to levels that surpass the immune system's stability limit, i.e., self-organized criticality. The autoreactive lymphocyte clones, which we name autoantibody-inducing CD4$^+$ T cells (aiCD4$^+$ T cells) are newly generated *via de novo* T cell receptor (TCR) revision from thymus-passed non-autoreactive clones at peripheral lymphoid organs. They not only stimulated B cells to generate varieties of autoantibodies but also helped final differentiation of CD8$^+$ T cell into cytotoxic T lymphocyte (CTL) *via* antigen cross-presentation to induce tissue injuries identical to SLE. Here we show the essential role of a translocon Sec61 for antigen cross-presentstion and lupus tissue injuries with regard to self-organized criticality theory.

Methods: Bone marrow-derived dendritic cell (BMDC) of BALB/c mice was cultured with fluorescent-labeled ovalbumin (OVA). Early endosome antigen 1 (EEA1) and calnexin were detected by using immunofluorescent staining to identify endosome and endoplasmic reticulum (ER), respectively. A translocon Sec61 was also detected to examine whether or not engulfed antigen is exported from endosome to cytoplasm through Sec61. For *in vivo* study, BALB/c mice were repeatedly immunized with OVA to induce SLE. The CD11c$^+$ DC isolated form spleen (spDC) of the mice immunized 12× with OVA was cultured with fluorescent-labeled OVA to examine localization of engulfed antigen. Localization of OVA, EEA1, calnexin and Sec61 in BMDC and spDC was examined under confocal laser microscopy. Further, exotoxin A was co-immunized with OVA to inhibit Sec61 *in vivo* in BALB/c mice. Renal lesion and the generation of CTL were assessed by proteinuria and the number of IFNγ-producing CD8$^+$ T cell.

Results: In BMDC, OVA was co-localized with an endosomal marker EEA1 until 15 min of culture, and subsequently separated from EEA1. OVA did not co-localize with an ER marker calnexin. Instead, OVA was co-localized with a translocon Sec61. The same result was obtained using spDC, suggesting that OVA could be exported from endosome directly to cytoplasm *via* Sec61. After repeated immunization with OVA, we found that the amount of Sec61 localized in endosome was gradually and significantly increased compared with control. While we showed previously that antigen cross-presentation is a pre-requisite for lupus tissue injury inducing nephritis, we did found that treatment of BALB/c mice with a Sec61 inhibitor exotoxin A inhibited both the generation of CTL and lupus nephritis.

Conclusion: Direct export of antigen from endosome to cytoplasm *via* Sec61 is essential not only for antigen cross-presentation but also development of lupus nephritis.

Fc Receptor Gamma-Dependent Autoimmune Endocarditis in K/BxN Mice. Patricia M. Hobday[1], Jennifer L. Auger[1], J. Sjef Verbeek[2], Jeffrey V. Ravetch[3] and Bryce A. Binstadt[1]. [1]University of Minnesota, Minneapolis, MN, [2]Leiden University Medical Center, Leiden, Netherlands, [3]The Rockefeller University, New York, NY

Background/Purpose: Arthritis and endocarditis co-exist in several human rheumatic diseases, including systemic lupus erythematosus, rheumatic fever, and rheumatoid arthritis. K/BxN TCR transgenic mice, well known for their inflammatory arthritis, also develop spontaneous endocarditis. FcRγ, the cytoplasmic signaling molecule shared by the three activating Fcγ receptors in the mouse (FcγRI, III, and IV), is required for endocarditis in K/BxN mice. Here we addressed two main questions: first, which of the three activating Fcγ receptors is required for endocarditis in this model and second, what FcRγ-expressing cell type drives endocarditis.

Methods: Knockout alleles of each of the activating Fcγ receptors (FcγRI−/−, FcγRIII−/−, and FcγRIV−/−) were bred into the K/BxN system. In addition, we utilized a reciprocal bone marrow transplantation approach to determine if endocarditis depended on FcRγ expression by bone marrow-derived cells or by radio-resistant host cells. We assessed hearts for the presence of endocarditis via standard hematoxylin and eosin staining. Additionally, we used immunohistochemistry to examine the expression of the three activating Fcγ receptors in the cardiac valves as well as the isotypes of antibodies bound to the inflamed cardiac valves.

Results: Although IgG1 is the predominant autoantibody isotype in K/BxN mice, we found that IgG1, IgG2b, and IgG2c were all bound to their inflamed cardiac valves. We also detected expression of each of the activating Fcγ receptors in the cardiac valves. K/BxN mice lacking expression of FcγRI, FcγRIII, or FcγRIV developed endocarditis with equivalent severity to control mice. The bone marrow transplant experiments revealed that recipient mice lacking FcRγ were protected from endocarditis. Surprisingly, the presence or absence of FcRγ on bone marrow-derived donor cells did not influence the severity of endocarditis.

Conclusion: Our results indicate that no single activating Fcγ receptor is solely required for the development of endocarditis in K/BxN mice. The simplest explanation for these findings is that there is redundancy among the activating Fcγ receptors in driving endocarditis. This interpretation is consistent with our data showing that multiple immunoglobulin isotypes are bound to the inflamed valves and that that each of the activating Fcγ receptors can be detected in the valves. A less likely explanation is that an FcRγ-utilizing receptor type other than the activating Fcγ receptors is at play. We also conclude that FcRγ chain expression by radio-resistant host cells rather than by radiosensitive, bone-marrow derived cells is required for the development of endocarditis. Candidate cell types include cardiac stromal cells and/or radio-resistant dendritic cells. Our findings provide new insight into the pathogenesis of cardiovascular inflammation in the setting of autoantibody-associated diseases.

A Specific Inhibitor of Spleen Tyrosine Kinase, PRT062607, Is a Potent Modulator of Innate Immune Cell Function. Lynn A. Kamen, Gillian Stephens, Anjali Pandey and Uma Sinha. Portola Pharmaceuticals, South San Francisco, CA

Background/Purpose: Tumor Necrosis Factor-α (TNF-α) is an essential component of the inflammatory stimuli leading to rheumatoid arthritis (RA). Therapeutics targeting TNF-α are the standard of care but are not always capable of inhibiting disease progression. Thus, there is an unmet need for novel targets for treatment of RA. Spleen tyrosine kinase (Syk) is a non-receptor tyrosine kinase that plays an important role in phagocyte (macrophage and neutrophil) activation. Phagocytes are known to be important in the pathology of RA; the purpose of this study was to evaluate the impact of Syk inhibition in modulating phagocyte activation.

Methods: Macrophages were generated by culturing peripheral blood monocytes from healthy human volunteers with M-CSF (5ng/mL) for five days. Neutrophils were isolated from human peripheral blood on a Ficoll gradient and separated from erythrocytes via dextran sedimentation. As a surrogate for pathogenic autoantibodies in the arthritic synovial joint, immune complex was used for activation of macrophages and neutrophils. Immune complex was prepared by preincubating chicken egg ovalbumin with goat anti-chicken egg ovalbumin IgG at 37°C. To mimic integrin-mediated activation, plate-bound poly-RGD (20 μg/mL) was used as a stimulus. TNF-α release from macrophages was measured via ELISA (R and D Systems). The SOD-inhibitable oxidative burst response in neutrophils was measured through cytochrome c reduction in a plate-based absorbance assay. Specific Syk inhibitor, PRT062607 (P505-15) was added *in vitro* to the experimental system containing human macrophages or neutrophils.

Results: Syk inhibition by PRT062607 suppressed inflammatory cytokine release. Cytokine levels, as measured by TNF-α release from macrophages stimulated with immune complex, was potently inhibited by PRT062607 (IC$_{50}$=0.070μM). Furthermore, PRT062607 treatment was a potent inhibitor of neutrophil-mediated superoxide production in response to various physiologically relevant stimuli (integrin ligation IC$_{50}$=0.037μM and immune complex stimulation IC$_{50}$=0.195μM). Interestingly TNF-α alone was able to facilitate neutrophil-mediated superoxide production, and this activity was potently suppressed by PRT062607 (IC$_{50}$=0.065μM).

Conclusion: Together these data indicate a novel role for Syk inhibition in controlling TNF-α-mediated inflammation. These results suggest that in addition to decreasing immune cell activation and inflammation in the joint, Syk inhibition could also partly mimic the effects of an anti- TNF-α therapy. Thus, Syk inhibition by a small molecule kinase inhibitor has the potential to be a novel mode of therapy in RA.

Fulminant Toll-Like Receptor 9-Induced Macrophage Activation Syndrome and Hemophagocytosis Occur Independently of Interferon Gamma. Scott W. Canna[1], Julia Wrobel[2], Portia A. Kreiger[3], Michele E. Paessler[1] and Edward M. Behrens[1]. [1]Childrens Hospital of Philadelphia, Philadelphia, PA, [2]The Children's Hospital of Philadelphia, Philadelphia, PA, [3]Nemours/A.I. DuPont Hospital for Children, Wilmington, DE

Background/Purpose: Macrophage Activation Syndrome (MAS) is a potentially lethal cytokine storm syndrome that complicates various rheumatic diseases. We have previously shown that Toll-like Receptor (TLR9) mediated MAS is Interferon gamma (IFNg) dependent, and others have demonstrated IFNg-dependence in models of Hemophagocytic Lymphohistiocytosis. We have also shown the critical role of IL-10 in regulating TLR9-induced MAS, and mice co-treated with TLR9-agonism and IL-10 receptor blockade (IL10RB) develop "fulminant MAS." This study seeks to determine the role of IFNg in the fulminant MAS model.

Methods: We gave CpG1826 repeatedly to WT and transgenic mice as described. Antibodies inhibiting the action of the IL-10 receptor (IL10RB, 1B1.3A) and IL-12p40 (C17.8) were given as described. All injections were intraperitoneal. We then evaluated for signs of MAS.

Results: Fulminant MAS resulted in greatly enhanced serum IL-10, IL-12, and IFNg. While dendritic cell populations were dominant producers of IFNg in IL-10 sufficiency, in fulminant MAS IFNg was also produced by hepatic NK and CD8 T cells. When IL-12 was blocked in fulminant MAS mice, disease progression was unaltered, despite much lower serum IFNg. Strikingly, we also observed the continued presence of hemophagocytes (HPCs) despite IL-12 blockade. This observation caused us to question whether fulminant MAS was due to enhanced IFNg activity or whether, distinct from the IL-10 sufficient scenario, other proinflammatory forces were at work. Administration of CpG and IL10RB to IFNg−/− mice resulted in fulminant MAS nearly comparable to that seen in WT mice. Notably,

IFNg$-/-$ mice were spared from severe anemia and severe hepatitis but developed all other aspects of fulminant MAS including HPCs. Thus, while certain aspects of disease (anemia and hepatitis) are IFNg-dependent, fulminant MAS, including hemophagocytosis, occurs independent of IFNg. Interestingly, blockade of type I interferon signaling (using IFNAR$-/-$ mice) did not prevent disease in the IL-10 sufficient situation, but partially abrogated fulminant MAS. HPCs also persisted despite Type I IFN receptor blockade.

Conclusion: In the TLR9-mediated model, IL-12 functions to induce IFNg. However, fulminant MAS is largely IFNg-independent. This suggests that therapeutic targeting of IFNg may not be sufficient in all cases of hemophagocytic syndrome. Furthermore, our results dissociate the development of IFNg-induced "consumptive" anemia and hepatitis, and the presence of HPCs. Thus, the goal of chemotherapeutic elimination of HPCs may not be of benefit for many aspects of the disease, since their presence does not correlate with either anemia or hepatitis.

Endogenous Complement Factor H Plays an Important Role in Controlling Immune Complex-Induced Inflammatory Arthritis. Nirmal K. Banda[1], Gaurav Mehta[1], Viviana P. Ferreira[2], Claudio Cortes[2], Michael K. Pangburn[3], William P. Arend[1] and V. Michael Holers[1]. [1]University of Colorado School of Medicine, Aurora, CO, [2]University of Toledo Health Science Campus, Toledo, OH, [3]University of Texas Health Sciences Center, Tyler, TX

Background/Purpose: The complement system, a major component of innate immunity, likely plays an important role in the pathogenesis of rheumatoid arthritis (RA). Factor H (fH) is an endogenous regulator of the alternative pathway (AP) that binds surface polyanions in combination with the C3-derived fragments C3b and C3d initially through its carboxy-terminal domain containing short consensus repeats (SCR) 19–20, thereby inhibiting both AP activation and engagement of the AP amplification loop. We have shown that the AP is uniquely both necessary and sufficient for the development of collagen antibody-induced arthritis (CAIA) in mice. However, the mechanisms whereby normal control of the AP is overcome and injury develops are unknown. The hypothesis pursued in the current studies is that fH plays a critical role in regulating the AP in immune complex-initiated injury in CAIA. We have examined the role of fH in CAIA by inhibiting its binding to tissues through administration of a recombinant dominant negative inhibitor containing murine SCR19–20 (rfH19–20), which impairs fH surface AP regulation, and the use of gene-targeted fH deficient mice.

Methods: CAIA was induced in C57BL/6 WT, $fH^{-/-}$ and $fH^{+/-}$ mice by injecting four anti-type II collagen (CII) mAbs i.p. on day 0 and lipopolysaccharide (LPS) i.p. on day 3. Intraperitoneal injections of 100 and 300 μg/mouse of rfH19–20 were carried out 15 min after the injection of mAb to CII on day 0 and again 15 min after LPS on day 3. Blood was drawn intraorbitally from all mice at day 0 prior to injection of mAb to CII, at day 3 prior to LPS injection, and at day 10 prior to sacrifice. All mice were sacrificed on day 10 for histopathologic scoring of injury and immunohistochemical analysis of C3 deposition. Control experiments were performed using rfH3–5 which does not inhibit fH binding to tissues. The absolute levels of C3, fH and C5a in serum of mice were measured by ELISA.

Results: Both doses of rfH19–20 significantly increased the clinical disease activity score (DAS) using a sub-maximal dose (0.5 mg/mouse) of anti-CII mAbs. Scores for histopathologic injury and C3 deposition on the surface of the cartilage and in the synovium increased with treatment in an identical fashion. No significant differences in the DAS were observed when WT mice were treated with 300 μg/mouse of control rfH3–5. $fH^{-/-}$ mice, compared with WT mice, were resistant to CAIA due to the significantly reduced serum levels of C3. WT and $fH^{+/-}$ mice have identical serum levels of C3, but $fH^{+/-}$ mice have 30% reduced levels of fH. WT and $fH^{+/-}$ mice developed indistinguishable DAS using a sub-maximal dose as well as a maximum dose (8 mg) of anti-CII mAb. In addition, though, the DAS at day 10 in $fH^{+/-}$ mice treated with 300 μg/mouse of rfH19–20 increased to 5.5 $\pm$ 0.65 compared with untreated $fH^{+/-}$ mice which was 1.75 $\pm$ 0.25 (p < 0.05).

Conclusion: We show for the first time that endogenous fH makes a significant contribution to regulating immune complex-induced injury in CAIA through binding to target surfaces via SCR19–20 and blocking AP activation and amplification.

Protein Kinase C Inhibitor Generates Human Tolerogenic Dendritic Cells That Induce Tr1 and Foxp3$^+$ Regulatory T Cells. Takuya Matsumoto, Hitoshi Hasegawa, Jun Ishizaki, Koichiro Suemori, Sachiko Onishi and Masaki Yasukawa. Ehime University Graduate School of Medicine, Toon, Japan

Background/Purpose: Tolerogenic dendritic cells (tDCs) play a critical role in immune tolerance and are involved in the pathogenesis of autoimmune diseases such as rheumatoid arthritis. Suppression by tDCs is primarily mediated via the induction of regulatory T cells (Treg). tDCs are induced in the presence of specific biological agents. Therefore, we screened the molecules that enhanced induction of tDCs from the libraries of lipids, nuclear receptor ligands, and kinase inhibitors. Of these, protein kinase C inhibitors (PKCIs) such as bisindolylmaleimide I, Go6983, and Ro32–0243, suppressed the expression of CD80, CD83, and CD86 on DCs and suppressed allogenic T cell responses. In this study, we showed the characterization of PKCI-treated human tDCs and application to the therapy for autoimmune diseases.

Methods: Mature DCs (mDCs) were prepared from human monocytes by treating with GM-CSF and IL-4 for 5 days, and then induced maturation wtih TNF-alpha for 48h. PKCI-treated tDCs were generated by adding bisindolylmaleimide I, Go6983, or Ro32–0243 during this process. We analyzed the cell surface expression on DCs, cytokine production, and phagocytic ability. Furthermore, we examined the effects of these molecules on stability and plasticity of DCs, antigen presenting, allogenic T cell responses, and induction of Tr1 and Treg cells.

Results: DCs treated with PKC inhibitors such as bisindolylmaleimide I, Go6983, and Ro32–0243 decreased the expression levels of CD40, CD80, CD83, CD86, and HLA class I significantly but not those of CD1a, CD11c, and HLA classII compared with mDCs. Moreover, PKCI-treated tDCs produced 15–20-fold and 2–4-fold higher concentration of IL-10 and TGF-beta than mDCs, respectively, resulting in a strong reduction of allogenic T cell responses. From the co-culture of DCs and naïve T cells, PKCI-treated tDCs induced IL-10-producing Tr1 cells and Foxp3$^+$ regulatory T cells. PKCI-treated tDCs retained phagocytic ability as well as immature DCs (iDCs). PKC I-treated tDCs kept the low expression levels of CD80, CD83, and CD86 and suppressive properties at least one week after stimulated with a cocktail of proinflammatory cytokines or LPS, whereas iDCs recovered the similar expression levels to mDCs and did not have suppressive properties.

Conclusion: We showed that PKCI-treated human DCs acted as a strong and stable tDCs. PKCI-treated tDCs may be useful method to the therapy for autoimmune diseases.

Generation of Myeloid-Derived Suppressor Cells in Vitro From Murine Bone Marrow Precursors. Julia Kurko, Beata Tryniszewska, Tibor A. Rauch, Colt Egelston, Tibor T. Glant and Katalin Mikecz. Rush University Medical Center, Chicago, IL

Background/Purpose: Myeloid-derived suppressor cells (MDSCs) are innate immune cells that expand under pathological conditions (such as cancer and autoimmune diseases) in response to local growth factors or cytokines. MDSCs are a heterogeneous population of immature myeloid lineage (monocyte-like and granulocyte-like) cells with immunosuppressive ability. These cells have the potential to down-regulate autoreactive T cell responses in autoimmune diseases such as rheumatoid arthritis (RA). Using proteoglycan (PG)-induced arthritis (PGIA), a mouse model of RA, we previously reported that MDSCs are present in synovial fluid (SF) of the arthritic joints of mice and suppress antigen-specific T cell proliferation. As the number of cells that can be collected from murine SF is limited and SF MDSCs do not expand in culture, we sought an alternative source for generating greater quantities of MDSCs for potential therapeutic intervention (via cell transfer) in PGIA.

Methods: Bone marrow (BM) cells were isolated from naïve BALB/c mice and cultured in the presence of recombinant murine granulocyte macrophage colony-stimulating factor (GM-CSF), granulocyte colony-stimulating factor (G-CSF) and interleukin-6 (IL-6) for up to 7 days. After

harvest, the phenotype of cells was evaluated by flow cytometry. Their suppressive function towards PG-specific T cells was tested by co-culture with PG-loaded BM-derived dendritic cells (DCs) and T cells from naïve PG-specific T cell receptor transgenic (PG-TCR-Tg) mice. The mechanisms of MDSC-mediated suppression were investigated using inhibitors of MDSC-produced effector molecules including arginase-1, inducible nitric oxide (NO) synthase (iNOS), and reactive oxygen species. Expression of MDSC effector molecules was analyzed by RT-PCR and Western blot.

Results: Similar to SF MDSCs, BM-derived MDSCs expressed the common myeloid marker CD11b. However, unlike SF MDSCs, BM MDSCs contained a smaller population of Ly6G positive (granulocyte-like) cells, and the majority of them expressed both Ly6G and the monocytoid cell surface marker Ly6C. Upon co-culture with PG-TCR-Tg T cells in the presence of PG-loaded DCs, BM MDSCs profoundly inhibited the proliferation of T cells, thereby confirming their suppressor activity. BM cells grown with GM-CSF, G-CSF, and IL-6 for only 3 days already showed potent suppressive effect on T cell proliferation. Despite expression of Ly6C by most BM MDSCs, these cells retained their suppressor activity after depletion of the Ly6C positive population. Experiments with inhibitors of MDSC effector molecules revealed that the primary mechanism of suppression of T cell proliferation was via NO release. Indeed, iNOS expression in BM MDSCs was found elevated at both mRNA and protein levels.

Conclusion: We developed an in vitro culture method of generating large quantities of immunosupressive murine MDSCs. Characterization of the phenotype, gene expression, suppressor activity of BM-derived MDSCs revealed that these cells are similar to SF MDSCs, but are dominated by a less mature (double Ly6C/Ly6G positive) population. BM-derived MDSCs appear to be suitable for in vivo cell transfer experiments.

Identification of Highly Potent and Selective Interleukin-1 Receptor-Associated Kinase 4 Inhibitors for the Treatment of Rheumatic Diseases. Divya Chaudhary[1], Shaughnessy Robinson[2], Craig E. Masse[1], Matthew D. Wessel[2], Shawn Watts[2], Jeremy Greenwood[2], Mee Shelley[2], Mark Brewer[2], Geraldine Harriman[1], Leah L. Frye[2], Ronald T. Wester[1], Rosana Kapeller[1] and Donna Romero[1]. [1]Nimbus Discovery, Inc., Cambridge, MA, [2]Schrödinger, Inc., New York, NY

Background/Purpose: Interleukin-1 receptor-associated kinase 4 (IRAK4) is a key mediator of the innate immune response orchestrated by interleukin-1 receptor (IL-1R), interleukin-18 receptor (IL-18R), IL-33 receptor (IL-33R), and Toll-like receptors (TLRs). IRAK4 activation is mediated by MYD88, a common signaling adaptor protein downstream of these receptors. Mutations leading to inactivation or activation of MYD88 have been reported in patients with immune deficiencies and cancer, respectively. In addition, IRAK4-deficient humans are protected from chronic inflammatory diseases. Thus, IRAK4 is an attractive therapeutic target for the treatment of autoimmune diseases such as lupus. Historically, identification of potent and selective IRAK4 inhibitors has been challenging due to structural features in the catalytic binding site that block access to the hydrophobic back pocket. We have developed new structure-activity relationship (SAR) insights, including the identification of unstable (high-energy) hydration sites, which guide the design of potent and selective small molecule ligands.

Methods: Using this innovative structure-based approach, we designed, synthesized and tested small molecule inhibitors based on hits originated from a virtual screen. These novel compounds were profiled for IRAK4 kinase inhibition, selectivity, and drug-like properties. Furthermore, selected compounds were tested in THP1 cells, human peripheral blood mononuclear cells (hPBMCs) and whole blood for impact on LPS-, IL-1-, R848-, and/or CpG-mediated signaling. The inhibitors were also tested *in vivo* in acute LPS challenge and chronic collagen induced arthritis (CIA) models.

Results: Here, we feature three highly potent, selective IRAK4 inhibitors, ND-346, ND-2110 and ND-2158. The K_is of ND-346, ND-2110, and ND-2158 for IRAK4 are 50, 7.5 and 1 nM, respectively. These compounds are highly selective against 334 kinases, and are potent inhibitors of IL-1-induced IRAK1 degradation in MRC5 cells, LPS-, IL-1-, R848 (TLR-7 agonist)- and CpG (TLR-9 agonist)-induced cytokine production in hPBMCs and whole blood. Furthermore, these compounds are efficacious in the acute LPS challenge model *in vivo*, and ND-346 shows efficacy in rat CIA at 10 mg/kg (PO, QD).

Conclusion: Utilizing unique and innovative structure-based drug design, we have rapidly discovered potent and selective IRAK4 inhibitors as potential drug candidates for the treatment of chronic rheumatic diseases.

Dysfunction of Natural Killer and Natural Killer T Cells in Patients with Adult Onset Still's Disease. Young-Nan Cho[1], Sung-Ji Lee[1], Tae-Jong Kim[2], Hye-Mi Jin[1], Dong-Jin Park[2], Seung-Jung Kee[1] and Yong-Wook Park[1]. [1]Chonnam National University Medical School and Hospital, Gwangju, South Korea, [2]Chonnam National University Medical School, Gwangju, South Korea

Background/Purpose: Adult onset Still's disease (AOSD) is an uncommon systemic inflammatory disorder of unknown etiology. Natural killer (NK) cell dysfunction is frequently observed in some human autoimmune disease, such as systemic lupus erythematosus and rheumatoid arthritis. However, NK cell function has not previously been investigated in AOSD. Furthermore, the relation between NK and NKT cells has not been determined. Purpose of this study is to examine the levels and functions of NK and NKT cells, to investigate relationships between NK and NKT cells, and to determine the clinical relevance of NKT cell levels in patients with AOSD.

Methods: Patients with active untreated AOSD (n = 25) and age- and sex-matched healthy controls (n = 25) were enrolled in the study. NK and NKT cell levels were measured by flow cytometry. Peripheral blood mononuclear cells were cultured in vitro with α-galactosylceramide (α-GalCer). NK cytotoxicities against K562 cells and proliferation indices of NKT cells were estimated by flow cytometry.

Results: Percentages and absolute numbers of NKT cells were significantly lower in the peripheral blood of patients than in healthy controls. Proliferative responses of NKT cells to α-GalCer were also lower in patients, and this was found to be due to proinflammatory cytokines and NKT cell apoptosis. In addition, NK cytotoxicities were found to be significantly lower in patients than in healthy controls, but NK cell levels were comparable in the two groups. Notably, this NKT cell deficiency was found to be correlated with NK cell dysfunction and to reflect an active disease status. Furthermore, α-GalCer-mediated NK cytotoxicity, showing the interaction between NK and NKT cells, was significantly lower in patients than in healthy controls.

Conclusion: Our findings show that NKT cells are numerically and functionally deficient in AOSD. In addition, we report a novel observation that NK cell dysfunction is related to NKT cell deficiency. These findings provide important information concerning the pathogenesis of AOSD.

CD1c-Expressing Myeloid Dendritic Cells From Joints of Rheumatoid Arthritis Patients Produce Increased Levels of T Cell-Attracting Chemokines and Strongly Activate Autologous T Cells. F.M. Moret, C.E. Hack, F.P.J.G. Lafeber, T.R.D.J. Radstake and J.A.G. van Roon. University Medical Center Utrecht, Utrecht, Netherlands

Background/Purpose: Myeloid dendritic cells (mDCs) are potent T cell-activating antigen-presenting cells that have been implicated to play a crucial role in the regulation of tolerance and pro-inflammatory immune responses in many disease states, including rheumatoid arthritis (RA). Despite this, studies that have reported on the role of naturally occurring circulating mDCs in RA are scarce. Recently, CD1c mDCs from RA patients were suggested to migrate from the circulation to the joint where they exhibit a semi-mature phenotype. However, data on the capacity of these CD1c mDCs to regulate T cell activation in RA are lacking. The present study investigated the expression profiles of co-stimulatory molecules and pro-inflammatory mediators secreted by CD1c mDCs from synovial fluid (SF) versus peripheral blood (PB) of RA patients and studied their capacity to stimulate autologous CD4 T cell proliferation and cytokine production.

Methods: CD1c mDC numbers and their expression of surface molecules involved in T cell activation were assessed by FACS analysis in SF and PB from RA patients (n=9). Production of inflammatory mediators by CD1c mDCs from SF and PB of RA patients (n=6) was determined after 20h of

culture by multiplex immunoassay (measuring 51 cytokines). The capacity of CD1c mDCs from SF (n=5) and PB (n=11) to activate autologous CD4 T cell proliferation in the absence of additional stimuli was measured after 6 days of culture by ^{3}H-thymidine incorporation assay. Additionally, T-cell cytokine production was measured upon ionomycin/PMA restimulation.

Results: The number of CD1c mDCs was significantly increased in SF versus PB of RA patients (mean 5.0% vs. 0.6%, resp., p<0.01). mDCs from SF showed increased expression of CD80 and CD86 (CD80: MFI 131 vs. 68, p<0.04; CD86: 157 vs. 89, p<0.02, resp.). Furthermore, the number of positive mDCs for HLA-II, CD80 and CD40 was significantly increased in SF versus PB (all p<0.05). Numerous cytokines were abundantly and equally produced by mDCs both from PB and SF (incl. IL-12, IL-23, IL-13, IL-21). mDCs from SF produced higher IP10, MIG, TARC, and OPG concentrations as compared to mDCs from PB (IP10: 247 vs. 54, p<0.05; MIG: 90 vs. 24, p<0.01; TARC: 26 vs. 1, p<0.01; OPG: 354 vs. 156, p<0.05, resp., all pg/ml). By contrast, MDC secretion by mDCs from SF was significantly lower than mDCs from PB (2456 vs. 4397 pg/ml, p<0.05, resp.). mDCs from SF had a strongly increased capacity to induce proliferation of CD4 T cells as compared to mDCs from PB (ratio DC:T cell 1:5, 26935 vs. 1503 CPM, p<0.01, resp.). The augmented T cell proliferation was associated with a strongly increased IFNγ, IL-17, and IL-4 cytokine production (ratio DC:T cell 1:5, SF vs. PB, IFNγ: 3428 vs. 179 pg/ml; IL-17: 363 vs. 39 pg/ml; IL-4: 193 vs. 17 pg/ml, resp.).

Conclusion: The present study indicates that increased numbers of CD1c mDCs in SF play an essential role in the inflammation cascade by the secretion of specific T cell-attracting chemokines and the activation of self-reactive T cells to induce Th1, Th17, and Th2 activity. Targeting of CD1c mDCs or the specific triggers of these cells could represent a novel therapeutic approach to prevent immunopathology of RA.

Hypoxia-Inducible Factor-1α: Trigger of Toll-Like Receptor Signalling-Engaged Inflammation in Rheumatoid Arthritis. Fanlei Hu[1], Rong Mu[1], Jiaxin Zhu[1], Wenwei Shao[2], Lianjie Shi[1], Philip L. Cohen[3], Xiaoyan Qiu[2] and Zhanguo Li[1]. [1]Peking University People's Hospital, Beijing, China, [2]School of Basic Medical Science, Peking University, Beijing, China, [3]Temple University, Philadelphia, PA

Background/Purpose: Hyperplasia of synovial fibroblasts, infiltration with lymphocytes, and tissue hypoxia are the major characteristics of rheumatoid arthritis (RA). Data has confirmed the central role of toll-like receptors (TLRs) in RA. However, much remains unknown regarding the impact of hypoxia on TLR signalling-induced inflammatory response in RA. The aim of this study was to reveal the effect of hypoxia and its regulator hypoxia-inducible factor-1α (HIF-1α) on the inflammatory response in rheumatoid arthritis synovial fibroblast (RASF) upon the recognition of pathogen molecules.

Methods: Hypoxia was induced in RASF by incubation with $Na_2S_2O_4$. TLR3 ligand polyIC, TLR2 ligand PGN, TLR4 ligand LPS, and TLR9 ligand CpG were used to stimulate the cells. Effects of hypoxia on these ligands-induced inflammatory cytokines and matrix metalloproteinases (MMPs) were determined by RT-PCR, realtime PCR, and ELISA. Overexpressing HIF-1α as well as knocking-down its expression by siRNA were used to reveal its fundamental role. RASF-induced inflammatory T cell expansion was determined by flow cytometry, realtime PCR, and ELISA analyses after RASF/T cell coculture.

Results: Hypoxia potentiated the expression of inflammatory cytokines, MMPs, and VEGF in RASF stimulated by different TLR ligands, especially polyIC, a synthetic mimic of dsRNA from virus or apoptotic cells. HIF-1α played a fundamental role in this synergy. Moreover, overexpression of HIF-1α enhanced RASF-mediated inflammatory T cell expansion, inducing more proinflammatory IFN-γ and IL-17 production.

Conclusion: Our findings suggest that hypoxia and HIF-1α may function collaboratively with TLR-engaged inflammatory response to excerbrate the pathogenesis of RA, and HIF-1α might serve as a therapeutic target for this disease.

1066

Extrathymic Autoimmune Regulator (AIRE) Expression in Rheumatoid Arthritis. A.R. Noort[1], K.P.M. van Zoest[1], M.C. Lebre[1], P. P. Tak[2] and S.W. Tas[1]. [1]Academic Medical Center/University of Amsterdam, Amsterdam, Netherlands, [2]Academic Medical Center/University of Amsterdam and GlaxoSmithKline, Amsterdam, Netherlands

Background/Purpose: The Autoimmune Regulator (AIRE) is a transcription factor that is involved in the negative selection of self-reactive thymocytes in the thymus and therefore is pivotal in the establishment of central tolerance. It has been suggested that non-canonical NF-kappaB signaling is required for thymic AIRE expression. Recently, AIRE protein has also been detected in peripheral lymphoid organs, predominantly in dendritic cells (DC). In these peripheral sites, AIRE was found to regulate the expression of a group of tissue-specific antigens that is distinct from those expressed in the thymus, suggesting that peripheral AIRE may play a complementary role in tolerance induction. It is currently unknown whether AIRE may play a role in inflamed tissues associated with ectopic lymphoid neogenesis, such as rheumatoid arthritis (RA) synovial tissue (ST).

Objective: To document and further characterize extrathymic AIRE expressing cells in ST and paired peripheral blood (PB) mononuclear cells (MCs) as well synovial fluid (SF) MCs of RA patients.

Methods: ST was obtained via mini-arthroscopy from inflamed joints of RA or undifferentiated arthritis (UA) patients. Expression of AIRE was evaluated using immunohistochemistry and immunofluorescence (IF) microscopy. AIRE expression was also investigated in PB and SF DC using flow cytometry.

Results: AIRE expressing cells were detected in 80% of analyzed RA ST and in contrast only in 25% of UA ST. Further characterization using double-immunofluorescence microscopy revealed that these cells were predominantly CD1c (BDCA1)[+] myeloid (m)DC. Interestingly, a significantly higher percentage of CD1c+ mDC in RA SF expressed AIRE (55 + 5 %; n=12) compared to RA PB (20 + 3 %; n=12; p<0.05) and healthy PB (19.7 + 2 %; n=5; p<0.05).

Conclusion: Extrathymic AIRE expressing cells are present in RA ST and RA SF, suggesting a role in synovial inflammation. These AIRE expressing cells appear to be mainly CD1c+ mDCs. Extrathymic AIRE expression in RA synovial inflammation may be an attempt to control inflammation through the induction of peripheral tolerance to antigens involved in the perpetuation of the chronic inflammatory response. This mechanism may be exploited to develop new treatments for RA patients.

1067

Spontaneous Aggregation of the Anti-Viral Mavs Protein in Certain Systemic Lupus Erythematosus Patients May Explain Excessive Type I Interferon Production. Philip L. Cohen[1] and Wen-Hai Shao[2]. [1]Temple University, Philadelphia, PA, [2]Temple University School of Medicine, Philadelphia, PA

Background/Purpose: Patients with systemic lupus (SLE) often have increased type I interferon levels (IFN-I) and activation of IFN-inducible genes (IFN signature). The mitochondrial adaptor protein MAVS (also known as IPS1, VISA or CARDIF) is a key intermediary in the RIG-I pathway, where viral RNA triggers a conformational change in RIG-I, leading to MAVS activation and then downstream activation of IKK and TBK1, with subsequent IFN production driven by IRF-3/7 (IRF3 for IFN-beta; IRF7 for IFN-alpha) and NFkB activation and translocation. Using *in vitro* methods, it has been observed that MAVS may form large prion-like aggregates that might stimulate IFN-I activation in a potent and prolonged fashion (Hou et. al., *Cell* 146:448, 2011). We wondered if such aggregates might be detectable *ex vivo* in SLE patients, and whether they might play a role in the sustained increased production of IFN-I.

Methods: Peripheral blood mononuclear cells (PBMCs) were isolated from 17 patients fulfilling ACR criteria for SLE, and from 9 controls. Thirty million PBMCs were lysed and supernatants loaded onto semi-denaturing 1.5% vertical agarose gels. After electrophoresis, the proteins were transferred to membranes for immunoblotting with anti-MAVS antibody or anti-beta-actin.

Results: Four of 17 SLE patients showed clear MAVS aggregation, with essentially all of their MAVS protein in a high molecular weight aggregated form. None of 9 controls had abnormal MAVS. Three of the four

aggregation-positive SLE patients had nephritis and the fourth had lung involvement. SLEDAI scores of MAVS-aggregate positive SLE patients did not differ from patients with normal molecular weight MAVS. Patient 4 (P-4) shows the aggregated MAVS phenotype in the western blot below (Panel B, P-4). Denatured MAVS immunoblotting is shown in panel A and actin immunoblotting in panel C. N-1 and N-2 are normal controls. P-1 has less protein loaded and no MAVS band is discernible.
Conclusion: This is the first report of aggregated MAVS in human cells. The significance of this abnormality needs further investigation, it is possible that prolonged and increased IFN-I production could result from such MAVS aggregation, and that the poorly degradable prion-like protein could signal IFN-I production for prolonged periods.

A Selective Inhibitor of Endosomal Toll-Like Receptors, IMO-8400, Suppresses Activation of Multiple Cytokines, Th17 Response and Inflammasome Activation. Weiven Jiang, Fugang Zhu, Dong Yu, Ekambar R. Kandimalla. Nicola La Monica and Sudhir Agrawal, Idera Pharmaceuticals, Cambridge, MA

Background/Purpose: In autoimmune diseases, activation of Th1 and Th17 pathways has been associated with disease maintenance and progression. Engagement of endosomal Toll-like receptors (TLRs) 7, 8 and 9 through interaction with immune complexes containing nucleic acids induces production of proinflammatory cytokines leading to the activation of Th1 and Th17 responses. Blocking the engagement of these receptors through an antagonist may inhibit this pathway, thus providing a novel approach to the treatment of autoimmune diseases.

Methods: In C57BL/6 mice, psoriasis-like skin lesions were induced by intradermal injection of IL-23. Skin lesions were examined histopathologically and gene expression was monitored. IL-23 injection stimulated upregulation in the skin of genes of multiple cytokines (including IL-12, IL-21, IL-23 and IL-17) keratinocyte peptides (including LL-37) and inflammasome protein NLRP3. Treatment of mice with IMO-8400 was carried out by subcutaneous administration.

Results: IMO-8400 was well tolerated at the dose level used in this study. IMO-8400 treatment showed reduction in epidermal hyperplasia and infiltration of leukocytes. In addition, mice treated with IMO-8400 showed suppression of multiple cytokines including IL-12, IL-21, IL-23 and IL-17 compared to untreated mice. Expression of inflammasome protein NLRP3 and of keratinocyte genes Defensin B4, S100a4 and LL-37 was also suppressed in IMO-8400 treated mice compared to untreated mice.

Conclusion: Treatment with IMO-8400 exerts a therapeutic effect on the IL-23 mediated induction of psoriatic lesions by blocking Th1 and Th17 pathways and NLRP3. IMO-8400 is in development for the treatment of lupus and other autoimmune diseases.

The Effects of TNF Stimulation On Control of Apoptosis in Neutrophils. Direkrit Chiewchengchol, Connie Lam, Kate Roberts, Helen Wright, Huw Thomas, Robert Moots and Steven Edwards. University of Liverpool, Liverpool, United Kingdom

Background/Purpose: TNF is a key regulator of immune function and plays a pivotal role in inflammatory conditions such as rheumatoid arthritis. Human neutrophils express and release TNF, and are activated by it. Neutrophil responses to TNF are bimodal: low concentrations of TNF (10 ng/mL) delay apoptosis but higher concentrations (>20 ng/mL) accelerate apoptosis. When neutrophils are activated to express TNF, complex regulatory mechanisms must control their response to both autocrine and paracrine signalling. This study investigated the mechanisms by which neutrophils respond to anti-apoptotic concentrations of TNF and control apoptosis delay.

Methods: Human neutrophils were exposed to 10 ng/mL of TNF: apoptosis was determined by flow cytometry (annexin V/PI binding); gene expression was determined by analysis of mRNA levels, flow cytometery and western blotting.

Results: Transcriptome analysis revealed that TNF signalling significantly increased mRNA levels for TNF, ICAM1, TNFAIP3, CD40, BFL1 plus several genes associated with NF-kB signalling. In contrast, mRNA levels of TNF receptor 1, TNF receptor 2, FADD, Bax and Caspase 8 were all significantly down-regulated. Many of these changes in mRNA levels were paralleled by changes in protein levels. These data indicate that neutrophils contribute to TNF-mediated signalling pathways via activated secretion of this cytokine. In parallel, they up-regulate genes that delay apoptosis (e.g. BFL1) but down-regulate expression of pro-apoptotic genes such as Bax and FADD.

Conclusion: These data shed important new insights into understanding the function of neutrophils in inflammation and inflammatory diseases; neutrophils contribute to TNF-mediated inflammation and in doing so become more resistant to apoptosis.

CD11c+ Dendritic Cells Play an Important Proinflammatory Role in Inflammatory Arthritis. Antonia Puchner[1], Stephan Blüml[2], Harald Leiss[2], Victoria Saferding[2] and Kurt Redlich[2]. [1]Medical University Vienna, Vienna, Austria, [2]Medical University of Vienna, Vienna, Austria

Background/Purpose: Dendritic cells (DCs) play an important role in bridging innate and adaptive immune responses by serving as antigen presenting cells. Therefore DCs are implicated in the initiation of chronic autoimmune diseases, including rheumatoid arthritis. Using the K/BxN serum transfer arthritis, a model of human rheumatoid arthritis, which depends only on the innate immune system, allowed us to investigate the innate role of dendritic cells in inflammatory arthritis.

Methods: KBxN serum transfer arthritis was induced in CD11c-diphteria toxin receptor (DTR) transgenic mice, which express the human diphtheria-toxin receptor under the CD11c promoter. This allows for specific depletion of CD11c+ cells by administration of diphtheria toxin (DT). DT or PBS was given on day −1, 3, 6 and 9 and the severity of arthritis was determined clinically and histologically. In addition, serum transfer arthritis was induced in wild type animals who also received DT.

Results: Efficient depletion of DCs after injection of DT was confirmed by flow cytometry and histological analysis of spleens of CD11c-DTR transgenic mice. Clinical scores of arthritis showed that CD11c-DTR transgenic mice had significantly reduced paw swelling and loss of grip strength after administration of DT when compared to PBS treated animals. Moreover, histological analysis showed decreased synovial inflammation and a trend towards reduced local bone destruction in these animals. In contrast, in wild type mice receiving DT we detected identical clinical signs of arthritis as in PBS treated animals, indicating that DT has no unspecific effects on the development of arthritis.

Conclusion: These data show that DCs are involved in innate reactions leading to inflammatory arthritis and therefore could be an important target for treating rheumatoid arthritis.

TLR3 As a Therapeutic Target for OA? Ashwini Maratha and Sinead M. Miggin. Immune Signalling Laboratory, Maynooth, Ireland

Background/Purpose: Osteoarthritis (OA) is a multifactorial and most disabling disease that affects millions of people globally, with a largely unknown aetiology. OA is now considered a whole-joint inflammatory disease, associated with synovitis of the fibroblast-like synoviocytes (FLS). FLS are sentinel cells that contribute to OA pathogenesis, possibly through activation of the innate immune Toll-Like Receptors (TLRs) aiding in induction of inflammatory mediators and cellular infiltration, however, the exact role of TLRs in OA is poorly understood. The aim of the research work was to characterise the role and functionality of TLRs in OA and to identify the key TLR/s that modulate OA pathology.

Methods: TLR3 neutralisation assays, ELISA, Proteomics, Confocal analysis, Immunoblot analysis, Luciferase reporter gene assays.

Results: Interestingly, we found that TLR3, activated by Poly(I:C)/ dsRNA, RNA from necrotic cells or OA synovial fluid, plays a key role in OA and this was confirmed by neutralisation of TLR3 expression which shifted the balance from pro-inflammatory to an anti-inflammatory cytokine milieu. Next, using a proteomic approach, we found that prohibitin 1 (PHB1), an anti-proliferative and anti-inflammatory molecule, was drastically down-regulated in FLS upon poly(I:C) stimulation and in whole synovial tissue biopsies from early and late stage OA. Interestingly, neutralisation of surface bound TLR3 in FLS restored the PHB1 levels and showed an immuno-modulatory/signal transduction modulatory role by employing anti-TLR3 antibody. These findings were supported by confocal and immunoblot analysis in FLS and through luciferase reporter gene assays in HEK293-TLR3, MAVS-wild type and deficient MEFs.

Conclusion: Thus, our data suggests that TLR3 hyper-activation plays a key role in perpetuating synovial inflammation in OA and suggests that therapeutic intervention of OA may be achieved through TLR3 blockade. *Kindly supported by the Health Research Board of Ireland.*

Enzymatic Lipid Oxidation Contributes to the Maintenance of Self-Tolerance by Regulating Antigen Clearance and Dendritic Cell Function. Stefan Uderhardt[1], Tobias Rothe[1], Elisabeth Zinser[1], Olga Oskolkova[2], Martin Herrmann[3], Alexander Steinkasserer[4], Valery Bochkov[2], Georg Schett[5] and Gerhard Kronke[1]. [1]University of Erlangen, Erlangen, Germany, [2]Department of Vascular Biology and Thrombosis Research, Center for Physiology and Pharmacology, Medical University of Vienna, Vienna, Austria, Vienna, Austria, [3]PhD, Erlangen, Germany, [4]Department of Immune Modulation at the Department of Dermatology, University Hospital Erlangen, Erlangen, Germany, [5]Institute for Clinical Immunology, University of Erlangen-Nuremberg, Erlangen, Germany

Background/Purpose: During inflammation and tissue damage, pathogens as well as dying cells are ingested by different phagocytes such as macrophages and dendritic cells. The uptake of particles and subsequent presentation of derived antigens by antigen presenting cells (APC) are key events in the initiation of an adaptive immune response. Thus, both the nature and the activation state of the respective phagocyte determine the resulting immune response ranging from specific immunity to tolerance. However, defects and alterations of these processes are associated with chronic inflammation and autoimmunity. Specific lipid oxidation products, generated by the enzyme 12/15-lipoxygenase (12/15-LO) were implicated in the active resolution of inflammation and limitation of inflammation-associated tissue damage. In this study, we investigated the potential role of enzymatic lipid oxidation by 12/15-LO during initiation of an adaptive immune response and the maintenance of self-tolerance.

Methods: We studied both the clearance of AC and pathogens, as well as the maturation and function of monocyte-derived, antigen-presenting phagocytes in wildtype and 12/15-LO $-/-$ animals *in vitro* and *in vivo*, respectively.

Results: We observed a pivotal role of 12/15-LO in the maintenance of self-tolerance as aged 12/15-LO-deficient mice spontaneously developed autoimmune features indicating a break of self-tolerance. Moreover, a loss of 12/15-LO resulted in an exacerbation of a murine disease model of experimental autoimmune encephalomyelitis (EAE), which resembles clinical and pathological hallmarks of human multiple sclerosis.

Consistently, 12/15-LO $-/-$ mice showed a disturbed clearance of AC under inflammatory conditions, with a clear shift of phagocytosis towards pro-inflammatory antigen-presenting cells. In addition, we could detect a marked expression of 12/15-LO in *in vitro*-generated bone marrow-derived dendritic cells (BMDC). Interestingly, BMDC isolated from 12/15-LO $-/-$ mice presented an increased expression of co-stimulatory molecules on their surface, accompanied by an altered pro-inflammatory cytokine profile. Under inflammatory conditions, the uptake of AC-derived model-antigens by APC from 12/15-LO $-/-$ mice resulted in an increased antigen presentation and subsequent T cell activation, both *in vitro* and *in vivo*. By adding 12/15-LO-generated phospholipid oxidation products, we were, in turn, able to restore an anti-inflammatory clearance of AC *in vitro* and *in vivo*, down-regulate co-stimulatory markers expressed by APC and, thereby, limit T cell activation *in vitro*.

Conclusion: Together, these data indicate a potential regulatory role of enzymatic lipid oxidation by 12/15-LO during the initiation of an adaptive immune response by both orchestrating a cell- and context-specific clearance of antigens by different phagocyte subsets and regulating the maturation and activation status of the respective APC.

Disclosure: S. Uderhardt, None; **T. Rothe**, None; **E. Zinser**, None; **O. Oskolkova**, None; **M. Herrmann**, None; **A. Steinkasserer**, None; **V. Bochkov**, None; **G. Schett**, None; **G. Kronke**, None.

Increased Oxidative Burst in Neutrophils but Not Monocytes in Systemic Lupus Erythematosus. Sandro F. Perazzio[1], Reinaldo Salomao[1], Neusa P. Silva[2] and Luis Eduardo C. Andrade[3]. [1]Federal University of Sao Paulo, Sao Paulo, Brazil, [2]Escola Paulista de Medicina - Universidade Federal de São Paulo, Sao Paulo, Brazil, [3]Universidade Federal de São Paulo, Sao Paulo, Brazil

Background/Purpose: The role of innate immunity in the pathogenesis of Systemic Lupus Erythematosus (SLE) has acquired increasing importance lately. Chronic Granulomatosus Disease (CGD), a hereditary inability of phagocytes in producing Reactive Oxygen Species (ROS), has been associated with increased frequency of discoid lupus erythematosus (2.7%) and with SLE (0.5%). This study aimed to evaluate the oxidative response in monocytes and neutrophils from SLE patients and healthy controls (HC) at basal state and after bacterial stimulus.

Methods: 300 SLE patients and 301 age- and gender-paired HC (blood donors) were clinically examined and evaluated for quantification of the oxidative burst in phagocytes by flow cytometry based on the oxidation of 2,7-dichlorofluorescein-diacetate before and after stimuli with *Staphilococcus aureus* and *Pseudomonas aeruginosa*. There was a 7-day wash-out period for immunosuppressant drugs before sample collection.

Results: No patient or HC presented oxidative burst profile compatible with CGD, however one patient was classified as carrier of defective gene (0.33%). SLE neutrophils had higher basal oxidative activity than HC [mean fluorescence intensity (MFI)$=53.77\pm11.38$ versus 15.08 ± 2.63, respectively; $p<0.001$]. ROS production was also significantly higher in SLE as compared with HC after stimulation with *S. aureus* (MFI$=355.46\pm58.55$ versus 151.92 ± 28.25, respectively; $p<0.001$) or *P. aeruginosa* (MFI$=82.53\pm10.1$ versus 48.99 ± 6.74, respectively; $p<0.001$). Furthermore, the neutrophilic response after bacterial stimuli (DMFI = post-stimulus MFI minus basal MFI) was more intense in SLE than in HC (*S aureus*: 301.69 ± 54.42 versus 118.38 ± 26.03, respectively; $p<0.001$; *P aeruginosa*: 28.76 ± 12.3 versus 15.45 ± 5.15, respectively; $p<0.001$). Oxidative burst profile was not associated with disease activity (SLEDAI≥6) or severity (SLICC-DI≥2). Neutrophil basal ROS production was higher in patients with lupus nephritis (median MFI$=39.43$; ranging from 1.0 to 167.4) than in patients without nephritis (median MFI$=27.29$; ranging from 1.2 to 143.9; $p=0.014$). In addition neutrophils from patients with lupus nephritis (n$=166$) presented higher increment in ROS production after stimulus with *S. aureus* (median DMFI$=320.1$; ranging from 194.9 to 826.1) than neutrophils from patients without nephritis (n$=133$; median ΔMFI$=278.5$; ranging from 149.9 to 649.9; $p=0.03$). These differences in ROS production were not observed in monocytes from patients with lupus nephritis. There was no association of PMN oxidative burst profile and the therapeutic regimen.

Conclusion: Neutrophils from SLE patients presented increased basal ROS production and increased oxidative response to bacterial stimuli. These findings were particularly evident in patients with kidney involvement. The present findings corroborate the important role of innate

immunity in SLE and implicate neutrophils in the pathophysiology of the disease.

TLR2 Deletion Promotes Arthritis and Joint Destruction Through Reduction of IL-10. Qi Quan Huang[1], Renee E. Koessler[1], Robert Birkett[2], Harris R. Perlman[1], Lianping Xing[3] and Richard M. Pope[4]. [1]Northwestern University, Chicago, IL, [2]Northwestern University Feinberg School of Medicine, Chicago, IL, [3]University of Rochester, Rochester, NY, [4]Northwestern Univ Med School, Chicago, IL

Background/Purpose: TLR2 signaling pathway has been suggested as a potential therapeutic target in RA. However, studies with mice deficient in TLR2 (TLR2−/−) and IL-1Ra suggest that TLR2 may suppress arthritis mediated through increased interferon-γ, and reduced TGFβ and T regulatory cell function. In order to determine the role of TLR2 deletion on the effector phase of arthritis, studies were performed with the K/BxN serum transfer model of RA, mediated by antibodies to glucose-6-phosphate isomerase (GPI) which results in an immune complex-mediated arthritis.

Methods: Wild type and homozygous $Tlr2^{\text{tm1Kir}}$ mutation ($Tlr2$−/−) mice on the C57Bl/6 background were injected intraperitoneally with 100 ml anti-GPI serum and evaluated between days 0 to 9 post-induction by ankle swelling and clinical score. Ankles were harvested and sections analyzed by hematoxylin and eosin, and TRAP activity staining for osteoclasts. IL-1b, IL-10, RANKL and osteoprotegerin (OPG) in ankle homogenates were quantified by ELISA. Bone marrow-derived macrophages (BMM) were generated from wild type and $Tlr2$−/− mice by *in vitro* differentiation in GM-CSF for 7 days. BMM activation was induced by incubation with model immune complexes employing mouse IgG coated on plastic plates for 4 hours. Supernatants were assessed for TNFα and IL-10 expression by ELISA. The macrophage Fc receptor mediated macrophage signaling was assessed by immunoblot analysis employing phospho-antibodies to Akt, p38, and ERK. Fc receptor expression on cell membranes was determined employing antibodies to CD16/CD32, analyzed by flow cytometry. Macrophage Fc receptor isoform expression at mRNA level was determined by quantitative real-time RT-PCR.

Results: The transfer of anti-GPI serum resulted in significantly worse arthritis in TLR2−/− mice compared to wild type controls. Histological exam demonstrated more inflammation and joint destruction. Examination of the joints homogenates collected at the peak of inflammation (day7 post-induction) revealed increased IL-1b and decreased IL-10 in TLR2−/− mice. TLR2 deficiency also resulted in increased osteoclasts, identified by TRAP staining. There was a trend toward reduction of OPG (p = 0.056) in the ankles of TLR2−/− mice, and a strong negative correlation (p < 0.001) between OPG and joint swelling. There was no difference in the expression of inhibitory or activating Fc receptors in TLR2−/− mice. However, activation of TLR2−/− macrophages with immune complexes resulted in significantly reduced IL-10, while there was no difference in TNFa, compared to the controls. Macrophages from the TLR2−/− demonstrated decreased activation of Akt, but not ERK or p38, following activation with immune complexes.

Conclusion: These observations demonstrate that deletion of TLR2 exacerbates serum transfer-induced arthritis. In the absence of TLR2, there was a reduction of IL-10 in the joints, and this may be due to the reduced activation of Akt by immune complexes. These observations demonstrate cross-talk between TLR2 and Fc receptor signaling modulates the effector phase of inflammatory arthritis.

1075

Effects of siRNA Depletion of Interferon Regulatory Factor 5 On Pro-Inflammatory Cytokine Production and IgG Secretion by Primary Human Immune Cells in Response to TLR7/8 Stimulation. Dinesh Srinivasan[1], Sandip Panicker[2], Gang Lu[1], Yajuan Gu[1], Rothschild Soto[2], Seng-Lai Tan[1] and Julie Demartino[1] [1]Hoffmann-La Roche, Nutley, NJ, [2]Hoffmann La Roche, Nutley, NJ

Background/Purpose: Interferon regulatory factor 5 (IRF5) has been identified as a genetic risk factor for multiple human autoimmune disorders, including systemic lupus erythematosus (SLE), rheumatoid arthritis, multiple sclerosis and systemic sclerosis. Knockout animal studies suggest IRF5 plays an important role in the regulation of pro-inflammatory cytokine production, type I interferon production as well as IgG secretion. The aim of this study was to examine the contribution of IRF5 to pro-inflammatory cytokine production and IgG secretion by primary human immune cells in response to TLR7/8 agonist, R848,. For comparison purpose, the role of NFkB and interferon regulatory factor 7 was also evaluated.

Methods: Monocytes and total B cells were isolated from healthy volunteers. Monocytes were further differentiated into monocyte derived dendritic cells (MDDC) using IL-4 and GM-CSF or into monocyte derived macrophages (MDMC) using GM-CSF. Expression of IRF5 was confirmed by Western Blot analysis and mRNA expression analysis. siRNA to IRF5 were introduced using Amaxa Nucleofector. Knockdown of IRF5 in the MDDC, MDMC and B cells was confirmed by Western Blot. Cells were then stimulated with R848 o/n and cytokine levels in the supernatant were measured. Cytokines measured included IL-6, TNF-a, IL-12 and IL-23 and were detected using Alphalisa or ELISA based methods. IgG levels in supernatant from B cells were measured after 7 days. Data were normalized to cell number as determined by *CellTiter-Glo®* viability assay (Promega).

Results: Western blot data and mRNA expression analysis confirmed the expression of IRF5 in the cell types tested. As expected, expression of IRF5 in MDDC and MDMC increased during differentiation. Using nucleofection, we typically obtained about 40–60% depletion of IRF5 proteinby the siRNA, which persisted up to 48h. We found that the knockdown of IRF5 in MDDC, MDMC and B cells significantly attenuated IL-6 and TNF-a produced by R848 stimulated cells. The level of attenuation was similar to that obtained using siRelA. No additional attenuation was observed when the siRNA to both IRF5 and RelA were combined. siIRF7 did not significantly attenuate IL-6 or TNF-a levels in MDDC. IL-12 and IL-23 production from MDDC stimulated with R848 were both attenuated by siIRF5. Interestingly, siRelA blocked IL-12 but did not affect IL-23 production from MDDC. In B cells, the siIRF5, but not siRelA, completely blocked R848 and CpGB-mediated IgG secretion.

Conclusion: In this report, we extend the known literature surrounding the role of IRF5 as a critical regulator of both pro-inflammatory cytokine production and IgG secretion downstream of TLR7/8. Furthermore, IRF5, but not NFkB, regulates R848-mediated IL-23production from MDDC and plays a critical role in IgG secretion by B cells.

1076

FLIP in Dendritic Cells May Regulate Hematopoietic Homeostasis and Modulating Inflammation and Immunity. Qi Quan Huang[1], Robert Birkett[2], Harris R. Perlman[1] and Richard M. Pope[3]. [1]Northwestern University, Chicago, IL, [2]Northwestern University Feinberg School of Medicine, Chicago, IL, [3]Northwestern Univ Med School, Chicago, IL

Background/Purpose: We previously demonstrated that FLIP in myeloid linage cells is necessary for neutrophil homeostasis and macrophage differentiation. Therefore studies were performed to determine the in vivo role of FLIP in CD11c positive dendritic cells.

Methods: Mice with Flip deficient in dendritic cells ($Flip^{\text{f/f}}$, $CD11c^{\text{cre/+}}$) were generated by crossing $Flip^{\text{f/f}}$ mice with a $CD11c^{\text{cre}}$ transgenic line. Cell types and differential in peripheral blood were determined by complete blood count. Cell types from different organs were determined by immunophenotyping employing multi-color fluorochrome-conjugated cell marker antibodies, analyzed by Flow cytometry. Age and gender matched mice were used as controls.

Results: Many phenotypic disorders developed in $Flip^{\text{f/f}}$, $CD11c^{\text{cre/+}}$ mice, including growth retardation (significantly reduced body size and weight) with increased severity in females, and approximately 15% died prematurely. Almost 40% of the mice that reached 4 months of age or older spontaneously experienced an arthropathy characterized by joint swelling and/or deformity. Proteinuria was not detected. All $Flip^{\text{f/f}}$, $CD11c^{\text{cre/+}}$ mice developed lymphadenopathy, but the spleens were normal both in size and in cell numbers. Immunophenotype analysis demonstrated a significant reduction CD11c,CD8 dendritic cells in the spleens of the $Flip^{\text{f/f}}$, $CD11c^{\text{cre/+}}$ mice. In $Flip^{\text{f/f}}$, $CD11c^{\text{cre/+}}$ mice granulocytes were significantly increased in peripheral blood, spleens, lymph nodes and peritoneal cavities and they infiltrated in all organs examined. Although circulating monocytes were significantly increased in $Flip^{\text{f/f}}$, $CD11c^{\text{cre/+}}$ mice, there is no difference in macrophage numbers in the organs examined. Although B cell numbers were increased in the lymph nodes of $Flip^{\text{f/f}}$, $CD11c^{\text{cre/+}}$ mice, which may contribute to lymphadenopathy, neither B cells nor T cells were increased in the peripheral blood or other organs.

Conclusion: The survival of CD11c+ dendritic cells in the spleen requires FLIP. The deletion of FLIP in CD11c dendritic cells also results in increased circulating neutrophils and a multiorgan neutrophil infiltration. A substantial proportion of these mice develop an arthropathy but proteinuria was not observed. FLIP expression in CD11c+ dendritic cells is necessary for survival in the spleen and for neutrophil homeostasis.

p21 Promotes Inflammatory Arthritis Resolution by Facilitating Alternative Activation of Macrophages. Angelica K. Gierut[1], Carla M. Cuda[2], Alexander V. Misharin[3], Rana Saber[3] and Harris R. Perlman[3]. [1]Northwestern Med Faculty Found, Chicago, IL, [2]Northwestern University Feinberg School of Medicine, Chicago, IL, [3]Northwestern University, Chicago, IL

Background/Purpose: Current understanding of pathogenesis suggests that RA is mainly a Th1 mediated process that promotes robust inflammatory cytokine production by "classically" activated macrophages. This is in contrast to Th2 diseases such as parasitic infection or allergy that balance potential catastrophic tissue destruction from large worm invasion, or chronic inflammatory response to ubiquitous proteins, by skewing macrophages to an alternatively activated state. Alternatively activated cells appear to be generated from local macrophage proliferation in pure Th2 environments. However, in conditions with concomitant Th1 stimuli, recruited monocytes can be skewed toward alternative activation as well. It is unknown what role alternative macrophages may play in RA. It seems reasonable to assume that their presence would be favorable given their "anti-inflammatory" properties. However, they theoretically have the potential to hinder response to, and clearance of, a yet unknown foreign antigen. Given that alternative macrophages display distinct proliferating capabilities, it seems reasonable to suspect that proteins controlling the cell cycle may be involved in their regulation. One such protein, a cyclin dependent kinase inhibitor, p21, is decreased in RA patient synovium, and is associated with worse serum transfer-induced arthritis (STIA) compared to wild type (WT) controls.

Methods: *In vitro* studies were done with bone marrow derived macrophages (BMDMs) and thioglycollate induced peritoneal macrophages (PMs). Cells were treated with stimuli for classical, alternative, and regulatory macrophage differentiation. Supernatants were analyzed for production of cytokines by ELISA, and for nitric oxide (NO) by colorimetry. Quantigene assays were performed for various genetic markers of macrophage phenotype. Mice were also injected IP with thioglycollate and IL-4, with or without BRDU added 3 hours prior to harvest. Peritoneal cells were assessed by flow cytometry. Finally, mice were treated with IV IL-4 + KBxN serum and observed for arthritis.

Results: *In vitro* analysis of skewed BMDMs and PMs revealed increased production of nitric oxide in p21−/− cells stimulated with interferon gamma + lipopolysaccharide compared to B6 control cells. Conversely, p21−/− BMDMs and PMs stimulated by IL-4 had less relm alpha mRNA, a marker of alternative activation. *In vivo* studies were concordant in that p21−/− mice treated with thioglycollate + IL-4 had less relm alpha protein expression by flow cytometry. Intriguingly, there was increased local proliferation of p21−/− PMs as measured by 3 hr BRDU incorporation. However, recently recruited p21−/− monocytes showed significantly less proliferation compared to B6. Finally, IV IL-4 significantly dampened STIA in B6 mice whereas arthritis in p21−/− mice was not attenuated.

Conclusion: p21 may promote homeostasis during inflammatory conditions by potentiating recruited monocytes and possibly local macrophage differentiation into alternatively activated states. This appears to be independent of its role as a cell-cycle inhibitor because monocytes recruited to inflammatory sites have *less* proliferation in the absence of p21.

Prolactin Is Increased in Responders to Anti-TNFα Treatment and the Role of the Prolactin Receptor in Rheumatoid Arthritis. Man Wai Tang[1], Danielle Marie Gerlag[2], Veronica Codullo[3], Elsa Vieira-Sousa[4], Anne Q. Reuwer[5], Marcel T. Twickler[5], Robert B. M. Landewé[6] and Paul Peter Tak[7]. [1]Academic Medical Center/University of Amsterdam, Amsterdam, Netherlands, [2]Academic Medical Center, Amsterdam, Netherlands, [3]Academic Medical Center/University of Amsterdam/University of Pavia, IRCCS Policlinico San Matteo Foundation, Amsterdam/Pavia, Netherlands, [4]Instituto de Medicina Molecular, Faculdade de Medicina da Universidade de Lisboa, Lisbon, Portugal, [5]Academic Medical Center/University of Amsterdam, Amsterddam, Netherlands, [6]Academic Medical Center/University of Amsterdam & Atrium Medical Center, Amsterdam, Netherlands, [7]Academic Medical Center/University of Amsterdam, Amsterdam, Netherlands

Background/Purpose: Rheumatoid arthritis (RA) is the most common rheumatic disease which mainly affects women. In the last decade, it is known that prolactin (PRL) is a sex hormone with immunomodulatory properties. It has been shown that high prolactin levels are associated with an increase of the disease activity postpartum and that the PRL inhibitor, bromocriptine, improves disease activity of patients with RA. Furthermore, the serum PRL levels correlated positively with the Larsen score.

Recently, the prolactin receptor (PRLR), belonging to the family of cytokine receptors, has been described in atherosclerotic plaques, mainly on macrophages.

The objective of the study is to determine 1) the level of PRL in RA patients related to rheumatoid factor (RF), anti-cylic citrullinated peptide antibodies (ACPA), erosive disease and response to anti-TNF treatment 2) PRLR expression in synovial tissue of RA, psoriatic arthritis (PsA) and osteoarthritis (OA) patients 3) the phenotype of the PRLR expressing cell.

Methods: Serum prolactin levels were measured using immunofluorescent metric assay in patients with RA before TNF-α blockade (n=101). The expression of PRLR was determined in synovial tissue (ST) of RA (n=91), PsA (n=15) and OA (n=9) patients using digital image analysis. Immunofluorescence (IF) was used to detect the PRLR expressing cell type.

Results: A trend towards higher PRL levels were found in patients who are rheumatoid factor positive compared to rheumatoid factor negative RA patients (5.0 (2–24) and 7.3 (2.5–36) μg/L; P=0.06). When the PRL levels were divided into 3 categories, the percentage of the RF positive patients had significantly higher PRL levels (P=0.021). A trend towards higher PRL levels were also seen in patients who are ACPA positive (P=0.063) and similar results with erosive disease (P=0.057). Baseline PRL levels were significantly lower in non-responders (median (range): 5.3 (2.0–22) ug/L) than in moderate (7.0 (2.5–36)) and responders (8.5 (4.0–19)) on anti-TNF treatment (P=0.025). Overall, the prolactin levels were similar between females and males.

PRLR expression was higher in RA (median (range): 0.055 (0.000–5.673) IOD/nuclei/mm^2) and PsA (0.182 (0.000–5.336)) compared to OA (0.000 (0.000–0.908); P=0.024; Fig 1). Using IF, co-localisation was observed with macrophages and endothelial cells. The expression of the PRLR was also confirmed by RT-PCR in macrophages.
Fig. 1 PRLR expression is higher in RA and PsA compared to OA.

Conclusion: Higher levels of PRL are found in patients who respond to anti-TNF treatment. The expression of the PRLR in synovial tissue, mainly by macrophages, is higher in the inflammatory diseases (RA and PsA) than in OA. Our combined data suggest an important role of prolactin and its receptor in RA.

Polyclonal CD4$^+$Foxp3$^+$ treg Cells Induce TGFb-Dependent Tolerogenic Dendritic Cells That Suppress Murine Lupus-Like Syndrome. Qin Lan[1] and Song G. Zheng[2]. [1]University of Southern California, Los Angeles, CA, [2]Keck School of Medicine of USC, Los Angeles, CA

Background/Purpose: Interplay between Foxp3$^+$ regulatory T cells (Treg) and dendritic cells (DCs) maintains immunologic tolerance, but the effects of each cell on the other are not well understood.

Methods: Naive CD4+Foxp3- cells isolated from DBA/2 mice were stimulated with anti-CD3/CD28 antibodies with IL-2 and TGF-β to develop polyclonal CD4+ iTregs. These cells were adoptively transferred to D2B6F1 mice that also received D2 spleen cells. Anti-IL-10R, Anti-TGFβ or ALK5 (TGFβRI) inhibitor was administrated in some groups of mice. To determine molecular mechanism, TGFβRII DC conditional KO mice were developed and colitis model was used. DC numbers and phenotypes were determined in chronic lupus mice before and after iTreg or Tcon cell treatment. DC were sorted in iTreg or Tcon treated groups and were adoptively transferred to another lupus mice to determine the therpeutic role of DC subsets.

Results: We report that polyclonal CD4$^+$Foxp3$^+$ Treg cells induced *ex-vivo* with TGFβ (iTreg) suppress a lupus-like chronic graft-versus-host disease by preventing the expansion of immunogenic DCs and inducing protective DCs that generate additional recipient CD4$^+$Foxp3$^+$ cells. The protective effects of the transferred iTreg cells required both IL-10 and TGFβ, but the tolerogenic effects of the iTreg on DCs, and the immunosuppressive effects of these DCs, was exclusively TGFβ-dependent. The iTreg were unable to tolerize *Tgfbr2*-deficient DCs.

Conclusion: These results support the essential role of DCs in "infectious tolerance" and emphasize the central role of TGFβ in protective iTreg/DCs interactions *in vivo*.

Effect of Anti-NKG2A Antibody Treatment On NK Cell Receptor Expression in Rheumatoid Arthritis Patients. Joseph Wahle, John Bui and Kristen Bontadelli. Novo Nordisk, Seattle, WA

Background/Purpose: This study explored the effect of *in vitro* blockade of the NKG2A HLA-E interaction on peripheral NK cells from rheumatoid arthritis patients. To block this interaction we have utilized an anti-NKG2A monoclonal antibody, NNC141-0100, a novel therapeutic mAb designed for the treatment of rheumatoid arthritis.

Natural killer cells are potent members of the innate immune system with both cytotoxic and cytokine producing ability. NK cells express a myriad of germ line encoded receptors on their surface that provide multiple pathways via which NK cells activity can be regulated. These receptors include both activating receptors, that recognize stress inducible ligands, and inhibitory receptors that provide protection to self via the recognition of HLA molecules. One such inhibitory receptor is NKG2A, which functions as a heterodimeric receptor with CD94, in order to recognize HLA-E and thereby block NK cell activation. Additionally, NK cells express a number of chemokine receptors and other homing related molecules. The expression of these molecules is crucial for the NK cell to maintain proper lymphoid and non-lymphoid tissue distribution as well as for NK cells to home to and remain at the site of inflammation.

Methods: A whole blood culture system that allows for up to 48 hours of whole blood culturing was utilized for all experiments. This technique allowed for exploring the effect of NKG2A blockade in the context of the complex interactions that exist in the periphery with minimal manipulation.

Results: The addition of the anti-NKG2A mAb to the whole blood cultures led to alteration of the surface phenotype of NK cells from rheumatoid arthritis patients. These alterations included the up-regulation of chemokine receptors as well as the modulation of CD27. This appeared to be a specific pattern of up-regulation as a wide panel of NK related receptors were explored and were not found to be altered. This up-regulation was also found to be rapid occurring within 24 hours of culture. Finally the effect was specific to RA patients as similar changes were not seen in normal donors.

Conclusion: These results indicate that treatment with an anti-NKG2A mAb may alter the homing potential of an NK cell to the site of inflammation. Once at the site of inflammation the presence of the anti-NKG2A mAb may skew the inhibitory balance and thus enable the elimination of stressed and/or inflamed cells. These two activities provide a novel mechanism of action, via the anti-NKG2A mAb, for the treatment of RA.

Toll-Like Receptor 7, 8 and 9 Activation of Primary Human Cells by Lupus Immune Complexes Is Dependent On Interleukin 1 Receptor Associated Kinase 4 Activity. Aaron Winkler, Weiyong Sun, Ken Dower, Elizabeth A. Murphy, Julia Shin, Michael Luong, Michael J. Primiano, Varenka A. Rodriguez, Tatyana Souza, Lih-Ling Lin, J. Perry Hall, Katherine Lee, Vikram R. Rao and Margaret Fleming. Pfizer, Cambridge, MA

Background/Purpose: Genetic, *in vitro* and *in vivo* evidence strongly implicate the activation of nucleic acid sensing toll like receptors (TLR) 7, 8, and 9 in the pathophysiology of systemic lupus erythematosus (SLE). IRAK4 is a serine/threonine kinase activated by TLRs that utilizes the MyD88 adaptor protein for signaling. The relative importance of IRAK4 scaffolding and kinase functions in signaling is not clear. Indeed, at least one recent report indicates profound differences between species, stimuli, and cell types with regard to the requirement of IRAK4 kinase activity for cell activation[1]. Utilizing a potent, selective and cell-permeable small molecule inhibitor of IRAK4, we queried the importance of IRAK4 kinase activity in primary human cell based assays utilizing SLE disease relevant stimuli.

Methods: Sera from SLE patients was screened for the ability to induce interferon-alpha (IFN-α) protein release from primary human plasmacytoid dendritic cells (pDC). Immunoglobulin-G (IgG) was purified from SLE sera that could induce IFN from pDCs, and then combined with debris from apoptotic U937 cells as a source of TLR 7, 8 and 9 ligands, to form SLE immune complexes (SLE-IC). Human peripheral blood mononuclear cells (PBMC) were stimulated with SLE-IC, and type I interferon (i.e., IFN-α) release in cell culture supernatant was assayed by ELISA. Type I IFN exposure can be monitored in whole blood from SLE patients using an IFN-responsive gene signature, so the expression of IFN-induced genes was assayed in RNA from SLE-IC stimulated PBMC using quantitative real-time polymerase chain reaction (qRT-PCR). As auto-antibody production by B cells is also a key component of pathophysiology in SLE, B cell activation and differentiation induced by TLR ligands was measured by flow cytometry, and cytokine release by B cells was measured by ELISA.

Results: The IRAK4 inhibitor potently blocked SLE-IC induced type I IFN release and IFN gene signature in PBMC. This compound also blocked B cell activation- B cell surface activation marker expression in response to R848 in whole blood, 7 day plasma cell differentiation in PBMC, and cytokine expression by purified B cells exposed to IFN-α and R848.

Conclusion: Using a potent and selective inhibitor of IRAK4 kinase activity in primary human cells, we can demonstrate that IRAK4 kinase activity is essential to inflammatory cytokine release, type I IFN production, and B cell activation, all of which are components of SLE pathophysiology *in vivo*.

Predictors of Persistence in People with Subacute Low Back Pain. Souraya Torbey, Ali Mansour, Kristina Herrmann, Marwan Baliki, Thomas J. Schnitzer and A. Vania Apkarian. Northwestern University, Chicago, IL

Background/Purpose: Acute pain is a vital adaptive and protective mechanism. Conversely, chronic pain is a persistent, maladaptive response that outlasts the normal healing period of an injury or insult, and may result in drastic deterioration of quality of life, sometimes for the rest of life. In a

longitudinal brain imaging study of people with subacute back pain, we recently identified brain markers by fMRI that predict transition to chronic pain. Here we investigate, in the same study, behavioral biomarkers that may be predictive of pain chronification.

Methods: 62 patients with new onset subacute back pain (less than 3 mo duration, no back pain for at least a year prior to symptom onset) were seen 6 times over one year. At each visit, pain intensity was determined using a 100mm visual analog scale, behavioral questionnaires completed and fMRI brain scans obtained. For this analysis, the subacute group was divided into persisting (SBPp) and recovering (SBPr) groups using a greater than 20 % change criterion, from the baseline visit to the one year visit. Multivariate logistic regression was utilized to evaluate individual behavioral parameters and their association with pain persistence.

Results: There were 32 males and 30 females, with mean age at study onset of 43 ± 11 yrs, mean pain duration 10 weeks, and mean initial VAS pain intensity was 64 ± 16. By the end of one year, there were 36 SBPr and 26 SBPp. No significant group differences in VAS pain intensity were evident at baseline. However, when evaluated over time, SBPp and SBPr segregated as early as their second visit (within 2 weeks) and the divergence persisted until the final visit at one year. The Neuropathic Pain Scale (NPS), the McGill Pain Questionnaire affective (MPQa), Pain detect (pDetect) and smoking status were significantly different between SBPr and SBPp groups at baseline (t-test). Smoking status at time of entry into the study was the strongest predictor of SBPr and SBPp groups at one year from symptom onset, odds ratio = 5, CI 1.6–16, $p < 0.007$, accuracy = 0.67. NPS, MPQa and pDetect were correlated with each other, and their logistic multiple regression was not significant. Thus, all three parameters reflect interrelated properties of back pain. In a multiple regression logistic model when we include all four parameters, only smoking status remains significant with a stronger odds ratio = 13.5, CI = 2.5–75, p=0.003, accuracy =0.84; thus after correcting for pain characteristics the effects of smoking on pain chronification are even stronger.

Conclusion: There is a strong association between smoking at the time of the onset of back pain symptoms and longer term pain chronification. As this observation was not a prespecified hypothesis of the study, we label the observed result as an association that needs to be validated in a systematic study.

Physicians' Recommendations for Total Knee Arthroplasty in Younger Persons with Moderate Osteoarthritis. Liana Fraenkel[1], Lawrence Weis[2] and Lisa G. Suter[2]. [1]Yale University School of Medicine, Veterans Affairs Connecticut Healthcare System, New Haven, CT, [2]Yale University, New Haven, CT

Background/Purpose: Rates of total knee arthroplasty (TKA) are increasing among all age groups. The most rapidly growing population of patients undergoing TKA are those under the age of 65. This reason for this increasing prevalence is unclear. While physicians' recommendations regarding use of TKA are likely to be fairly uniform for patients with severe OA, little is known regarding physicians' decision-making for younger patients with less severe arthritis. The objective of this study was to gain insight into the factors influencing physicians' recommendations for younger persons with OA using an experimental $2 \times 2 \times 2$ design.

Methods: A convenience sample of rheumatologists and orthopedic surgeons, recruited at their respective national meetings, completed a survey including a standardized scenario of a 62 year old person with knee OA who has moderate knee pain limiting strenuous activity despite medical management. The scenarios varied on patient gender, employment status (business manager vs retired), and x-ray (mild vs moderate OA). Each subject rated their recommendation for a single scenario (distributed randomly) on a 7-point scale. Recommendation was treated as a dichotomous variable: For vs Against TKA.

Results: 406 surgeons [mean age (SD) = 49 (10), 18% female] and 494 rheumatologists; [mean age (SD) = 48 (10), 44% female] participated. Overall, 51% of both surgeons and rheumatologists recommended TKA. As expected, both groups recommended TKA more frequently for scenarios including more severe radiographic OA (Table 1). However, this feature had a greater influence among rheumatologists than orthopedic surgeons. Orthopedic surgeons were more likely to recommend TKA for male vs female patients. Whereas, rheumatologists were less likely to recommend referral for TKA for business managers compared to housewives or retired men. The

influence of physicians' demographic characteristics on TKA recommendation is presented in Table 2. Younger physicians, regardless of specialty, were more likely to recommend TKA ($p < 0.05$). Rheumatologist' recommendations for TKA did not vary by geographic location; however, American and Asian surgeons were more likely to recommend TKA compared to their European counterparts.

Table 1. Influence of Patient Characteristics on Physicians' Recommendations for TKA

Patient Characteristics	Percent of Rheumatologists Recommending TKA	Percent of Orthopedic Surgeons Recommending TKA
Moderate vs Mild radiographic changes	60 vs 41, p<0.0001	56 vs 47, p=0.05
Male vs Female	49 vs 52, p=0.5	59 vs 44, p=0.002
Working outside of the home vs Retired/Housewife	42 vs 56, p=0.002	49 vs 53, p=0.4

Table 2. Influence of Physician Characteristics on their Recommendations for TKA

Physician Characteristics	Percent of Rheumatologists Recommending TKA	Percent of Orthopedic Surgeons Recommending TKA
Age (<50 vs ≥ 50)	55 vs 46, p=0.03	57 vs 47, p=0.04
Male vs Female	50 vs 53, p=0.5	51 vs 56, p=0.7
Location (Asia vs Europe vs US)	54 vs 49 vs 52, p=0.8	67 vs 34 vs 52, p=0.006

Conclusion: Physicians recommendations for TKA vary significantly for younger patients with moderate OA. Recommendations are influenced by both physician and patient characteristics.

In Vivo Kinematics of Three-Component Mobile-Bearing Total Ankle Replacement for Rheumatoid Arthritis. Keiji Iwamoto[1], Tetsuya Tomita[1], Takaharu Yamazaki[2], Kenrin Shi[1], Norimasa Shimizu[1], Masahiro Kurita[1], Kazuma Futai[1], Yasuo Kunugiza[1], Hideki Yoshikawa[1] and Kazuomi Sugamoto[1]. [1]Osaka University Graduate School of Medicine, Osaka, Japan, [2]Osaka University, Osaka, Japan

Background/Purpose: The standard treatment for end-stage arthritis of the ankle joint due to rheumatoid arthritis (RA) has been an ankle arthrodesis. Patients with RA who require surgery usually already have degeneration of the subtalar and midtarsal joints. Fusion of the ankle and hindfoot will result in functional problems with gait. Thus, total ankle replacement (TAR) that can relieve pain while retaining ankle movement is important for patients with RA. However, high complication rates and low survivorship are still problematic in TAR, as compared to total knee and hip replacements. This could primarily be due to implant loosening and subsidence induced by excessive articular contact stress during ankle motion. A better understanding of ankle kinematics after TAR may be important to explain the failures in TAR, especially those attributed to loosening and subsidence. The purpose of this paper was to study in vivo kinematics of a three-component mobile-bearing TAR by 3D-evaluation of fluoroscopic imaging of ankle motion.

Methods: We investigated ten ankles in 7 patients with RA implanted with a three-component mobile-bearing TAR (FINE Total Ankle System, Nakashima Medical, Okayama, Japan), which allows not only internal/external rotation but also anteroposterior translation. Fluoroscopic images were obtained while each patient was asked to perform normal gait with full weight-bearing on the implanted ankle. Thereafter tibio-talar motion was analyzed by 2D/3D registration technique; a reproduction method of the spatial position of each component in TAR, from single-view fluoroscopic images by use of computer-assisted design models. We evaluated the dorsi-/plantarflexion angle, internal/external rotation angle and anteroposterior translation between the components.

Results: The average range of tibio-talar motion during the stance phase of gait with full weight-bearing on the implanted ankle was $11.2 \pm 2.7°$. The average range of internal/external rotation was $3.9 \pm 1.4°$. However, large intersubject variability resulted in the lack of a uniform pattern of rotational movement. The average absolute amount of anteroposterior translation was 1.6 ± 0.7mm.

Conclusion: The range of motion, with regard to plantar/dorsi flexion, was not so wide as expected, and was almost the same with other non-mobile

TAR. As intended by mobile bearing design, however, the tibial and talar components rotated internally/externally with respect to each other. Antero-posterior translation was also observed but was within small amount. These results suggest that mobile bearing TAR should be advantageous in durability with expectation that it could compensate rotational malposition of the components as well as malalignment of the subtalar joint.

Differences in Baseline Characteristics Between TKR and THR Patients: Results From a National Research Consortium. Patricia D. Franklin[1], Benjamin Snyder[1], Jeroan Allison[2], Wenjun Li[1], Milagros Rosal[1], Leslie R. Harrold[3], Bruce Barton[2] and David Ayers[1]. [1]University of Massachusetts Medical School, Worcester, MA, [2]University of Massachusetts Medical School, [3]UMass Medical School, Worcester, MA

Background/Purpose: Both total knee replacement (TKR) and total hip replacement (THR) reliably relieve pain, restore function, and ensure mobility in patients with advanced joint arthritis; however these results are not uniform across all patient populations. Previous studies have shown baseline differences between patients undergoing TKR and THR. We compared baseline demographic and symptom profiles in a national research consortium of advanced OA patients undergoing primary TKR and THR to evaluate these differences.

Methods: Patients undergoing primary TKR and THR between 7/1/2011 and 3/30/2012 were identified from the national research consortium which collects comprehensive data on enrolled patients from 89 surgeons across 27 states. Gathered data includes patient demographics, comorbidity (Charlson Comorbidity Index), operative joint pain severity, physical function (SF-36; Physical Component Score (PCS)), emotional health (SF-36 Mental Component Score (MCS)), and musculoskeletal burden of illness (Hip and Knee Disability and Osteoarthritis Outcome Scores;Oswestry Disability Index. Descriptive statistics compared baseline demographic and symptom profiles.

Results: Our analysis compared 1362 primary TKR patients and 1013 primary THR patients. TKR patients were significantly older (66.5 vs. 64.3 years), more obese (BMI 31.7 vs. 29.3), and less educated ($p < 0.005$). TKR patients had higher rates of comorbidities, specifically diabetes, gastrointestinal ulcers, and cerebrovascular disease ($p \leq 0.006$). THR patients had significantly worse physical function (PCS 31.6 vs. 33.3), lower back pain (35.6% vs. 30.5% moderate-severe), and operative joint pain, stiffness, and function ($p < 0.005$).

Conclusion: Patients undergoing primary TKR are older with more comorbidities, however THR patient baseline functional and musculoskeletal disability are significantly greater than primary TKR patients, which may help explain the variability in results shown after primary TKR as compared to primary THR.

1086

Has the Level of Disability At Time of TKR Changed Over the Past 10 Years?: Results From Two National Cohorts. Patricia D. Franklin[1], Wenjun Li[1], Benjamin Snyder[1], Courtland Lewis[2], Philip Noble[3] and David Ayers[1]. [1]University of Massachusetts Medical School, Worcester, MA, [2]CT Joint Replacement Institute, St. Francis Hospital, Hartford, CT, [3]Baylor College of Medicine, Houston, TX

Background/Purpose: A growing numbers of younger adults report knee pain consistent with OA, although parallel analyses of knee x-rays show no increase in classic radiographic signs of OA. To evaluate whether surgeons are performing TKR at an earlier stage in the condition, we compared pre-operative demographic and symptom profiles from 2 national cohorts of TKR patients, one from 2011–2012 and another from 2000–2004.

Methods: Following informed consent, we collected comprehensive demographic, comorbidity, and patient-reported pain and physical function from a national sample of 2011-12 TKR patients, across 27 states with 89 surgeons. Comparable data collected by one implant manufacturer between 2000–2004 from 136 surgeons in 31 states were analyzed. Descriptive statistics compared the demographic and symptom profiles of the two cohorts.

Results: There were minimal differences between the two cohorts in terms of age (2011-12: 66.5 years, vs. 2000/4: 67.6 years; p0.05). The more recent patient cohort consisted of fewer females (57%) compared to the earlier group (66%). Pre-operative physical function scores (SF36/PCS) were 3 points higher in 2011-12 than 2000-04 (33.6 ± 0.3 vs. 30.3 ± 0.1; $p < 0.0000$). The 2000–2004 cohort (n=7686) had a mean BMI of 32 vs 31.7 for the 2011-12 cohort (n=1362). When compared to the national PCS norm of 50 (SD=10), TKR patients from both time periods reported pre-operative function levels almost 2 standard deviations below the national norm.

Conclusion: The profile of primary TKR patients changed between 2000-04, and 2011-12. Today, patients are younger and have a higher pre-operative physical function scores. They continue to report significant levels of disability with mean pre-TKR PCS significantly lower than average OA patients.

1087

Do Younger TKR Patients Have Similar Disability At Time of Surgery As Older Adults? Patricia D. Franklin[1], Wenjun Li[1], Leslie R. Harrold[2], Benjamin Snyder[1], Courtland Lewis[3], Philip Noble[4] and David Ayers[1]. [1]University of Massachusetts Medical School, Worcester, MA, [2]UMass Medical School, Worcester, MA, [3]CT Joint Replacement Institute, St. Francis Hospital, Hartford, CT, [4]Baylor College of Medicine, Houston, TX

Background/Purpose: The trend toward greater numbers of working-aged patients choosing TKR has raised concerns that younger patients may receive surgery prematurely. We compared the severity of operative knee pain and functional status in younger versus older TKR patients.

Methods: Patients undergoing primary TKR from 7/1/11 through 3/30/12 were identified from a national research consortium which enrolls patients from 89 surgeons in 27 US states. Patients, surgeons and hospitals submit data including the SF 36 Physical Component Score (PCS), the Knee injury and Osteoarthritis Outcome Score (KOOS) and the Oswestry Low Back Pain Disability Questionnaire. The KOOS data were used to estimate the Western Ontario and McMaster Universities Arthritis Index (WOMAC). We compared those <65 to those who were ≥65 years of age using descriptive statistics.

Results: Primary TKR was performed in 570 younger (<65) and 769 older (≥65) patients. Younger patients were less likely to be white (89% vs. 92%, p=0.02), and had a greater body mass index (mean BMI 33.0 vs. 30.7, $p < 0.0001$). Younger patients reported greater pain (48.9 vs. 53.8, $p < 0.001$) and stiffness (38.5 vs. 46.7, $p < 0.001$) in the operative knee joint. Overall function as measured by the WOMAC and SF36 PCS were similar in the two age groups (WOMAC 51.9 vs. 53.8; PCS 32.8 vs. 33.8). Function levels in both groups reflect significant impairment at time of surgery.

Conclusion: At the time of TKR, younger and older patients have similar levels of functional impairment suggesting surgeons use comparable standards for selecting TKR in younger and older adults.

1088

Factors Influencing Long-Term Recovery of Total Knee Arthroplasty. C. Allyson Jones[1], Gian S. Jhangri[2] and Maria E. Suarez-Almazor[3]. [1]Departments of Physical Therapy and School of Public Health, University of Alberta, Edmonton, AB, [2]School of Public Health, University of Alberta, Edmonton, AB, [3]University of Texas MD Anderson Cancer Center, Houston, TX

Background/Purpose: Although a number of studies have examined short term outcomes after total knee arthroplasty (TKA), few have prospectively examined the long term trajectory of recovery of health-related quality of life. The aim of this study was to identify patient-related outcomes that explained the pattern of pain and functional recovery over 10 years for TKA.

Methods: This is a prospective observational study that followed a community-based cohort of patients receiving elective primary TKA within a month before surgery, 6 months, 3 years and 10 years after surgery. Data were collected from patient interviews, chart reviews and regional administrative databases. Joint pain and function were measured using the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC). Health status

was evaluated over time using the SF-36. Effect sizes were calculated to measure change over time. Pre-operative and operative factors were inspected as possible variables that predicted the pattern of recovery. Linear mixed models for pain and functional recovery were used to evaluate changes over time while adjusting for covariates.

Results: Of the 289 patients followed, the mean age was 69.4 (SD 9.2) yrs;170 (59%) were female. At 10 years 145 patients responded. The mean number of comorbid conditions was 3.5 (SD 2.0) at baseline and 4.7 (SD 2.3) at 10 years. WOMAC pain score mean difference from baseline to 6 months was 33.0 (95% 30.5, 35.5) with the largest effect size (ES) of 1.89. Long-term change was much smaller from 6 months to 3 years (ES 0.18) and from 3 to10 years (ES 0.03). Smaller changes were seen with function; baseline to 6 months (ES 1.65), 6 months to 3 years (ES 0.07) and 3 to 10 years (ES −0.13). The ES of the SF-36 physical summary score at 6 months was 1.17 and over the 10 years was 1.87. After adjusting for age and gender, the 10 year trajectory for pain was explained by baseline health status (SF-36 summary scores), and baseline WOMAC pain (p< 0.05). The 10 year trajectory for function had similar covariates which explained the trajectory, in that baseline WOMAC function and health status were significant factors. In-hospital complications, prosthesis-type, and obesity did not impact long-term recovery pattern.

Conclusion: Pain and functional recovery after TKA occurs primarily within 6 months after surgery with negligible change from 3 to 10 years. Greater pain, dysfunction and lower overall health at baseline explained slower long-term recovery patterns for TKA.

Disclosure: **C. A. Jones**, None; **G. S. Jhangri**, None; **M. E. Suarez-Almazor**, None.

1089

The Number of Ruptured Tendons As a Prognostic Factor for Reconstructing Extensor Tendon Rupture in Patients with Rheumatoid Arthritis. Yu Sakuma, Kensuke Ochi, Takuji Iwamoto, Shinji Yoshida, Asami Saitou, Katsunori Ikari and Shigeki Momohara. Institute of Rheumatology, Tokyo Women's Medical University, Tokyo, Japan

Background/Purpose: Extensor tendon rupture seen in patients with rheumatoid arthritis (RA) is usually surgically treated in combination with extensor tendon reconstruction and wrist arthroplasty. However, limited data exist in literature concerning factors significantly correlating with poor prognosis of the extensor tendon reconstruction. The purpose of this study is to investigate factors significantly correlating with poor prognosis of the extensor tendon reconstruction.

Methods: Total of 68 RA patients (mean age of 52 years old; 57 females) who underwent combined surgical procedures of tendon reconstruction and wrist arthroplasty because of spontaneous extensor tendon ruptures were investigated. The result of extensor tendon reconstruction was evaluated as "good", "fair" and "poor". This evaluation was defined based on active flexion and extension lag of metacarophalangeal (MP) joint of the affected fingers at 3 months after the surgery. The cases in which active flexion arc was greater than 45 degrees and extension lag was less than 15 degrees were defined as "good". The cases, in which active flexion arc was greater than 45 degrees and extension lag ranged from 15 to 45 degrees, or active flexion arc was less than 45 degrees and extension lag was less than 15 degrees, were defined as "fair". All other cases were defined as "poor". We investigated the relation among clinical factors such as age at surgery, the number of ruptured extensor tendons, duration between onset of rupture and surgery, methods for reconstructing ruptured tendons, surgical procedures for wrist arthroplasty, the time interval between surgery and beginning of postoperative rehabilitation, and the frequency of ambulatory visit for rehabilitation, and the postoperative results by using multiple regression analysis. The correlation between factors relating to the postoperative result and duration between onset of rupture and surgery were additionally analyzed using single regression analysis.

Results: Forty-two (61.8%) patients were evaluated as "good", while 19(28.0%) and 7(10.3%) patients were evaluated as "fair" and "poor", respectively. Number of ruptured tendons was the only independent variable which significantly related to poor postoperative results (p=0.0002). The longer duration between onset of rupture and surgery had significant correlation between increased number of ruptured tendons (p=0.03).

Conclusion: Increased number of ruptured extensor tendons significantly correlated with poor postoperative result of extensor tendon reconstruction in patients with RA. The number of increased ruptured extensor tendons also significantly correlated with duration between onset of rupture and surgery. We therefore recommend surgical intervention at early stage of extensor

tendon rupture, in which only few tendons are suspected to be involved, to result in better prognosis.

A Comparison of Patient-Reported and Measured Range of Motion in a Cohort of Total Knee Replacement Patients. Jamie E. Collins, Benjamin N. Rome, Vladislav Lerner, Jeffrey N. Katz and Elena Losina. Brigham and Women's Hospital, Boston, MA

Background/Purpose: Range of motion (ROM) is an important component of the assessment of total knee replacement (TKR) outcome. Traditionally, ROM is measured by a clinician or trained researcher, making ROM less practical than self-report measures that can be obtained by phone or mail. Recently, Gioe et al. developed a method that presents patients a set of lateral knee photographs depicting varying levels of flexion and extension and asks the patients to select the photographs that most closely resemble their motion. We aimed to compare this self-reported method of assessing flexion and extension with clinical measurement before and after TKR.

Methods: As part of a prospective cohort study of consecutive patients undergoing TKR, patients were asked to self report flexion and extension on their operated knee using the method of Gioe et al. In addition, flexion and extension were measured using a goniometer by a trained research assistant. These measures were obtained preoperatively and at three and six months postoperatively. We compared self-reported ROM category with measured ROM for both flexion and extension using ANOVA. We dichotomized flexion at 90 degrees and determined the sensitivity and specificity of the self-report flexion categories for identifying patients with poor ROM.

Results: One hundred and one patients provided both self-report and RA-measured ROM at baseline. There was a significant association between self-report ROM category and ROM measurement for both flexion and extension (P<0.001). The Spearman correlation coefficient was 0.51 for extension and 0.45 for flexion, indicating moderate correlation. We combined all 3 visits to assess sensitivity and specificity of self-report flexion categories. Overall 15 of 25 patients with poor measured flexion (≤90°) also self-reported poor flexion (to 90° or lower) for a sensitivity of 60% and 177 of 190 patients without poor flexion (>90°) did not self-report poor flexion (to 100° or higher) for a specificity of 93%. The negative predictive value for self-report was 95%, indicating that the vast majority of patients self-reporting adequate flexion do not have poor flexion.

Table 1. Performance of self-report flexion categories for identifying patients with poor ROM

		Measured Flexion	
		≤90°	>90°
Self Report – How well can you bend your knee?	To 90° or lower	15	13
	To 100° or higher	10	177
	Total	**25**	**190**
	Sensitivity	60.0%	
	Specificity	93.2%	
	Predictive Value+	53.6%	
	Predictive Value-	94.7%	

Conclusion: Patient self-reported ROM may be a useful outcome measurement for TKR when clinical ROM measurement is not possible. These findings are based on a small sample in one center and should be confirmed. Self-report is particularly effective (>90% specificity) in confirming adequate ROM.

Trends in Patient Physical Activity Before and After Primary Total Hip Arthroplasty. Anne Lübbeke, Dorith Zimmermann, Constantinos Roussos, Alexis Bonvin, Robin Peter and Pierre Hoffmeyer. Geneva University Hospitals, Geneva, Switzerland

Background/Purpose: Total hip arthroplasties (THA) are performed to reduce pain and enhance patients' function and physical activity (PA) level. PA is also recognized as the most important patient-related factor determining

implant survival. Furthermore, unrealistic patient expectations regarding PA after surgery have been identified as one of the reasons for increased dissatisfaction. Detailed assessement of PA before and after THA is lacking. Our objective was to evaluate (1) how patient's PA level evolves: prior to disease onset, prior to THA, and at 5 and 10 years postoperative, and (2) whether PA level before and after THA has changed over the last decade across birth cohorts of identical age.

Methods: Patients included are part of a prospective hospital-based cohort of all THAs of a University hospital and followed longitudinally since 1996. We included all primary THAs between 1/2000 and 4/2012. PA was assessed by the physician and self-reported, preoperatively and at 5 and 10 years postoperative. Moreover, PA was evaluated with the UCLA activity scale. To determine PA evolution over the course of OA and THA, cross-sectional analyses were performed to assess mean UCLA scores over four periods: prior to disease, prior to surgery, 5- and 10-years postoperative independently of the year of surgery. Separate analyses were performed for men and women and by age categories (<55, 55–64, 65–74, ≥75 yrs. at operation). To analyze secular trends in PA, cross-sectional analyses were performed at three time periods within identical ages categories (2000–2003, 2004–2007, 2008–2011).

Results: Overall, lifestyle was assessed preoperatively for 2916 THAs and postoperatively for 1565 THAs. The UCLA score was assessed at follow-up for 1345 THAs. Mean age at operation was 68.4 years, 56% were women.

Prior to surgery 61% of patients reported a sedentary lifestyle compared to 45% at 5 years postoperative (RD 16%, 95% CI 12; 20). The proportion of patients with sedentary lifestyle prior to surgery decreased from 68% in 2000–2003 to 54% in 2007–2011 (RD 14%, 95% CI 9; 18) despite a similar mean age (p=0.1). Sedentary lifestyle 5 years after surgery was reported by 53% of those operated 2000–2003 compared to 39% of those operated 2004–2007 (RD 14%, 95% CI 9; 20).

Mean UCLA scores prior to OA onset, prior to THA and 5 and 10 years postoperative were respectively in men 8.4, 3.7, 6.2 and 6.2 and in women 6.1, 3.4, 5.1 and 4.8.

Prior to surgery UCLA scores were similar across age categories ranging form 3.7 in the youngest to 3.2 in the eldest group (p=0.8). Five years postoperative UCLA scores declined as age increased. Across the four age categories the mean UCLA scores were respectively 6.7, 6.4, 5.6 and 4.2 (p<0.0001). Ten years postoperative mean UCLA scores were 6.4, 6.4, 5.2 and 3.8, respectively (p<0.0001).

Conclusion: Primary THA substantially and durably improved PA levels in men and women and in all age categories. Activity levels were lower in women than in men at all times. In the last decade the proportion of patients with an active lifestyle before and after THA increased by 14%.

Effect of FULL Contact FOOT Orthosis On Plantar Fasciitis. Hilda A. Oliveira[1], Anamaria Jones[1], Emilia Moreira[1], Fabio Jennings[1] and Jamil Natour[2]. [1]Universidade Federal de Sao Paulo, Sao Paulo, Brazil, [2]Universidade Federal de São Paulo, São Paulo, Brazil

Background/Purpose: Plantar fasciitis (PF) is an inflammation of the foot *plantar fascia*, characterized by stiffness in the medial arch and ankle, especially during first steps, and can have a significant effect on activities of daily living. Insoles are one of the most often employed methods for the treatment of PF. The full contact foot orthosis is the most recommended, as it redistributes the load uniformly throughout the sole of the foot. However, few studies have demonstrated the effectiveness of this device and there is no consensus on which type of insole is the most adequate. The aim of the present study was to assess the effectiveness of a full contact foot orthosis regarding pain, foot function and quality of life in patients with PF.

Methods: Seventy-four patients were randomly allocated to an experimental group (n=37) using a full contact foot orthosis or a control group (n=37) using a sham insole. Evaluations were performed of pain (VAS), quality of life (SF-36), foot function (FFI and FSHQ), six-minute walk test and static/dynamic baropodometry (AM Cube FootWalk Pro program). The groups were evaluated at baseline and after 45, 90 and 180 days after randomization by a blinded evaluator.

Results: The groups were homogeneous at baseline regarding clinical and demographic characteristics. In the comparisons over time, we found better results for the experimental group for pain during walking on the right feet (p=0.008 - Figure 1). In the intragroup analysis we found in both groups

improvement regarding pain during walking on the left feet, the six-minute walk test, foot function and some quality of life parameters, with no statistically significant differences between groups. No changes in foot pressure were found with the use of the insole.

Figure 1 - Walking pain - right feet
Conclusion: The benefit of the use of full contact foot orthosis for the treatment of PF was restricted to the improvement in pain during walking in right feet.

Obesity Is Not a Risk Factor for Poor Pain and Function Two Years After Total Knee Replacement. Lisa A. Mandl. Mark P. Figgie, Alejandro Gonzalez Della Valle, Michael Alexiades and Susan M. Goodman, Hospital for Special Surgery, New York, NY

Background/Purpose: Almost 90% of referring physicians think obesity increases the likelihood of poor outcomes after total knee replacement (TKR). However, current data are conflicting. The purpose of this study is to assess of the association of body mass index (BMI) with pain, function and satisfaction 2 years after primary TKR.

Methods: Institutional TKR Registry patients who had a primary TKR between July 2007 and June 2009 and BMI>18.5 were enrolled. Poor pain and function were defined as WOMAC score <= 60. Data were collected prior to surgery and 2 years post-op. Multivariate regressions were performed to evaluate the association between BMI at baseline and poor pain and function at 2 years, controlling for gender, age, race, Deyo Comorbidity score and educational attainment. Expectations were measured with a validated TKR Expectations Survey.

Results: 2524 patients were included in the analysis. BMI > 40 were more likely to be non-Caucasian, female, have less education and more co-morbidities. Pre-operatively, both pain and function were least severe in <25 BMI category, increasing as BMI increased. At 2 years, change in WOMAC pain and function showed a step wise, dose dependant improvement across BMI categories, with BMI > 40 showing the most improvement. At 2 years, there was a statistically significant trend towards lower BMI categories having the least pain (p-value=0.0003) and best function, (p-value<0.0001), but the differences between groups were not clinically significant. In the multivariate regressions, there were no statistically significant associations between any BMI category or number of co-morbidities and poor pain or function at 2 years. Being female significantly increased the risk of having poor pain (OR 1.6; 95% CI 1.2–2.2) or poor function (OR 1.5; 95% CI 1.1–2.1) at 2 years. Being Caucasian decreased the risk of poor pain (OR 0.6; 95% CI 0.4–0.9) or poor function (OR 0.5; 95% CI 0.3–0.7). Having only high school education also increased the risk of poor pain (OR 1.5; 95% CI 1.1– 2.1) and poor function (OR 1.9; 95% CI 1.4–2.6) at 2 years. Age group 61–70 showed a decreased risk of poor pain compared to age <=60, (OR 0.5; 95% CI 0.4– 0.8). At 2 years, 20.4% of patients lost weight, (mean weight loss 0.6 lbs +/− 2.7), with the greatest loss in BMI >40 (2.7 lbs, +/− 5). There were no significant differences in expectations or satisfaction between BMI categories.

Conclusion: Although obese patients have worse pain and function at the time they elect TKR, their outcomes at 2 years are not clinically significantly different than other patients. However, race and educational

attainment were significantly associated with poor outcomes. Obese patients have similar expectations and are as satisfied as patients with lower BMI. More research should be done on the effect of race and education on TKR outcomes. Obesity should not be regarded as a risk factor for poor outcomes after primary TKR.

The Relationship Between Lumbar Spine Individual Radiographic Features and Low Back Symptoms with and without Associated Leg Symptoms: The Johnston County Osteoarthritis Project. Adam P. Goode[1], Janet K. Freburger[2], Timothy S. Carey[3], Chad E. Cook[4], Jordan Renner[5], Sean D. Rundell[6] and Joanne M. Jordan[7]. [1]Duke University, Durham, NC, [2]University of NC CB 7590, Chapel Hill, NC, [3]Cecil G. Sheps Center for Health Services Research University of North Carolina, Chapel Hill, NC, [4]Walsh University, OH, [5]University of North Carolina, Chapel Hill, NC, [6]University of Washington, Seatle, WA, [7]University of North Carolina Thurston Arthritis Research Center, Chapel Hill, NC

Background/Purpose: Little is known of the relationships between low back symptoms (LBS) and associated leg symptoms and lumbar spine individual radiographic features (IRF). We examined the associations between LBS, with and without associated leg symptoms, and lumbar spine IRF of disc space narrowing (DSN), vertebral osteophytes (OST) and facet joint osteoarthritis (FOA) and determined if these associations differed by race or gender.

Methods: 840 newly enrolled participants in the Johnston County Osteoarthritis Project from 2003-04 having data on lumbar spine IRF (DSN, OST and FOA) were the subjects (mean age 60.1 (SD 10.3), 62.3% female, 37.6% African American, mean body mass index (BMI) 31.3 (SD 7.4)). Lateral lumbar spine films were graded for each lumbar level in a semi-quantitative fashion (0–3) for DSN and OST according to the Burnett Atlas, while FOA was graded present or absent. Low back symptoms with and without associated leg symptoms were determined with the following questions "On most days have you had symptoms of pain, aching or stiffness in your low back? "and" On most days do you have pain (sciatica) radiating down your right or left leg?" Two outcome groups were created: LBS and LBS with associated leg symptoms. Each group was compared separately to those with no symptoms. Logistic regression models were used for all analyses while adjusting for BMI, race, gender and age. Interactions between lumbar spine IRF and race or gender were tested with likelihood ratios tests (p<0.10 for significance).

Results: Low back symptoms and LBS with associated leg symptoms

were present in 51.8% and 24.9% of participants, respectfully. Disc space narrowing was present in 57.6%, OST present in 88.1% and FOA present in 57.9% of participants. Those with LBS were 32% as likely than those without LBS to have DSN (adjusted odds ratio [aOR] 1.32 ((95% CI 1.09, 1.52)). No association was found with FOA and either LBS or LBS with associated leg symptoms. No significant association was found between OST and LBS with associated leg symptoms.

A significant interaction (p<0.001) was observed between race and OST with LBS. African Americans (AAs) with OST were more likely (aOR 1.78 ((95% CI 1.25, 2.55)) to report LBS than AAs without OST. There was no effect among Caucasians.

Conclusion: Modest associations were found between DSN and LBS but no significant associations were found with LBS and associated leg symptoms. LBS with associated leg symptoms may have an etiology other than disc degeneration; suggesting that plain film radiographs may have limited clinical utility for this subgroup.

1095

Metal Concentrations in Patients with Failed Metal-On-Metal Hip Prostheses Determine the Inflammatory Phenotype in Peri-Implant Tissue. Erja-Leena Paukkeri[1], Riku Korhonen[1], Antti Eskelinen[2], Marko Pesu[3], Kaija Vasama[4], Teemu Moilanen[2] and Eeva Moilanen[1]. [1]The Immunopharmacology Research Group, University of Tampere School of Medicine and Tampere University Hospital, Tampere, Finland, [2]Coxa Hospital for Joint Replacement, Tampere, Finland, [3]Immunoregulation, Institute of Biomedical Technology, University of Tampere, Tampere, Finland, [4]Fimlab Laboratories, Tampere, Finland

Background/Purpose: Hip arthroplasty is the standard treatment of a painful hip destruction in rheumatoid arthritis and osteoarthritis. The use of metal-on-metal (MoM) bearing surfaces in total hip arthroplasty gained popularity especially in young and active patients during the last decade. Recently, worrisome failures due to inflammatory soft tissue reactions related to wear particles have been widely reported. The pathogenesis of this reaction is unknown. The aim of the present study was to clarify the inflammatory responses in peri-implant tissue in patients with a failure of MoM articulation.

Methods: Sixteen patients with a failed Articular Surface Replacement (ASR) implant were included in the study. Blood metal ion levels were analysed with coupled plasma mass spectrometry before revision surgery. Samples of peri-implant tissues collected during revision surgery were degraded by enzyme digestion and the distributions of cell populations were analysed by flow cytometry.

Results: In macroscopic observation, peri-implant reactions had variable amounts of necrotic and granulomatous tissue and cystic pseudotumour formation. All patients expressed elevated levels of blood chromium and cobalt, but the patient-to-patient variation was significant. In histological examination, intensive inflammatory cell infiltration was a characteristic feature, but only few metal containing cells were observed. An analysis by flow cytometry showed that the distributions of the inflammatory cells were mainly polarized either to macrophage-rich ($CD45^+/CD14^+$) or T-lymphocyte-rich ($CD45^+/CD3^+$) phenotypes with the average portions being 54 % (macrophages) and 20 % (T-lymphocytes) in macrophage-dominated inflammation and 25 % (macrophages) and 54 % (T-lymphocytes) in T-lymphocyte-dominated conditions. The portions of B-lymphocytes ($CD45^+/CD19^+$) and granulocytes ($CD45^+/CD15^+$) were small. Interestingly, the levels of blood chromium and cobalt were significantly higher in patients with macrophage-dominated inflammation than in patients with T-lymphocyte-dominated inflammation.

Conclusion: The results suggest that the adverse reactions induced by MoM wear particles contain heterogeneous pathogeneses and the metal levels seem to be an important factor in the determination of inflammatory phenotype. The present results support the hypothesis that higher levels of metal particles cause tissue necrosis and macrophages are recruited to clear the necrotic debris. The lymphocyte-dominated inflammation may, on the other hand, reflect a delayed hypersensitivity reaction induced by lower metal concentrations.

1096

Lower Income Paradoxically Associated with Better Patient-Reported Outcomes After Knee Arthroplasty in the U.S. Jasvinder A. Singh[1] and David Lewallen[2]. [1]University of Alabama at Birmingham, Birmingham, AL, [2]Mayo Clinic college of medicine, Rochester

Background/Purpose: To assess whether income is associated with patient-reported outcomes (PROs) after primary total knee arthroplasty (TKA).

Methods: We used the prospectively collected data from the Mayo Clinic Total Joint Registry to assess the association of income with index knee functional improvement, and moderate-severe pain at 2- and 5-year follow-up after primary TKA using multivariable-adjusted logistic regression analyses. Analyses were adjusted for various characteristics previously shown to be associated with PROs after TKA, namely demographics (age, gender, body mass index (BMI), comorbidity as measured by Deyo-Charlson index, American Society of Anesthesiologist (ASA) score as a measure of perioperative mortality, implant fixation (cemented/hybrid versus not cemented), underlying diagnosis (osteoarthritis, rheumatoid/inflammatory arthritis or other) and distance from medical center (categorized <100, 100–500 and >500 miles/overseas). ASA score was not collinear with Deyo-Charlson index (correlation coefficient <0.40).

Results: There were 7,139 primary TKAs at 2-years and 4,234 at 5-years. In multivariable-adjusted analyses, at 2-year follow-up, both lower income groups (<=\$35K and >\$35–45K) were significantly associated with lower odds ratio (OR) [95% confidence interval (CI) of moderate-severe pain, OR 0.6 [95% CI, 0.4, 0.9] (p=0.02) and 0.7 [95% CI, 0.5, 0.9] (p=0.02). The overall improvement in knee function was rated as 'better' more often at 2-years by patients with income in the <=\$35K compared to patients with income >\$45K, with OR of 1.9 [95% CI, 1.0, 3.6] (p=0.06), respectively. At 5-years, numerically similar but non-significant odds were noted.

Conclusion: We found that lower income was associated with better pain outcome and more improvement in knee function postoperatively. Insights into mediators of these relationships need to be investigated to understand how income influences outcomes after TKA.

The Association of Fat Distribution and Clinically Defined Hand Osteoarthritis: The Netherlands Epidemiology of Obesity Study. A. Willemien Visser, Marieke Loef, Andreea Ioan-Fascinay, Martin den Heijer, Frits R. Rosendaal and Margreet Kloppenburg. Leiden University Medical Center, Leiden, Netherlands

Background/Purpose: Obesity, assessed as body mass index (BMI) ≥ 30 kg/m^2, is an important risk factor for osteoarthritis (OA). BMI depends only upon height and weight and therefore gives no insight in underlying causal pathways. The aim of this study was to investigate whether the association of BMI and OA in the hands, being non-weight bearing joints, can be explained by the amount of fat mass (FM) and the abdominal fat distribution.

Methods: Data from participants of the NEO (Netherlands Epidemiology of Obesity) study, a population-based cohort of men and women aged 45–65 years with a BMI ≥ 27 kg/m^2 and a control group with a BMI < 27 kg/m^2, were used. BMI was assessed by measured weight in kg and length in cm. Waist-to-hip ratio (WHR) was calculated from waist and hip circumference measured in cm. FM was assessed in kg using bioelectrical impedance analysis. In 30% of participants MR imaging of the abdomen, at the level of the 5th lumbar vertebra, was used to assess the relative amounts of visceral adipose tissue and subcutaneous adipose tissue in cm^3. Hand OA was defined using the criteria of the American College of Rheumatology; pain was measured using a standardized questionnaire and physical examination of the hands was performed by trained research nurses. Pearson correlations were calculated between BMI and WHR and FM, visceral fat and subcutaneous fat. Odds ratios (OR) with 95% confidence intervals (CI) were calculated to associate BMI, WHR, FM, visceral fat and subcutaneous fat with hand OA using logistic regression analyses, stratified for sex and adjusted for age.

Results: Data from 4562 participants (mean age 56 years, 48% male) were analyzed, including 425 controls with a BMI < 27 kg/m^2. Median BMI of the total study population was 30.3 kg/m^2 (IQR 28.4–33.1), median FM was 33.5 kg (IQR 27.5–40.8) and median WHR was 0.94 (IQR 0.88–0.99). Abdominal fat was measured in a subset of 1524 participants: median visceral fat was 122.8 cm^3 (IQR 86.4–167.0) and median subcutaneous fat 306.7 cm^3 (IQR 239.7–388.8). Hand OA was present in 8% of men and 21% of women. BMI was strongly correlated to FM (men r=0.89, women r=0.90) and subcutaneous fat (men r=0.72, women r=0.82), and moderately to visceral fat (men r=0.54, women r=0.57). WHR was moderately correlated to visceral fat (men r=0.59, women r=0.46), and only weakly to very weakly correlated to subcutaneous fat (men r=0.36, women, r=0.17). BMI was associated with hand OA in women (OR 1.02; 95% CI 1.00–1.04), but not in men. WHR was strongly associated with hand OA in men (OR 132.2; 95% CI 9.2–1901.9) and in women (OR 10.1; 95% CI 2.0–50.0). In both sexes, FM and subcutaneous fat were not significantly associated with hand OA. Visceral fat was associated with hand OA only in men (OR 1.005; 95% CI 1.001–1.009).

Conclusion: BMI was associated with clinical hand OA only in women. FM and subcutaneous fat, which were strongly correlated with BMI, were not associated with hand OA in both men and women. In men, the WHR and visceral fat were associated with hand OA, suggesting involvement of visceral fat in the development of hand OA. In women, other underlying processes might play a role.

1098

Knee Osteoarthritis and Frailty in Older Adults: Findings From the Multicenter Osteoarthritis Study and Osteoarthritis Initiative. Devyani Misra[1], Michael C. Nevitt[2], Cora E. Lewis[3], James Torner[4], David T. Felson[1] and Tuhina Neogi[1]. [1]Boston University School of Medicine, Boston, MA, [2]University of California-San Francisco, San Francisco, CA, [3]University of Alabama, Birmingham City, Birmingham, AL, [4]University of Iowa, Iowa City, Iowa City, IA

Background/Purpose: Both knee osteoarthritis (OA) and the frailty syndrome affect older adults and both are associated with functional limitation and disability. Frailty in elders is a state of increased vulnerability to adverse outcomes, such as falls, fractures, hospitalization and even death. While frailty is perceived to occur in thin older adults, it has been shown to be present in those who are obese, a common feature of those with knee OA. If knee OA and frailty are associated, then by extension those with knee OA might be at risk for not only the known OA outcomes of pain, functional limitation, and disability, but also the adverse outcomes related to frailty. We therefore examined the cross-sectional association of knee OA and frailty in community-dwelling older adults using data from two large cohorts.

Methods: The Multicenter Osteoarthritis (MOST) Study and the Osteoarthritis Initiative (OAI) are two NIH-funded longitudinal observational studies of individuals with or at high risk for knee OA. We included subjects from these two studies who had knee x-rays read and information on frailty parameters available at baseline and at the 30-mo (MOST) or 24-mo (OAI) follow-up visits. Prevalent knee OA was defined at the follow-up visit described above as: 1) **Radiographic knee OA (ROA):** Kellgren and Lawrence (KL) grade ≥2; 2) **Symptomatic knee ROA**: presence of ROA plus frequent knee pain; 3) **Severity of ROA**: highest KL grade of either knee, with replaced knees considered to be KL grade 4; 4) **Number of knees with ROA**: subjects categorized as having no knee ROA, unilateral knee ROA, or bilateral knee ROA. Frailty was defined using the Study of Osteoporotic Fractures (Ensrud) index as presence of 2 of 3 of the following criteria: 1) Weight loss >5% between baseline and the follow-up visit; 2) Inability to rise from chair 4 times without using support at the follow-up visit; 3) Poor energy from the SF12 questionnaire at the follow-up visit. We evaluated the cross-sectional association of knee OA (4 definitions) with prevalent frailty at the follow-up visit using Poisson regression to calculate prevalence ratios (PR), adjusting for age, sex, BMI, physical activity, education, smoking, co-morbidities (modified Charlson score), race and study site.

Results: Among 7822 participants (3026 MOST, 4796 OAI; mean age 62±8.81, 59% women, mean BMI 29±5.44), there were 213 (186 poor energy, 116 inability to rise from chair and 145 weight loss) prevalent frail subjects. Prevalence of frailty was higher in those with radiographic knee OA and symptomatic knee OA, and increased in prevalence with

increasing x-ray severity and with number of knees involved with OA (**Table**).

Table 1. Cross-sectional Association of Knee OA with Prevalent Frailty

		Presence of Frailty	
Knee OA Status	Crude PR	Adjusted* PR (95% CI)	
Radiographic Knee OA (yes vs. no)	1.67	1.41 (1.02, 1.94)	
Symptomatic Knee OA (yes vs. no)	2.36	1.86 (1.38, 2.50)	
Severity of Radiographic Knee OA:	1.0	1.0 (Ref)	
KL=0 (reference)	1.41	1.27 (0.75, 2.15)	
KL=1	1.64	1.49 (0.96, 2.31)	
KL=2	1.71	1.42 (0.90, 2.26)	
KL=3	2.52	1.78 ((1.12, 2.83)	
KL=4			
Number of Knees with OA:	1.0	1.0 (Ref)	
None (reference)	1.04	1.02 (0.67, 1.55)	
Unilateral	2.10	1.68 (1.19, 2.38)	
Bilateral			

*Adjusted for age, sex, BMI, physical activity, smoking, education, knee injury, co-morbidities, study site

Conclusion: Frailty is present more frequently in persons with knee OA than those without. Further research is needed to explore whether knee OA predisposes to frailty, and whether early management of knee OA might prevent frailty and its related adverse outcomes.

Whole Blood Lead Is Associated with Symptoms, but Not Radiographic Osteoarthritis, in Multiple Joint Sites: The Johnston County Osteoarthritis Project. Amanda E. Nelson[1], Xiaoyan A. Shi[2], Todd A. Schwartz[3], Jordan B. Renner[4], Kathleen L. Caldwell[5], Charles G. Helmick[5] and Joanne M. Jordan[1]. [1]University of North Carolina Thurston Arthritis Research Center, Chapel Hill, NC, [2]SAS Institute, Inc, Cary, NC, [3]University of North Carolina Gillings School of Global Public Health, Dept of Biostatistics, Chapel Hill, NC, [4]University of North Carolina School of Medicine, Dept of Radiology, Chapel Hill, NC, [5]Centers for Disease Control and Prevention, Atlanta, GA

Background/Purpose: We have previously identified associations between whole blood lead (Pb) and knee osteoarthritis (OA) and with biomarkers of joint metabolism. We hypothesized that Pb may be associated with burden of OA as assessed by multiple joint radiographs and symptoms.

Methods: Whole blood Pb concentrations, representing recent exposure and Pb mobilized from bone, were determined at the Centers for Disease Control and Prevention using inductively coupled plasma-dynamic reaction cell-mass spectrometer analysis; levels were categorized into quartiles for analysis. We used composite scores obtained from previously described factor analysis (1) of radiographic OA (rOA) scores from the hands, knees, and spine, and symptoms scores of the low back, hands, knees, and hips, to reflect body burden of OA as outcome measures (categorized due to non-normal distributions). Generalized logit and proportional odds models were used for these multi-level outcomes, and were adjusted first for age, body mass index (BMI), race, and sex, and then additionally for the other joint site scores.

Results: This cross-sectional analysis includes data (collected at a single visit during 2003-8) for 1659 individuals, 33% male and 35% African American with a mean age of 65 years and BMI 30 kg/m[2]. At individual sites, rOA with symptoms was present in 13% for hand, 12% for hip, 24% for knee, and 28% for spine. Whole blood Pb was associated with spine rOA scores (30% increased odds of having higher spine rOA scores in the highest Pb quartile compared to the lowest, adjusted OR 1.34 [95% CI 1.01–1.77]), although this was no longer significant after adjustment for the composite scores of other joint sites (Table). The composite score of symptoms, however, was associated with Pb in models adjusted for covariates (OR 1.84 [95% CI 1.41, 2.40]) and after adjustment for rOA scores (Table), such that those in the highest quartile of Pb had 70–85% higher odds of reporting more symptoms compared to those in the lowest Pb quartile.

Composite Factor Score	Joints Included	Score calculation*	Adjusted† OR (95% CI) for highest quartile of Pb‡
IP/CMC	20 (DIP-8, PIP-8, thumb IP-2 & CMC-2)	Mean of summed KLG	0.89(0.64–1.23)
MCP	8 (all MCPs except thumb)	Mean of summed KLG	1.10(0.80–1.54)
Knee	4 (bilateral TFJ and PFJ)	Mean of summed KLG and OST scores	0.77(0.55–1.08)
Spine	5 (L1/2 to L5/S1) OST & DN at each level	Mean of summed OST & DN scores	1.16(0.84–1.61)
Symptoms	7 (hands-2, knees-2, hips-2, low back-1)	Mean of summed 0–3 score	**1.71(1.24–2.36)**

*Scores were calculated as the mean score, then standardized by dividing by the standard deviation
†Adjusted for age, sex, race, BMI, and all other factor scores
‡Mean Pb level (SD) in μg/dL: Q1 (referent); 0.9 (0.2); Q2: 1.5 (0.2); Q3: 2.1 (0.2); Q4: 4.9 (3.9)
IP: interpholongeol; CMC; c●; D●P: Distol IP; PIP: Pr● IP; MCP: metocarpopholongeol; KLG: Kellgren Lawrence Grade; OR: odds ratio; CI: confidence interval; TFJ: ●femoral; PFJ: pa●; OST: Osteophyte grade; DN: Disc narrowing grade; ●b: Whole blood lead level

Conclusion: There was a statistically significant positive association between blood Pb levels and the composite symptoms score, reflecting symptoms at multiple joint sites. No associations were seen for multiple joint rOA in this cross-sectional study.

A Functional Growth Hormone Receptor Polymorphism, Exon 3 Deleted Ghr, Is Associated with Radiographic Knee Osteoarthritis in Females with Familial Osteoarthritis At Multiple Sites: The Garp Study. Kim M.J.A. Claessen[1], Margreet Kloppenburg[2], H.M. Kroon[1], Jessica Bijsterbosch[1], Alberto M. Pereira[1], Hans A. Romijn[1], Tahar Straaten van der[1], Marian Beekman[1], P.E. Slagboom[1], Nienke R. Biermasz[1] and Ingrid Meulenbelt[3]. [1]Leiden University Medical Center, Leiden, Netherlands, [2]Department Rheumatology and Department of Clinical Epidemiology, Leiden University Medical Centre, Leiden, The Netherlands, Leiden, Netherlands, [3]The Netherlands Genomics Initiative-Sponsored Netherlands Consortium for Healthy Aging, Rotterdam, Netherlands

Background/Purpose: Genetic influences contribute considerably to the development of osteoarthritis (OA), and are most likely of a polygenic nature. Until now, genetic studies have identified several genetic variants associated with primary OA, providing strong clue for the involvement of endochondral ossification in OA onset. Endochondral ossification is the main process in longitudinal skeletal growth, and is tightly regulated by a complex network of hormones, growth factors and extracellular matrix components. One of the main players in this process is growth hormone (GH), exerting its effects predominantly through stimulation of insulin-like growth factor-1 (IGF-1) secretion. This qualifies genetic variations within genes involved in the GH/IGF-1 axis as obvious candidates for association studies in primary OA.

Recently, presence of a common growth hormone receptor (GHR) polymorphism, exon 3 deletion (d3-GHR), associated with increased GH sensitivity of the GHR, was demonstrated to have functional consequences in various clinical conditions. The aim of the present study was to investigate the effects of the d3-GHR polymorphism on the extent and characteristics of radiographic in patients with primary OA at multiple joint sites.

Methods: In a case-control study, we compared frequency of GHR$_{fl-d3}$ genotype between patients with familial primary OA from the GARP (Genetics, ARthrosis and Progression) Study, and controls. Kellgren-Lawrence scores were used to assess ROA in the knee, hip and hand; the Osteoarthritis Research Society atlas for the assessment of individual ROA features. Patients and controls were genotyped for 7 single nucleotide polymorphisms (SNPs) encompassing the d3-GHR gene to allow high throughput genotyping. One tagSNP was used as proxy for d3-GHR (full LD, pairwise r^2=1). Binary logistic regression analyses with robust standard errors were performed, to assess the relationship between d3-GHR and ROA.

Results: We studied 373 patients (mean age 60.1, 82% female) and 752 controls. GHR$_{fl-d3}$ genotype was significantly associated with ROA, especially in females (adjusted odds ratio (OR) (95%CI) 1.5(1.1–2.1), p=0.017). Strongest association was found with knee OA (adjusted OR 2.0(1.3–3.0), p=0.002), followed by hand OA (adjusted OR 1.5(1.1–2.1), p=0.024). No

such a relationship was found in males. GHR_{fl-d3} genotype was related to both osteophytes and joint space narrowing.

Conclusion: GHR_{d3-fl} genotype was associated with knee and hand ROA in females with a severe primary OA phenotype, indicating a role for the GH/IGF1 axis in the pathophysiology of primary OA.

Condroitin Sulfate Decreases Chemokine Levels and Synovitis in knee osteoarthritis Patients.

Jordi Monfort[1], Paula Escudero[2], Cristobal Orellana[3], Laura Piqueras[4], Laura Tio[5], Francisco Montañés[1], Natalia García[5], Chantal Company[2], Pere Benito[1] and Maria Jesús Sanz[2]. [1]Hospital del Mar, Barcelona, Spain, [2]Universitary Clinic Hospital Research Foundation-INCLIVA, University of Valencia, Valencia, Spain, [3]Corporació Sanitaria Parc Taulí, Sabadell, Spain, [4]University Clinic Hospital Research Foundation-INCLIVA, University of Valencia, Valencia, Spain, [5]GRICIC. FIMIM, Barcelona, Spain

Background/Purpose: Synovitis is one of the major signs of structure damage in osteoarthritis (OA) progression. Chondroitin sulfate (CS) is an effective drug in the treatment of OA since it can reduce joint swelling and effusion in OA patients as described in the NIH-funded GAIT study. Therefore, the aim of this study was to compare the effect of CS vs. acetaminophen on synovitis in OA patients and to evaluate their impact on chemokine concentrations.

Methods: Synovitis (synovial hypertrophy+effusion≥4mm) assessed by sonography and synovial effusion quantified by artrhocentesis were evaluated in 45 patients treated with CS (800mg/day) or acetaminophen (4g/day) for 6 months. Patients were followed-up until month 9 to evaluate the carry-over effect. Symptomatic effect of both treatments was also evaluated by Lequesne Algo-functional Index (baseline,1.5, 3, 6 and 9 months). The levels of CXCL16, fractalkine/CX_3CL1, MCP-1/CCL-2, RANTES/CCL5 and GRO-α/CXCL1 were determined by ELISA in the plasma and synovial samples collected in each visit. Analysis of continuous variables was based on analyses of covariance (ANCOVA) model. Study of the chemokine variations between each time and the baselines was performed by a Wilcoxon two-related samples test Comparison between the two groups was obtained using an independent sample t-test for quantitative variables or a chi-squared test for qualitative variables. P values ≤0.05 were considered statistically significant for each variable.

Results: Eligible patients had clinical and radiographic evidence of OA (K&L grade 2 and 3) with synovitis. Mean age of patients was 70.4 years being women 72.1% of them. Mean BMI was 28.97. At the end of the study, CS significantly reduced synovitis compared to acetaminophen ($p<0.01$).This significant reduction was also detected in MCP-1 and fracktalkine synovial levels. Compared to baseline, CS treated patients showed significant reductions in synovitis (25.5%) and significant impairment of synovial hypertrophy (61.9% reduction). These effects were accompanied by significant decreases in synovial and serum MCP-1 content. In contrast, in the acetaminophen-treated group no effect on synovitis was observed and increased synovial RANTES levels were even detected. Additionally, CS but not acetaminophen effectively reduced functional incapacity after 6 months of treatment (CS-treated group: 11.5±2.5 vs. 7.9±3.0; $p<0.01$; acetaminophen-treated group: 9.9±4.1 vs. 8.3±4.9; n.s.). CS functional improvement remained after 3 months treatment cessation (month 9) thus confirming CS carry-over effect.

Conclusion: These results indicates that CS but not acetaminophen effectively reduces synovitis and clinical symptoms in OA patients. Evidence of an anti-inflammatory effect for CS has been also provided since it can decrease synovial and plasma levels of relevant chemokines. This study also adds further support and extends the finings described in the NIH-funded GAIT study and suggests that CS seems to be a more effective therapeutic tool for OA and synovial inflammation than analgesics.

1102

Immunoreactive Collagen Type II Cleavage Products and Their Nitrated Forms in Rheumatoid Arthritis and Osteoarthritis: An Outpatient Cross-Sectional Study.

Ruediger Mueller[1], Axel Finckh[2], Guy Heynen[3] and Johannes von Kempis[4]. [1]Cantonal Hospital, St. Gallen, Switzerland, [2]Geneva University Hospitals, Geneva 14, Switzerland, [3]Consulting, CH-6300 Zug, Switzerland, [4]MD, St. Gallen, Switzerland

Background/Purpose: Catabolism of type II collagen (COLII) involves multiple metalloproteinases, aggrecanases and cathepsin, releasing heterogeneous triple helix cleavage products. The complex regulation of these enzymes and of inducible NOS (iNOS)includes inflammatory cytokines. Col2-1 peptide (Col), located towards the N-telopeptide region of COLII contains a tyrosine residue susceptible to endogenous nitration by reactive nitrogen species, forming Col-2-1-NO2 (NCol). Specific immunoassays allow for estimation of nitration index (NI). Using these assays in OA and RA should show differences since RA, unlike OA, is treated with DMARDs known to inhibit structural damage progression.

Methods: Serum (S) and Urine (U) Col and NCol were measured by ELISA in a cross-sectional study (49 RA and 118 outpatients with active hand OA). The ratio of NCol (nmol)/Col (nmol) provided NI. Clinical variables were age, sex, DAS and VAS. Urinary fractional excretions (UFE) of biomarkers was calculated in RA patients.Statistical analysis used STATA® Version 12.1

Results: OA patients were older (64 years vs 58 in RA). Mean DAS28 was 2.64 with 60% receiving corticoids or synthetic and biological DMARD treatment in RA. VAS pain was higher in OA than RA patients (46 vs. 34;$p<0.0001$). Mean SCol concentrations (nmol/l) and SNCol (pmol/l) were higher in RA (308±17 and 687 ±90) than OA (241 ± 13 and 465±39; $p<0.0001$). Mean UCol (nmol/mmol creatinine) was higher in RA than in OA (16.3 vs. 8.1; $p<0.0001$) whereas UNCol (pmol/mmol creatinine) values were similar between the 2 groups (22.4 ±4.3 in RA and 26.2 ±2.1 in OA; $p>0.1$). Col and NCol UFE were 2.87% (2.25–3.48; 95%CI) in RA and 2.63 % (1.81–3.46; 95%CI) and highly correlated (r-square=0.53; $p<0.0001$).The SCol2-1NI was similar in RA (0.238 %, 95% CI: 0.214–0.262) and in OA (0.217, 95% CI: 0.19–0.24; $p>0.05$) but the UCol2-1NI was markedly lower in RA (0.164, 95%CI: 0.141–0.187) than OA (0.37, 95%CI: 0.33–0.42; $p<0.0001$). In both RA and OA, pairwise comparisons of serum and urine NI indicated highly significant differences ($p<0.0001$). None of the disease activity indices were associated with any of the two biomarkers or their ratios in serum or urine.

Conclusion: Data indicate excess nitrated forms of Col2-1 in the urine of patients suffering from active OA in comparison to DMARD treated RA patients, indicating that a greater proportion of OA SNCol immunoreactive forms pass through the renal glomerular membrane than in RA. In RA, fractional excretion of both Col and NCol was low and similar for Col and NCol, excluding a differential renal handling of the detected epitopes. The excess of urinary nitrated forms in OA vs RA may result from the OA disease process itself or from DMARD interference with the iNOS activity in RA. Within patients' differences between serum and urine NI values indicate biological heterogeneity of immunoreactive species containing the Col2-1 epitope. The clinical relevance of this heterogeneity is unknown since the half-life of measured components have not been studied. Additional investigations with specific enzyme inhibitors in OA and biological DMARDs in early RA are warranted to quantify the dynamics of serum and urine components of Col2-1 and its nitrated forms.

1103

Cumulative Occupational Physical Load As Risk Factor for Knee Osteoarthritis.

Allison M. Ezzat[1], Jolanda Cibere[2], Mieke Koehoorn[1], Eric C. Sayre[2] and Linda C. Li[1]. [1]University of British Columbia, Vancouver, BC, [2]Arthritis Research Centre of Canada, Vancouver, BC

Background/Purpose: Knee osteoarthritis (OA) results from the interaction of multiple risk factors, one of which may be physically demanding occupations. The purpose of this study was to determine the association between cumulative occupational physical load (COPL) and the presence of knee OA, defined as Symptomatic Radiographic Osteoarthritis (SOA) or Magnetic Resonance Imaging Osteoarthritis (MRI-OA).

Methods: This was a cross-sectional analysis of symptomatic (n=255) and asymptomatic (n=72) knee cohorts recruited as a random sample from the same population. Participants were 40 to 79 years old. Inclusion criteria

for the symptomatic cohort, Model for the Development of Early Knee Osteoarthritis (MoDEKO), were: 1) pain, aching, or discomfort in/around the knee on most days of the month at any time in the past; 2) pain, aching or discomfort in/around the knee in the past 12 months. In the asymptomatic cohort, participants responded no to both knee pain questions. All participants received a standardized knee exam, fixed flexion knee radiographs and MRI, and completed a comprehensive questionnaire, which included a detailed lifetime occupational history of activity level (5 levels) and knee bending/kneeling activities (3 levels) for each occupation held. Self-reported COPL was calculated by multiplying the number of years in each occupation by the activity level and by the knee bending within that occupation, then summing all occupations. COPL was then grouped into quartiles (QCOPL). SOA was defined by the Kellgren Lawrence x-ray grade > 2, plus the presence of knee pain. MRI-OA was defined using a novel definition by Hunter et al[1] which required either both group A features: osteophyte formation and full thickness cartilage loss; or one group A and two group B features: bone marrow lesion or cyst, meniscal subluxation or tear, partial cartilage loss, or bone attrition. Weighted analysis was done using logistic regression to examine the association between QCOPL and the presence of SOA and MRI-OA, respectively, after adjusting for age, sex, body mass index, and two-way interactions.

Results: Participants (women=167, men=160) were on average 58.5 (SD=11.0) years old with a BMI of 26.3 (SD=4.7). Of those, 102 (31.2%) participants had SOA. A monotonic statistically significant relationship was found between QCOPL and SOA with adjusted odds ratio (OR) of 8.16 (95% CI = 1.89, 35.27) for QCOPL 4 (highest) vs. QCOPL 1 (lowest), and 5.73 (95% CI= 1.36, 24.12) for QCOPL 3 vs. 1. A total of 131(40.1%) participants had MRI-OA. Adjusted OR were also monotonic and statistically significant: QCOPL 4 vs. 1 (OR= 9.54; 95% CI = 2.65, 34.27); QCOPL 3 vs. 1 (OR= 9.04; 95% CI = 2.65, 30.88); QCOPL 2 vs. 1 (OR = 7.18; 95% CI = 2.17, 23.70).

Conclusion: COPL is a significant risk factor for knee OA. A dose response relationship between COPL and both SOA and MRI-OA was found. MRI-OA is a new definition, which has potential to capture early structural disease in a way not previously quantified. Due to the nature of the cross-sectional study design, these results should be interpreted cautiously but provide evidence for further prospective, longitudinal studies.

The Association of Demographic, Modifiable, Structural and Biomechanical Risk Factors with Medial and Lateral Patellofemoral Joint Structural Damage On MRI: The Multicenter Osteoarthritis Study. Joshua J. Stefanik[1], Ke Wang[1], K. Douglas Gross[2], Frank Roemer[3], John A. Lynch[4], Neil Segal[5], Cora E. Lewis[6], Michael C. Nevitt[4], Ali Guermazi[1] and David T. Felson[1]. [1]Boston University, Boston, MA, [2]MGH Institute of Health Professions, Boston, MA, [3]Klinikum Augsburg, Augsburg, Germany, [4]University of California-San Francisco, San Francisco, CA, [5]University of Iowa, Iowa City, [6]University of Alabama, Birmingham City, Birmingham, AL

Background/Purpose: Past investigations into risk factors for patellofemoral joint (PFJ) osteoarthritis (OA) have been limited by the use of radiography, which is insensitive to identify PFJ OA and have focused on only a few risk factors. MRI offers a unique opportunity to directly visualize tissue damage in the PFJ, and risk factors related to medial PFJ damage, which was recently reported as common (Gross, ARD, 2012), can be distinguished from those related to lateral damage. The purpose of this study is to evaluate the association between PFJ structural damage on MRI with a wide spectrum of risk factors including: demographic, modifiable, structural, and biomechanical factors.

Methods: We analyzed data from the baseline exam of MOST, a NIH-funded cohort study of persons aged 50–79 years with or at risk for knee OA. Knees for this study came from persons with x-ray OA in tibiofemoral joint and/or PFJ. *Demographic* risk factors included age, sex, and race. *Modifiable* risk factors included BMI, occupational history, quadriceps strength, and hamstring-quadriceps strength ratio. *Structural* risk factors included Insall-Salvati ratio (measure of patella alta), lateral trochlear inclination (measure of trochlear morphology), and femur length. *Biomechanical* risk factors included varus and valgus alignment (from long limb x-rays). Cartilage damage and bone marrow lesions (BMLs) were assessed on MRI using the WORMS scale in 4 regions (medial and lateral patella and trochlea). PFJ structural damage was defined in two ways: 1) full-thickness cartilage loss (WORMS 2.5; ≥5 on a 0–6 scale) and 2) full-thickness cartilage loss in addition to a BML (≥1 on a 0–3 scale). We examined the cross-sectional

association between risk factors and PFJ structural damage using logistic regression with GEE to account for the correlation between regions from the same knee. We performed analyses in the PFJ overall (damage in any of the four regions) and for the medial and lateral PFJ separately.

Results: 1268 regions from 317 knees were studied (mean age 63.5 years, mean BMI 30.5 kg/m², 67% female). Full-thickness cartilage damage was present in any PFJ region, medial, and lateral in 20%, 16%, and 25% of regions, respectively. The hamstring-quadriceps ratio, Insall-Salvati ratio, and lateral trochlear inclination demonstrated the strongest associations with overall and lateral PFJ damage (see table). Females and older subjects were more likely to have medial but not lateral PFJ damage. Femur length was strongly associated with lateral PFJ damage. Similar results were seen for the PFJ damage definition including a BML.

Association between demographic, modifiable, structural, and biomechanical risk factors and full-thickness cartilage damage (WORMS 2.5; ≥5) in the PFJ

Neutral (Reference)	1.0	1.0	1.0
Valgus	1.5 (0.97, 2.4)	1.1 (0.5, 2.4)	**2.2 (1.1, 4.3)**
Varus	0.9 (0.6, 1.3)	1.3 (0.7, 2.4)	0.6 (0.3, 1.1)

Conclusion: PFJ structural damage is more strongly related to structural and demographic factors than to modifiable ones. Risk factors may be different for medial and lateral PFJ structural damage. Future studies should evaluate risk factors separately for medial and lateral PFJ damage.

Lateral Tibio-Femoral Shift Related to Medial Knee Osteoarthritis. Roy H. Lidtke[1], Berna Goker[2], Abdurrahman Tufan[2], Laura E. Thorp[1] and Joel A. Block[1]. [1]Rush University Medical Center, Chicago, IL, [2]Gazi University Medical School, Ankara, Turkey

Background/Purpose: Medial knee osteoarthritis (MKOA) has been shown to be related to malalignment of the knee joint with several radiographs used to quantify the abnormality. Radiographic observations of a lateral tibial shift in subjects with MKOA has led the authors to hypothesize that this finding is more prevalent in MKOA than normal controls and is associated with MKOA measurable gait parameters.

Methods: 90 subjects (69F 21M, Age 60±8, BMI 28.3±4.0) with radiographic and symptomatic medial knee OA (K-L grade 2–3, ambulatory pain >30 mm on a 100 mm VAS) were compared to 24 (18F 6M) age (59±10) and BMI (28.8±8.3) matched controls with no knee pain (K-L grade 0–1). Full limb mechanical axis and AP X-rays of the ankles were obtained. The tibial lateral shift (*figure 1*), defined as the distance between the center of the intercondylar notch of the femur and midpoint of the tibial plateau, was measured using Image J software (US NIH, Bethesda, MD, http://rsbweb.nih.gov/ij/). Subjects underwent gait analyses using an optoelectronic camera system and multi-component force plate. Comparisons were performed after matching for speed. The peak external knee Adduction Moment (%body weight * height, %BW*Ht) and knee adduction angular impulse was calculated and used as the primary endpoint. Paired t-tests were used to compare group differences. Pearson's correlations were calculated to analyze the relationship between knee moments and the other radiographic parameters with significance set at $p<0.05$.

Results: The mean ± S.D. lateral tibio-femoral shift was 5.18±2.45 mm in the MKOA group compared to 1.5±1.22 mm in the control group ($p<0.01$). Interestingly there was no relationship between the lateral shift and mechanical axis ($r=0.11$, $p=0.23$). There was an apparent relationship between the external knee adduction moment and lateral tibial shift in the MKOA group with greater lateral tibial shift related to greater knee moments ($r=0.46$, $p<0.01$). There was no relationship between knee adduction moments and lateral tibial shift in the control group ($r=0.13$, $p=0.09$). There was a relationship between knee angular impulse to the lateral shift in the MKOA group ($r=0.48$, $p<0.01$).

Conclusion: Lateral tibio-femoral shift is greater in MKOA than in normal controls and is related to increased medial knee loads. These findings suggest that the lateral tibio-femoral shift may be a new radiographic marker for MKOA. Further studies are needed to determine the clinical validity of assessing the tibio-femoral shift.

Evaluation of Foot Posture and Plantar Pressure Changes in Knee Osteoarthritis: Preliminary Report. Necati Balci and Lale Cerrahoglu. Celal Bayar University Medical School, Manisa, Turkey

Background/Purpose: Disturbances of weight bearing and walking pattern occur in patients with knee osteoarthritis (OA) due to impairments in knee joint. These impairments may lead to changes in the mechanical alignment of lower limb and dynamic function of the foot. Therefore, it has been given special attention to foot orthoses and footwear modifications as a non-operative treatment of knee OA. However, in order to fully understand the effect of these interventions on the knee and other lower limb joints, greater knowledge of foot structure is required. We aimed to study the plantar pressure and foot posture characteristics of knee OA and their relationship with disease characteristics.

Methods: A total of 78 feet of 39 patients with bilateral knee OA (ACR criteria) were evaluated regarding clinical and biometrics data. Demographic and disease characteristics were obtained. The radiographical evaluation was done based on anterior-posterior tibio-femoral radiographs using the Kellgren-Lawrence (KL) grading scale (0-4). Barefoot dynamic plantar pressure and the Arch index (AI) were measured by the 3D footscan system. The Foot posture index (FPI-6) was obtained. Correlation (Pearson's correlation coefficient) and regression analyses were performed between various plantar pressure analysis, clinical parameters and disease-related parameters.

Results: Thirty nine patients (11 male) with mean age 51,53 (standard deviation (SD):11,89) and mean BMI 30,5 (SD:4,9) were recruited. For dynamic plantar pressures; grade in right knee according to KL radiologic criteria correlates with left foot medial heel, left midfoot and left middle forefoot pressures ($r=0,40$, $p=0,010$; $r=0,33$, $p=0,040$; $r=0,36$, $p=0,022$ respectively). Grade in left knee according to KL radiologic criteria correlates with left heel, left midfoot and inversely correlates with right foot toe pressure ($r=0,33$, $p=0,036$; $r=0,41$, $p=0,010$; $r=-0,41$, $p=0,009$ respectively). For foot posture; grade in right knee according to KL radiologic criteria correlates with right FPI-6, grade in left knee according to KL radiologic criteria correlates with left FPI-6, right FPI-6 and left AI ($r=0,38$, $p=0,015$; $r=0,41$, $p=0,008$; $r=0,41$, $p=0,009$; $r=0,33$, $p=0,036$ respectively). In multivariate regression analysis it is found that left KL grade was most affected from left AI ($p=0,045$).

Conclusion: The dynamic variables of plantar pressure and foot posture are sensitive to the OA grading. These results suggest that people with the higher OA grade exhibit a more pronated foot type and shifted pressure distribution. We can

maintain a superior biomechanical correction by advanced evaluation of foot structure in non-operative treatment of knee OA such as orthoses and footwear modifications. As a result, the assessment of patients with knee OA in clinical practice should include simple foot measures and evaluation.

Baseline Knee Flexion Pain, Age and Joint Line Tenderness Predict the Progression of Asymptomatic, Radiographic Knee Osteoarthritis to Symptomatic Knee Osteoarthritis Over 5 Years. Abhiram Gande[1] and James J. Irrgang[2]. [1]University of Pittsburgh School of Medicine, Pittsburgh, PA, [2]University of Pittsburgh, Pittsburgh, PA

Background/Purpose: Knee Osteoarthritis (OA) is the most prevalent form of OA. Historically, not all people who have tell-tale signs of radiographic knee osteoarthritis progress to symptomatic knee osteoarthritis, and vice versa. According to a meta-analysis by Bedson et. al, the prevalence of radiographic knee OA (Rad OA) in symptomatic patients can range between 15–76%. However, Duncan et. al observed a strong correlation between increased symptoms and radiographic OA findings. Such inconsistencies may be resolved with a better understanding of the risk factors for symptomatic knee OA. To date, there has been no survey of risk factors involved in the progression of baseline asymptomatic Rad OA to symptomatic Rad OA (Symp OA). Therefore, we evaluated the abilities of various physical exam measures and demographical variables in predicting such progression over five years.

Methods: Data from the Knee Osteoarthritis Initiative (OAI), a prospective longitudinal study of biomarkers involved in the onset and progression of OA in nearly 5000 subjects, were used for this study. Inclusion criteria were individuals who had Rad OA—score ≥ 2 on the Kellgren/Lawrence (K-L)—at baseline. The cases progressed to develop Symp OA—knee pain on most days of the month over the last 12 months—at 3 years, and remained symptomatic at 4 and 5 years, while the controls remained asymptomatic at all three time points from baseline. Cases and controls were matched for baseline knee K-L score, presence of unilateral or bilateral index knees and consistency of symptoms at all three time points (3, 4, and 5 years). The predictor variables were age, gender, BMI, abdominal circumference, walking ability (20m and 400m walk times), chair stands time, presence of Hand OA, varus/valgus malalignment, medial and lateral joint line tenderness, knee flexion pain, flexion contracture or hyperextension sign, bulge sign, patellar tap sign and isometric quadriceps strength corrected for body weight. Univariate conditional logistic regression was performed and p-values, odds ratios and 95 %confidence intervals were calculated.

Results: The baseline sample included 2093 individuals with Rad OA (K-L ≥ 2). The matching process yielded 94 cases and controls, with similar demographic data (Table 1). Logistic regression analysis revealed that age ($p=0.04$), medial joint line tenderness ($p=0.008$), lateral joint line tenderness ($p=0.01$) and knee flexion pain ($p=0.047$) were significant predictor variables. 95% confidence intervals were >1 and odds ratios were >1 for the four significant variables.

Conclusion: Age, knee flexion pain, medial and lateral joint line tenderness are measures with significant ($p<0.05$) predictive ability of progression from baseline Rad OA to Symp OA. As such, these commonly used demographic and physical exam measures can help physicians identify individuals with asymptomatic radiographic OA who may be at risk for developing chronic knee pain. Ultimately, older age and positive signs on these physical exam measures can serve as markers to initiate aggressive management to help prevent the onset of symptomatic knee OA.

A Randomized Controlled Trial of Hylan G-F 20 for the Treatment of Carpometacarpal Osteoarthritis. Lisa A. Mandl[1], Scott Wolfe[2], Aaron Daluiski[2], Robert N. Hotchkiss[1], Stephen L. Lyman[3] and Jeffrey N. Katz[4]. [1]Hospital for Special Surgery, New York, NY, [2]Hospital For Special Surgery, New York, NY, [3]Hospital Special Surgery, New York, NY, [4]Brigham and Women's Hospital, Boston, MA

Background/Purpose: Painful carpometacarpal osteoarthritis (CMC OA) is associated with substantial impairment, and is often unresponsive to medical treatment. Hylan G-F 20 has been shown to improve pain and function in patients with knee OA; however, its effectiveness in CMC OA is unknown.

Methods: 200 patients with radiologic evidence of CMC OA and no inflammatory arthritis were randomized to receive one of the following three

regimens: 1cc of Hylan G-F 20 weekly for 2 weeks; 1cc triamcinolone acetonide (40mg) followed 1 week later by 1cc 0.5% bupivacaine; or 0.5% 1cc bupivacaine weekly for 2 weeks. Randomization was double blind and stratified on previous intra-articular steroid treatment. An experienced hand surgeon performed all injections without radiologic guidance. Patients were assessed 26 weeks after the first injection. An intention to treat, last-value carried forward analysis was performed on all patients who had at least one post-injection visit.

Results: 188 patients were eligible for this analysis. Average age was 66.5 years (range 45–89), 67.7% female and 90.4% Caucasian. 33%, 31% and 38 % had previously received a corticosteroid injection in the Hylan G-F 20, triamcinolone and bupivacaine groups respectively. 100 (53%) had Kellegren and Lawrence (K+L) Grade <=3 in the CMC joint and 88 (47%) had K+L Grade 4. At 26 weeks, pain as measured by the Visual Analogue Scale (VAS) showed statistically and clinically significant improvement in all treatment groups. However, there was no statistically or clinically significant difference in VAS between treatment arms at 26 weeks. No treatment arm resulted in clinically meaningful improvements in function, as measured by the Disabilities of the Arm, Shoulder and Hand Questionnaire (DASH). In a multivariate regression analysis, controlling for age, sex, K+L grade, baseline pain and treatment assignment, neither K+L Grade nor treatment assignment was associated with a difference in pain at 26 weeks. Among those with severe K+L Grade 4 CMC OA, all three treatments led to clinically and statistically significant improvements in pain at 26 weeks, with no differences between groups.

Table 1.

	Hylan G-F 20 Mean ± s.d.	Triamcinolone Mean ± s.d.	Bupivacaine Mean ± s.d
All Patients (188)			
VAS Baseline (100=severe)	60.7 ± 19.3	63.2 ± 20.2	57.1 ± 20.1
VAS 26 weeks	49.8 ± 26.3	50.1 ± 29.4	42.9 ± 26.5
Delta VAS	-10.9 ± 26.7	-13.1 ± 29.9	-14.2 ± 20.8
p-value within group change	**0.002**	**0.003**	**<0.0001**
DASH Baseline	28.8 ± 17.3	28.9 ± 17.9	25.7 ± 17.1
DASH 26 Weeks	26.1 ± 19.0	27.0 ± 18.0	24.2 ± 17.4
Delta DASH (N=175*)	-3.53 ± 11.4	-2.88 ± 14.9	-1.39 ± 12.3
p-value within group change	**0.02**	0.14	0.07
K+L <3 (N=100)			
VAS for Pain	61.7 ± 19.5	64.8 ± 18.8	51.1 ± 23.4
VAS at 26 weeks	51.6 ± 28.8	56.8 ± 31.6	40.6 ± 28.9
Delta VAS	-10.1 ± 23.7	-7.96 ± 29.1	-10.5 ± 21.3
p-value within group change	**0.02**	0.22	**0.02**
K+L 4 (N=88)			
VAS for Pain	59.3 ± 19.3	61.1 ± 22.1	61.9 ± 16.0
VAS at 26 weeks	47.3 ± 22.6	41.3 ± 23.9	44.8 ± 24.8
Delta VAS	-12.0 ± 30.9	-19.8 ± 30.0	-17.1 ± 20.2
P-value within group change	**0.009**	**0.003**	**<0.0001**

* N=175 due to missing data

Conclusion: In patients with CMC OA, intra-articular Hylan G-F 20 was not superior to corticosteroids or bupivacaine in reducing pain and improving function at 26 weeks. All three treatments resulted in significant improvements in pain, even among patients with severe CMC OA. A variety of injectable therapies appear to be effective treatments for this condition, even in those with severe arthritis.

Effects of Strontium Ranelate On Hand Osteoarthritis - Analysis of Data From the Sekoia Trial. E. Maheu[1], C. Cadet[2] and F. Berenbaum[1]. [1]AP-HP St Antoine Hospital, Paris, France, [2]Paris, France

Background/Purpose: Strontium ranelate (SrRan) has shown the ability to reduce radiological progression of knee osteoarthritis (OA) over 3 years. Patients with knee OA are also frequently affected by hand OA. In this secondary analysis, we assessed the effects of SrRan on radiological and symptom progression of hand OA.

Methods: This international 3-year, randomized, placebo-controlled phase III trial was designed to assess the effect of SrRan 1g and 2g/day compared to placebo on the radiographic progression of knee OA. Main inclusion criteria were symptomatic primary knee osteoarthritis (ACR criteria), a Kellgren-Lawrence (KL) grade II or III, and a joint space width (JSW) between 2.5-5 mm. There were no specific inclusion criteria regarding hand

OA. Hand OA radiographic and clinical assessments were secondary outcomes. During the study, baseline and final postero-anterior radiographs of each hand were performed and scored by 2 independent readers, blinded to treatment and time sequence, using KL (range 0–128), Kallman (0–204) and Verbruggen (0–218) scoring methods. Clinical symptoms were assessed at each visit by the Auscan (0–300) and Functional Index for Hand OA (FIHOA) (0–30). Between-group analyses were performed using a general linear model with baseline, center and gender as covariates.

Results: Of the 1669 patients included in the SEKOIA trial, 999 had radiologic hand OA at baseline (73%). 71% were female. Mean age was 64±7 years, body mass index 29.6±4.7 kg/m^2, and initial knee JSW 3.4±0.8 mm. Hand OA was mild in radiologic severity: KL score 21±13, Kallman score 25±22 and Verbruggen score 14±15. Mean Auscan global score was 96+80 mm and mean FIHOA score was: 4±5.

The radiographic progression of hand OA observed over 3 years was modest in the placebo group with a mean change of 2.4±3.3 for KL score, 3.7±5.3 for Kallman score and 2.0±3.9 for Verbruggen score. There was no difference between the treatment groups for any radiological score. A significantly higher rate of patients reported an improvement of 20% or more in the Auscan pain subscale in the SrRan 2 g group (95% CI [0.1; 16.3]; p=0.047) compared to placebo.

In erosive patients (≥2 erosive joints, N=71), a significant improvement of KL score (p=0.031) in the SrRan 2 g compared to placebo was observed. In symptomatic patients (FIHOA >5 and pain within the 48 hours prior to the visit, N=126), a trend toward a higher improvement of KL score was noted in the SrRan 2 g group compared to placebo (p=0.079)

Conclusion: Overall, mild hand OA patients showed a very slow radiological progression, with no between-group difference over 3 years. However, in subgroup analyses, a slight beneficial effect of strontium ranelate 2g could be observed on pain and a positive effect on the change in KL score was suggested in the more severe hand OA patients. These results encourage conducting a specific trial in hand OA in the next future.
