Background/Purpose: The aim of this systematic literature review was to inform the task force for updating the European League Against Rheumatism recommendations for the management of Behçet's Syndrome (BS), about the evidence for treatment of skin, mucosa and joint involvement of BS.

Methods: A systematic literature search, data extraction and statistical analyses according to pre-specified eligibility criteria were performed using the GRADE approach. The protocol for the systematic literature review was registered at PROSPERO (CRD42015027033). The Cochrane Library, including the Cochrane Central Register of Controlled Trials (CENTRAL), Cochrane Database of Systematic Reviews (CDSR), Database of Abstracts of Reviews of Effects (DARE), Health Technology Assessments (HTA), MEDLINE (from 1950), EMBASE (from 1980) and International Pharmaceutical Abstracts Database (IPAD) were systematically searched. Randomised controlled trials (RCT), non-randomised controlled clinical trials and open label trials (OLT) on BS comparing an active intervention (alone or in combination) with any control or placebo were eligible. If controlled trials were not available for answering a specific research question, uncontrolled evidence from cohort studies or case series involving ≥ 5 patients were considered. The quality of evidence was assessed by using the GRADE approach. Risk ratios were calculated for the binary outcomes whereas for the continuous outcomes we calculated the standardized mean difference (SMD).

Results: Among the 3927 references that we have screened, 22 studies satisfied the inclusion criteria for mucocutaneous involvement and 15 studies for joint involvement. Seventeen of these studies were randomized controlled trials assessing mucocutaneous and/or joint involvement. RCTs with colchicine, azathioprine, interferon-alpha, thalidomide, etanercept and apremilast showed different levels of beneficial results on different types of skin and mucosa lesions and arthritis. Differences in the outcome measures that were used across the included studies made it difficult to compare the results. These agents were generally well tolerated with few adverse events causing withdrawal from the study in BS patients.

Conclusion: It was gratifying to see that randomized controlled trials formed the majority (17/22, 77%) of the sources forming the basis for the recommendations related to skin mucosa and joint involvement in the updated EULAR Recommendations for the management of BS.

Inflammation As an Under-Recognized Cause of Ascending Aortic Aneurysms: A Single-Center Clinical and Pathological Study of 53 Cases over 6 Years

Tariq Al-Araimi[1] and Arthur Bookman[2], [1]Department of Medicine, Toronto, ON, Canada, [2]Division of Rheumatology, University Health Network, University of Toronto, Toronto, ON, Canada, Toronto, ON, Canada

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016

Session Title: Vasculitis - Poster III: Rarer Vasculitides

Session Type: ACR Poster Session C

Session Time: 9:00AM-11:00AM

Background/Purpose: This study is aimed at estimating the prevalence of inflammatory ascending aneurysms, describing clinical and histopathological findings, and assessing whether appropriate follow-up was arranged post discharge

Methods: Data from Enterprise Data Warehouse was retrieved for all cases of ascending aortic aneurysms from Jan 2009-Dec 2015 requiring surgery at the University Health Network for the following diagnostic codes: thoracic aortic aneurysm, ruptured (I71.1) or without mention of rupture (I71.2); aortic aneurysm of unspecified site, ruptured (I71.8) or without mention of rupture

(I71.9). After eliminating duplicate retrievals, 743 had their ascending aorta resected. Of these, 730 had aneurysmal dilatation, defined as maximum diameter ≥40mm measured by pre-operative echo or cardiac CT/MRI. All cases with ascending non-infectious inflammatory aneurysms were identified and reviewed for clinical presentation, imaging, histopathological and management method.

Results: Among the 730 cases studied, 53 (7.3%) were of a non-atherosclerotic, non-infectious inflammatory pathogenesis. Mean age was 67 years (18-68), with 50.9% women. Asymptomatic presentation occurred in 52.9%, 7.8% had constitutional symptoms and 43.1% had symptoms that could be attributed to an aneurysm. Isolated aortitis with no other evidence of arterial involvement presented in 41 (77.3%), and 12 had underlying rheumatic disease: Rheumatoid Arthritis (4), Polymyalgia Rheumatica (3), Giant Cell Artertitis (3), Systemic Lupus Erythematosus (1) and Cogan's Syndrome (1). Echocardiographic findings demonstrated a maximum mean aneurysm diameter of 54.7± 6.8mm, aortic insufficiency (AI) in 73.5%, stenosis (AS) in 9.4% and mixed AS & AI in 3.8%. A bicuspid aortic valve was found in 15.1%. Twenty-five (47.1%) had the aortic aneurysm distal to the ascending aorta and changes of calcification or atherosclerosis seen on CT (10) or intraoperatively (12). Histopathology revealed Giant Cell Aortitis in 35.8% (19), Takayasu's Arteritis in 5.7% (3), Lymphoplasmacytic Aortitis in 22.6% (12), Mixed Lymphoplasmacytic with Giant Cells in 15.1% (8) and unclassified in 20.8% (11). No lymphoplasmacytic cases were stained for IgG4. Four patients received perioperative steroids. Only 1 had aortitis mentioned in the discharge summary. Of the 53, 24 had a follow-up visit, 8 of which had aortitis diagnosis in the follow-up notes. Two were referred to a rheumatologist, 4 had their family MD notified, and 2 already had a rheumatologist. Rheumatologist referrals status for the remaining 45 (84.9%) patients after discharge is unknown.

Conclusion: Ascending Aortitis is under-recognized as a cause of ascending aortic aneurysms. Diagnosis is often incidental as most patients are asymptomatic. The presence of an aortic bicuspid valve or aortic stenosis and changes of atherosclerosis on imaging or in the intraoperative period do not rule out an inflammatory aortic aneurysm. IgG4 staining should be routine practice for all patients with lymphoplasmacytic aortitis. Cardiovascular surgeons, Pathologists and rheumatologists need to develop protocols for appropriate care of this patient subset. Further multi-center studies are needed.

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016

Session Title: Vasculitis - Poster III: Rarer Vasculitides

Session Type: ACR Poster Session C

Session Time: 9:00AM-11:00AM

Background/Purpose: Idiopathic Aortitis (IA) is poorly defined, with no specific criteria for its classification or diagnosis, except for presence of aortic inflammation and the absence of clinical features of another systemic condition. We aim to establish a prospective cohort of patients with surgically diagnosed aortitis and compare disease features in patients with IA and aortitis secondary to a systemic inflammatory condition (SA).

Methods: This is a single-center, prospective cohort study. Patients are recruited following identification of aortitis on surgical specimen. Baseline assessment includes clinical assessment, inflammatory markers (ESR and CRP), serology to exclude a connective tissue disease and infectious causes, and full imaging of the aorta and its branches. Patients are classified as either IA or SA, and followed prospectively. Clinical assessments and measurements of ESR and CRP are done at least yearly, and full imaging of the aorta and branches at least every 2 years. Primary outcome of interest is radiographic progression of aortitis (new aortic or branch lesions or progression of existing lesions). Secondary outcomes include the need for delayed immunosuppressive therapy, need for aortitis-related surgeries, or a change in diagnosis (from IA to SA).

Results: Fourteen patients have been enrolled to date, 8 IA, 6 SA (5 giant cell arteritis (GCA), 1 rheumatoid arthritis (RA)). The majority of patients are female (7/8 IA, 6/6 SA); average age 74 and 75 years in IA and SA respectively. Four out of eight patients with IA and 2/6 with SA had aortic branch lesions at baseline. Mean follow-up is 2.3 and 1.8 years in IA and SA groups, respectively. One patient (with SA) was found to have worsening aortic dilatation 15.4 months post-biopsy (PB); new aortic branch involvement was observed in 3/8 patients with IA (identified at mean 9.3 months PB) and in 3/6 SA (identified at mean 13.3 months PB). Surgical re-intervention was required in 2 patients with IA (mean 6.5 months PB). Two patients with IA received a combination of prednisone (initiated at a mean dose of 45 milligrams (mg) daily) and methotrexate (20mg weekly) starting at 36.0 months 38.2 months PB respectively for worsening aortitis. Two patients with SA received prednisone for worsening of their underlying condition, not related to diagnosis of aortitis: one was finishing a course of prednisone initiated for flare of RA prior to diagnosis of aortitis and the other was treated for symptomatic GCA 3.2 months PB (starting dose of 40 mg daily). One patient with IA died due to a cause unrelated to aortitis 17.5 months PB.

Conclusion: Preliminary data suggest patients with IA and SA may experience a significant rate of radiographic vascular progression, particularly in terms of development of branch vessel abnormalities. The number of events was too low to detect significant differences between IA and SA with respect to any of the studied parameters. Further enrollment and a longer duration of follow-up are needed. Controlled studies would be required to assess whether treating IA with corticosteroids at the time of diagnosis would reduce radiographic progression or other complications.

SESSION INFORMATION
Session Date: Tuesday, November 15, 2016
Session Title: Plenary Session III: Discovery 2016
Session Type: ACR Plenary Session
Session Time: 11:00AM-12:30PM

Background/Purpose: The possible association between tumor necrosis factor inhibitors (TNFi) in the treatment of juvenile idiopathic arthritis (JIA) and an increased risk of malignancy remains uncertain. We combined and analyzed data from two large administrative claims sources to further evaluate malignancy rates in JIA.

Methods: Using national U.S. Medicaid claims from 2000-2010 inclusive and U.S. MarketScan claims from 2010-2014 inclusive, we identified cohorts of children with JIA using physician diagnosis codes and medication prescriptions. We identified non-JIA comparator cohorts of children diagnosed with attention-deficit hyperactivity disorder (ADHD). Children with any physician diagnosis code for malignancy prior to the start of follow-up were excluded, and all children had a ≥ 6 month baseline assessment period. JIA medication exposures included MTX (methotrexate or leflunomide), TNFi, and other systemic immunosuppressant agents (non-TNFi biologics or other non-biologics (e.g., cyclosporine)). All follow-up time following any medication exposure was considered exposed. Incident cancers were identified using a combination of diagnoses and treatment codes (claims for chemotherapy, radiation, or surgery). SEER cancer surveillance data were used to calculate expected cancer rates according to the age, sex, and race distribution of each cohort. Standardized incidence ratios (SIR) were calculated for the observed cancer

outcomes compared to SEER estimates.

Results: We identified 2,657,899 children with ADHD and 27,621 children with JIA and observed 841 and 23 incident malignancies, respectively (Table). The outcome identification algorithm appeared specific and sensitive for incident cancer, since the large ADHD comparator had SIR of 1.18 [1.11-1.27]. SIRs were significantly increased among all JIA patients (2.7 [1.7-4.0]) and among those who did not receive any medications of interest (2.4 [1.1-4.5]). We observed 8 malignancies after 15,269 person-years of observation in children who received TNFi; the corresponding SIR (3.3 [1.4-6.6]) was similar to that for children who did not receive TNFi. Based on 7 cases, the SIR associated with any use of other systemic immunosuppression was markedly elevated (14.0 [5.6-28.9]), and included use of abatacept, cyclosporine, rituximab, tacrolimus, and tocilizumab each by 1 patient and anakinra by 2 patients.

Conclusion: We did not observe a marked incremental increase in incident malignancies following treatment with TNFi compared to malignancy rates associated with the diagnosis of JIA. Receipt of non-MTX, non-TNFi systemic immunosuppressive therapies, a likely indication of severe or uncontrolled JIA, was strongly associated with an increased rate of malignancy.

SESSION INFORMATION
Session Date: Tuesday, November 15, 2016
Session Title: Plenary Session III: Discovery 2016
Session Type: ACR Plenary Session
Session Time: 11:00AM-12:30PM

Background/Purpose: Tofacitinib is an oral Janus kinase inhibitor under investigation for treatment of psoriatic arthritis (PsA). This study evaluated tofacitinib efficacy and safety vs placebo (PBO) in patients (pts) with active PsA.

Methods: This was a randomized, PBO- and active-controlled, double-blind, multicenter, Phase 3 study. Eligible pts had a diagnosis of PsA for ≥6 months, fulfilled ClASsification criteria for Psoriatic ARthritis (CASPAR), had active arthritis (≥3 tender/painful and ≥3 swollen joints) and active plaque psoriasis, inadequate response to ≥1 csDMARD, and were tumor necrosis factor-inhibitor-naïve. Pts were randomized 2:2:2:1:1 to tofacitinib 5 mg twice daily (BID; n=107), tofacitinib 10 mg BID (n=104), adalimumab 40 mg subcutaneous injection once every 2 weeks (n=106), PBO→tofacitinib 5 mg BID (n=52) or PBO→tofacitinib 10 mg BID (n=53). Pts who initially received PBO advanced to tofacitinib 5 or 10 mg BID in a blinded manner at Month (M) 3. Ongoing treatment with a stable dose of 1 csDMARD was mandatory. Pts were followed through M12. The primary endpoints were ACR20 response rate and change from baseline in Health Assessment Questionnaire Disability Index (ΔHAQ-DI) at M3.

Results: Pt demographics and baseline disease characteristics were similar across groups (Table 1). Of the 422 randomized pts, 405 (96.0%) completed M3 and 373 (88.4%) completed M12. Significantly greater improvements in ACR20 response rates and ΔHAQ-DI were observed for both tofacitinib doses vs PBO at M3 and were maintained to M12 (Table 2); greater improvements were also observed for adalimumab vs PBO. Tofacitinib 5 and 10 mg BID demonstrated superiority vs PBO for ACR20 response rate as early as Week 2 (22.4% and 31.7% vs 5.7%; $p<0.001$). Secondary efficacy endpoints supported the primary findings (Table 2). Safety findings through M12 were similar between groups (Table 3). The most common adverse events over 12 months were upper respiratory tract infection (7.5–10.6% of pts across groups), nasopharyngitis (7.5–11.5%), and headache (3.8–10.6%).

Conclusion: Tofacitinib was superior to PBO in ACR20 response rate and ΔHAQ-DI at M3, with superiority vs PBO as early as Week 2 (first assessment) for ACR20, which was maintained to M12. Secondary endpoints supported the primary analyses. No new safety risks were identified vs previous studies in RA or psoriasis pts.

Session Date: Tuesday, November 15, 2016

Session Title: Plenary Session III: Discovery 2016

Session Type: ACR Plenary Session

Session Time: 11:00AM-12:30PM

Background/Purpose: Type I interferon, (IFN-I) is strongly implicated in the pathogenesis of SLE as well as rare monogenic 'interferonopathies' such as Aicardi-Goutieres Syndrome (AGS) caused by mutations in the DNA exonuclease, TREX1. A new DNA activated IFN-I pathway, cyclic GMP-AMP (cGAMP) synthase (cGAS), was recently discovered and linked to mouse models of AGS and Lupus. To identify potential inhibitors of the DNA-cGAS interaction, we performed *in silico* screening of chemical and drug libraries and tested the lead candidate, X6, in the mouse model of AGS.

Methods: *In silico* structure-based drug screening and ligand binding studies were performed by the CANDO platform followed by docking analysis via Autodock Vina and Chimera. In vitro cGAS activity/cGAMP production was analyzed by Thin Layer Chromatography (TLC). Following DNA cell transfections, cytokines were quantified by qPCR, ELISA or an ISRE-luciferase reporter assay. Trex1-/- mouse were treated orally with 25mg/kg/day drug X6 (n=8) for 8 weeks from birth. Multiple Reaction Monitoring by Ultra-Performance Liquid Chromatogram coupled with tandem Mass Spectrometer (UPLC-MS/MS) was used to quantify cGAMP. Heart pathology on Hematoxylin and Eosin stained slides was blindly scored by a pathologist.

Results: In silico analysis of drug libraries identified several antimalarial drugs (AMD) which could potentially inhibit cGAS activity by interacting with the cGAS/DNA dimer complex. TLC revealed that AMDs attenuated cGAS activity and inhibited cGAMP production in a dose dependent manner. These AMD also inhibited IFN-b expression in THP1 cells transfected with dsDNA and in 293T cells transfected with cGAS/STING plasmids validating that cGAS is a target of AMD. Based on the relative potencies of AMD and additional modeling, we synthesized several new AMD derivatives. One of these compounds, X6, had excellent water solubility and cell penetration. X6 localized to the cytosol and had a lower toxicity profile compared to quinacrine. Biochemical and cellular assays revealed that X6 was a potent inhibitor of IFN-I production. Since deficiency of the TREX1 in mice (TREX1-/-) leads to an autoimmune myocarditis and lupus-like systemic autoimmunity with increased Interferon Signature Genes (ISGs) expression and cGAMP production, we treated these mice with X6. When compared to vehicle control treated TREX1-/- mice, drug X6 reduced ISGs ISG15 ($p<0.01$) and ISG20 ($p<0.01$) expression in the spleen and CXCL10 ($p<0.01$) and ISG15 ($p<0.05$) expression in the heart. In addition, treatment with X6 resulted in a statistically significant reduction in cGAMP in the heart ($p<0.05$) as well as a reduction in endocardial fibrosis severity scores ($p<0.05$) compared to control.

Conclusion: Our studies indicate that, in addition to reducing activation of intracellular TLRs, AMD attenuate cGAS activity. Since disease in TREX1-/- mice is absolutely dependent on the cGAS pathway as indicated by rescue of disease in double knockouts, we show here that the novel AMD derivative, X6, attenuates disease by inhibiting cGAS activity and IFN-b expression in vivo. This class of drugs could be beneficial for the treatment of AGS and /or Lupus.

Session Date: Tuesday, November 15, 2016

Session Title: Plenary Session III: Discovery 2016

Session Type: ACR Plenary Session

Session Time: 11:00AM-12:30PM

Background/Purpose: The Medicare Access and CHIP Reauthorization Act (MACRA) of 2015 has put into place an aggressive timeline for a Merit-Based Incentive Payment System (MIPS) and for Alternative Payment Models (APMs). For rheumatologists to be successful under these payment reforms, it will be critical to understand and improve performance on quality measures. In this study, we used data from the ACR's Rheumatology Informatics System for Effectiveness (RISE), a national electronic health record (EHR)-enabled quality improvement registry, to examine variation in performance on quality measures across practices.

Methods: RISE's informatics platform continuously collects data from the EHRs of participating practices, allowing centralized aggregation and analysis of performance on quality measures. Rheumatologists can view their performance on measures using a web-based registry dashboard that is updated every 24 hours. We analyzed data collected between April 1, 2015 and March 31, 2016 on all patients seen by 223 clinicians across 49 practices in which EHR mapping is complete. Quality measures in the areas of rheumatoid arthritis, drug safety, osteoporosis, preventive care and gout were examined. Performance on quality measures, defined as the percentage of eligible patients receiving recommended care, was examined at the practice level.

Results: Data from 346,358 patients was examined. Mean (SD) age was 58 (16.6) years, 75.2% were female, 25.6% were racial/ethnic minorities, and 65.8% had commercial insurance. Most rheumatologists were in a group practice (90.0%); 8.8% were in solo practice and 1.2% part of a larger health system. Performance on quality measures varied significantly across practices (Table). Twelve of 17 measures had a maximum observed performance of >99% across practices. The largest gaps in quality of care at both the practice and clinician levels were observed for osteoporosis, gout and preventive care (e.g. body mass index screening and counseling), suggesting room for improvement in these areas. For 6 of 9 measures for which the Centers for Medicare and Medicaid Services has set national benchmarks, the average performance of RISE practices exceeded targets.

Conclusion: We found significant variation in performance on quality measures across RISE practices, with the largest gaps seen in osteoporosis, gout care and preventive care. We also found that some practices have achieved a very high level of performance. As rheumatologists aim to improve quality of care and prepare for upcoming MACRA payment reforms, RISE will, by design, allow participants to measure, benchmark, and continuously monitor performance improvement. **Table. Performance on selected quality measures in the RISE registry.**

Quality Measure			Performance across RISE practices	Performance across RISE practices	CMS Benchmark
	Measure Denominator (n)	Measure Numerator (n)	Average Performance (%)	25th, 50th, 75th, 100th percentile	
RA: Disease Activity Measurement	50,416	33,076	61.9	30.6, 70.9, 90.4, 100	
RA: Functional Status Measurement	50,416	29,546	56.4	23.6, 65.2, 87.5, 100

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016

Session Title: Plenary Session III: Discovery 2016

Session Type: ACR Plenary Session

Session Time: 11:00AM-12:30PM

Background/Purpose: Despite more aggressive treatment strategies and new biologic DMARDs, the prevalence of osteoporosis (OP) leading to fracture in RA remains high. It is unknown whether these treatment changes and release of the 2010 ACR glucocorticoid (GC) induced OP (GIOP) guideline changed physicians' OP management practices. To evaluate this, we assessed the frequency, trends, and predictors of OP management care in patients with RA compared with OA in the US.

Methods: Patients studied had RA or OA with ≥1 year participation from 2003 through 2014 in the National Data Bank for Rheumatic Diseases. OP management care was defined as either having a bone mineral density (BMD) test or treatment with any anti-OP medications (excluding calcium or vitamin D) in the prior 6 months. Calendar years were evaluated to detect trends for outcome, with 2003 as reference period. Andersen-Gill formulation of Cox proportional hazards models were used to determine adjusted trends of and factors associated with OP management care.

Results: During a median (IQR) followup of 5.5 (2.3-9.0) years in 11,669 RA and 2,829 OA patients, the frequencies of BMD testing were 57% *vs.* 54% and treatment with any anti-OP medication 44% *vs.* 42%. Only ~50% of RA and OA patients with prior fragility fractures or long-term GC exposure were on anti-OP treatment. In multivariable analysis, RA patients were 12% more likely to have OP management care compared to OA patients. Factors significantly associated with having OP management care in RA patients were older age, postmenopausal status, prior fragility fracture or diagnosis of OP, GC exposure ≥3 months, treatment with any biologic, and rheumatology care (*Table*). Cox models showed stable OP management trends between 2003 and 2009, with a significant downward trend after 2009 without any improvement in GC-exposed patients after the release of the 2010 ACR GIOP guideline (*Figure*). The same downward trend was also observed in long-term GC exposed by bisphosphonate-nonexposed RA patients.

Conclusion: The application of OP management care is slightly higher in RA patients compared to OA, but the frequency of such care in patients at high risk for fracture remains suboptimal. Despite the availability of advanced treatments, the care for OP has not been improving, which may be due to both patient (unwillingness to take more drugs, cost) and physician barriers (lack of time, and focusing more on disease activity and other comorbid conditions). To reduce the morbidity and mortality burden of OP fractures, clarification of the reasons for suboptimal management and effective interventions are needed.

Table. Potential predictors for both types of osteoporosis management care in patients with rheumatoid arthritis and osteoarthritis

Variables	OP management care, HR (95% CI)	
	RA patients, N=11,669	OA patients, N=2,829
Age groups		
<40 years (referent)	1.0	1.0
40-50 years	1.70 (1.38-2.09)	1.67 (0.57-4.87)
51-64 years	2.22 (1.78-2.78)	1.80 (0.61-5.36)
≥65 years	2.59 (2.07-3.28)	1.72 (0.57-5.12)
Gender		
Female		
Premenopausal (referent)	1.0	1.0
Postmenopausal	1.62 (1.37-1.92)	2.71 (1.49-4.91)
Male	0.59 (0.49-0.72)	0.65 (0.35-1.23)
Education level	1.03 (1.01-1.05)	1.05 (1.01-1.09)
No insurance	0.66 (0.50-0.86)	0.96 (0.53-1.73)
Residency in a rural area	0.88 (0.81-0.96)	0.92 (0.75-1.11)
Primary physician, rheumatologist	1.43 (1.26-1.63)	1.19 (1.00-1.41)
Vaccination for influenza	1.11 (1.03-1.20)	1.20 (1.01-1.43)
BMI in categories		
<18.5 kg/m2	1.14 (0.89-1.45)	0.83 (0.26-2.64)
18.5-24.9 kg/m2 (referent)	1.0	1.0
25.0-29.9 kg/m2	0.87 (0.79-0.96)	0. 79 (0.64-0.98)
30.0-39.9 kg/m2	0.80 (0.73-0.89)	0.68 (0.55-0.84)
≥40 kg/m2	0.56 (0.47-0.67)	0.55 (0.40-0.76)
HAQ	1.05 (0.99-1.11)	0.89 (0.78-1.01)
Glucocorticoid use		
Never-used (referent)	1.0	1.0
<3 months	1.12 (0.96-1.31)	0.90 (0.68-1.19)
3-12 months	1.24 (1.09-1.40)	1.24 (0.91-1.68)
>12 months	1.38 (1.26-1.51)	1.72 (1.32-2.22)
Use of DMARDs		
MTX monotherapy (referent)	1.0	-
Any TNFi	1.21 (1.08-1.36)	-
Non-TNFi biologics	1.34 (1.09-1.65)	-
Any others	1.15 (1.03-1.29)	-
Prior fragility fracture	1.10 (1.00-1.22)	1.22 (0.98-1.52)
Prior diagnosis of OP	1.52 (1.37-1.67)	1.35 (1.35-1.65)

**Other covariates included in the model, ethnicity, disease duration, Rheumatic Disease Comorbidity Index, smoking status, were not significantly associated with OP care. The model also included the each calendar from 2003 to 2014.*

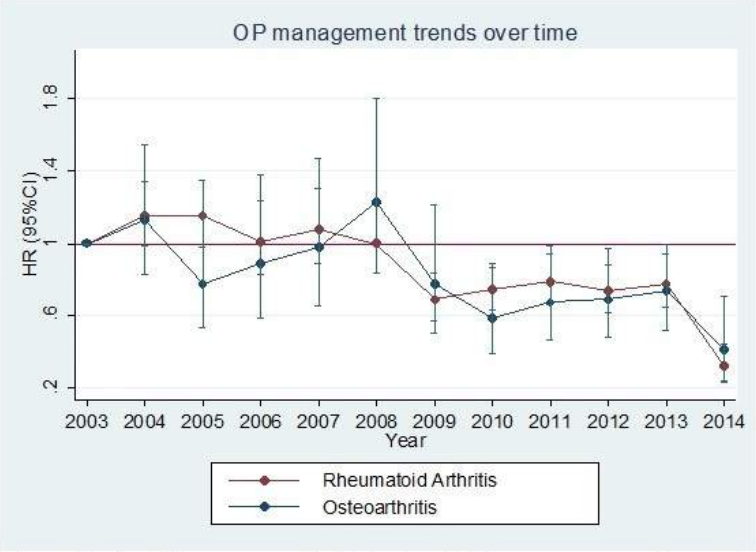

Figure. Trends of "OP management" (either having a BMD test or treatment with any anti-OP medications, excluding calcium or vitamin D) in patients with rheumatoid arthritis and osteoarthritis

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016

Session Title: Plenary Session III: Discovery 2016

Session Type: ACR Plenary Session

Session Time: 11:00AM-12:30PM

Background/Purpose: Head-to-head comparisons of biological (b)DMARDs in the treatment of RA should provide rigorous evidence on the comparative efficacy of different treatments. Although there are several head-to-head trials comparing TNF inhibitors (TNFi) with bDMARDs that have different mechanisms of action,[1-3] there have been no reports of prospective head-to-head trials comparing the efficacy and safety of bDMARDS within the same class, including TNFi.

Methods: EXXELERATE (NCT01500278) was a 104-wk randomized, investigator-blind, parallel-group, head-to-head superiority study comparing the early (Wk 12)- and later (Wk 104)-term efficacy and safety of certolizumab pegol (CZP)+MTX and adalimumab (ADA)+MTX (Figure). Patients (Pts) were randomized 1:1 to CZP+MTX or ADA+MTX. At Wk 12, pts were classified as responders (achieving either DAS28[ESR] ≤3.2 or DAS28[ESR] reduction from baseline [BL] of ≥1.2 at Wk 12) or non-responders (NR). NRs to one were switched to the respective other TNFi (Figure). Primary endpoints were the percentage of pts achieving ACR20 at Wk 12 and low disease activity (LDA; DAS28[ESR] ≤3.2) at Wk 104 (Wk 12 NRs were considered LDA NRs). Secondary endpoints included the proportion of pts achieving ACR20 at Wk 6, DAS28(ESR) LDA at Wks 6, 12, 52, and the proportion of Wk 12 responding pts achieving LDA at Wk 104. Exploratory endpoints included the proportion of Wk 12 responding pts achieving ACR20/50/70, and DAS28(ESR) and CDAI defined LDA and remission (REM), at each study visit.

Results: At BL, 915 pts were randomized to either CZP+MTX (n=457) or ADA+MTX (n=458). At Wk 12 there were 359 CZP+MTX (78.6%) and 369 ADA+MTX (80.6%) responder pts. No statistically significant difference was observed between ACR20 response at Wk 12 (69.2% and 71.4%; odds ratio (OR): 0.90 [95% CI: 0.67, 1.20]), and DAS28(ESR) LDA at Wk 104 (35.5% and 33.5%; OR: 1.09 [95% CI: 0.82, 1.45]) for CZP+MTX and ADA+MTX, respectively. No differences between treatment arms were evident in secondary and exploratory efficacy endpoints (Table). A similar proportion of CZP+MTX and ADA+MTX pts reported treatment emergent adverse events (TEAEs; 75.4% and 73.8%), serious TEAEs (13.0% and 11.1%), and serious infections and infestations (3.3% and 3.1%), by treatment at AE onset (event rate per 100 pt years 257.5 vs 260.0).

Conclusion: EXXELERATE, the first direct head-to-head comparison of two TNFis, reinforces the early and later term efficacy of both CZP and ADA in combination with MTX without demonstrating clinical evidence of differences between both agents. CZP+MTX and ADA+MTX demonstrated comparable safety over 2 years. **References:** 1. Porter D. Lancet 2016;S0140-6736(16)00380–9; 2. Gabay C. Lancet 2013;381(9877):1541–1550; 3. Weinblatt M. Cigarette Smoking Increases the Risk of Anti-Double-Stranded DNA Positive SLE Among Women in the Nurses' Health Studies

Medha Barbhaiya[1], Sara Tedeschi[2], Bing Lu[1], Susan Malspeis[3], Jeffrey A. Sparks[3], Elizabeth W. Karlson[1] and **Karen H. Costenbader**[1], [1]Rheumatology, Immunology and Allergy, Brigham and Women's Hospital and Harvard Medical School, Boston, MA, [2]Division of Rheumatology, Immunology and Allergy, Brigham and Women's Hospital and Harvard Medical School, Boston, MA, [3]Rheumatology, Immunology, and Allergy, Brigham and Women's Hospital and Harvard Medical School, Boston, MA
First publication: September 28, 2016

SESSION INFORMATION
Session Date: Tuesday, November 15, 2016
Session Title: 2016 Rheumatology Research Foundation Edmond L. Dubois, MD Memorial Lectureship
Session Type: ACR Concurrent Abstract Session
Session Time: 2:30PM-4:00PM

Background/Purpose: SLE is heterogeneous with subtypes characterized by different systemic manifestations and autoantibodies. Past studies suggest that smoking may be a risk factor for SLE, although evidence is conflicting and prospective cohort studies have not demonstrated this association to date. Among SLE patients, current smokers have been found to be significantly more likely than never smokers to have anti-double stranded DNA (dsDNA) antibodies. We aimed to prospectively evaluate the association of smoking with risk of incident SLE in a large prospective cohort study, examining risk of the subtypes of dsDNA positive (+) versus negative (-) SLE.

Methods: NHS enrolled 121,701 U.S. female registered nurses in 1976. NHSII began in 1989, enrolling 116,430 female nurses. Lifestyle, environmental exposures and medical history are collected on biennial questionnaires. Incident SLE cases are identified using the connective tissue disease screening questionnaire, followed by medical record review for ACR criteria. Participants without smoking data at baseline were excluded. Time-varying smoking status was assessed categorically (never/past/current). Cumulative smoking in pack-years was also calculated biennially through the 2-year cycle prior to SLE diagnosis. Cox regression models assessed associations of smoking with SLE overall and stratified by dsDNA + or - at diagnosis, controlling for time-varying covariates. Hazard ratios (HR) from the two cohorts were meta-analyzed using DerSimonian and Laird random effects models. As alcohol and smoking behaviors are strongly correlated and alcohol intake is associated with reduced SLE risk, we analyzed age-adjusted, alcohol-adjusted, and multivariable-adjusted models.

Results: 160 incident SLE cases developed in NHS (1978-2012) and 123 in NHSII (1991-2013). Mean age at diagnosis was 53.8 (9.5) yrs in NHS and 43.4 (8.0) yrs in NHSII. In NHS, 33% were current smokers at baseline, and 13.4% were current smokers in NHSII. Among SLE, 46% of NHS and 58% of NHSII were anti-dsDNA+ at diagnosis; 20% in NHS and 11.8% in NHSII had renal involvement at diagnosis. Smoking status or pack-years was not associated with SLE risk overall **(Table)**. However, current (vs. never) smokers had greatly increased risk of dsDNA+ SLE (HR 1.89, 95% CI 1.20-2.98), but not of dsDNA- SLE, after adjustment for potential confounders including alcohol. Women who smoked >10 pack-years (vs. never) had a highly elevated risk of dsDNA+ SLE (HR 1.72, 95%CI 1.16-2.55).

Conclusion: We have uncovered a strong and specific association of smoking (both current smoking and increased pack-years) with risk of dsDNA+ SLE among women. This novel finding suggests a biologic mechanism in dsDNA+ SLE pathogenesis not involved

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016

Session Title: 2016 Rheumatology Research Foundation Edmond L. Dubois, MD Memorial Lectureship

Session Type: ACR Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: Cardiovascular disease (CVD) risk is elevated in SLE patients compared to non-SLE patients. However, how CVD rates differ in SLE patients compared with other chronic disease states, in particular diabetes mellitus (DM), has not been examined. To provide insights for clinicians seeking to understand the magnitude of CVD risk in SLE patients, we compared their risk to that of patients with DM, a known CVD risk factor. We examined annual rates and relative risks of CVD events (acute myocardial infarction [MI], stroke, and combined MI or stroke) in a nationwide cohort of US Medicaid recipients with either SLE or DM.

Methods : We utilized Medicaid Analytic eXtract (MAX) data, containing billing claims for Medicaid patients from the 29 most populated US states, 2007-10. We identified adults aged ≥18-65 with prevalent SLE or DM (≥3 ICD-9 codes for SLE or DM, each separated by ≥30 days) and >6 months of enrollment prior to 3rd code (index date). We performed 1: 2 matching (SLE: DM) based on age (month/year), sex, and index date. Sociodemographic data (including age, sex, race/ethnicity, calendar year, US region, zip code-level socioeconomic status) and medical/cardiac comorbidities were collected during the baseline period (6 months prior to and including index date). ICD-9, CPT, and DRG codes were used to identify outcomes. Outcomes were assessed from index date, including acute MI, stroke, and combined MI or stroke. Subjects were followed to first CVD event, death, Medicaid disenrollment,

or end of follow-up. We used Cox sub-distribution regression models to calculate hazard ratios (HR_{SD}) for CVD events, accounting for the competing risk of death and adjusting for sociodemographics and medical/cardiac comorbidities (**Table**).

Results : 32,089 prevalent SLE patients were matched to 64,178 prevalent DM patients. In both cohorts, 92.8% were female and mean age was 41.3 (±12.1) years. There were more Blacks (41.1 vs. 30.5%) and fewer Whites (36.3 vs 45.1%) in the SLE vs. DM cohort. Mean follow-up was 1.67 (±1.03) years for SLE patients and 1.79 (±1.07) years for DM patients. Baseline CVD risk factors were more prevalent among DM vs. SLE patients: hypertension (38.0 vs. 33.7%), hyperlipidemia (22.5 vs. 10.6%), and obesity (11 vs. 4.5%). In the SLE cohort in particular, the incidence of stroke was higher than that of MI (**Table**). Annual rates and adjusted risks of MI were similar in the two cohorts (multivariable-adjusted HR_{SD} 1.01 [95% CI 0.84-1.22] for SLE vs. DM). By contrast, stroke rates were higher among SLE vs. DM patients and the multivariable-adjusted HR_{SD} for stroke was 1.38 (95%CI 1.20-1.60).

Conclusion : Despite a lower prevalence of many traditional CVD risk factors compared to age- and sex-matched DM patients, SLE patients had similar adjusted risks of MI and 38% higher adjusted risks of stroke. These findings may signal potential additional SLE-specific and thrombotic risk factors associated with elevated risk of stroke among SLE patients.

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016
Session Title: 2016 Rheumatology Research Foundation Edmond L. Dubois, MD Memorial Lectureship
Session Type: ACR Concurrent Abstract Session
Session Time: 2:30PM-4:00PM

Background/Purpose: Published studies of cancer risk in SLE to date have never focussed solely on clinically confirmed, incident patients. Prior studies thus may not reflect the cancer experience of all SLE patients. To fill this knowledge gap, our purpose was to describe cancer incidence in a large inception SLE cohort.

Methods: Patients meeting ACR criteria for new-onset SLE were enrolled across 32 centres. At enrolment and annual assessments, new cancer diagnoses were recorded by the examining physician. Cancers were confirmed by reviewing medical files including pathology reports. Of 1848 patients enrolled across 1999-2011, 1676 had at least one follow-up. Patients were followed until death, last visit, or end of study interval for this analysis(August 2015). Comparison general population cancer rates, weighted according to the age and sex structure of the SLE cohort, were obtained from participating countries.

Results: Mean age at SLE diagnosis was 34.6(standard deviation, SD 13.3). Mean follow-up was 6.85(SD 3.6), for a total of 11,481 patient-years. We observed 46 invasive cancers in 46 subjects. At cancer diagnosis, mean age was 51.6(SD 15.0) and average SLE duration was 4.8(SD 3.1) years. The most common cancer type was breast (n=10), followed by non-melanoma skin cancer (n=8), lung(n=6), prostate(n=5), 4 head and neck (tonsillar, tongue, and 2 oral), cervical(n=2), thyroid(n=2), melanoma(n=2) and one each of non-Hodgkin lymphoma, leukemia, multiple myeloma, , renal carcinoma, gastric carcinoid, thymoma, and dermatofibrosarcoma. Twenty of the 46 patients (43.5%) who developed cancers were current (n=4) or ex-smokers (n=16); five of the six lung cancers were current or ex-smokers. The over-all cancer rate in the SLE population was 4 events per 1000 patient-years(95% CI, 2.9 to 5.4) versus the general population rate of 2.7 events per 1,000 person-years. In young SLE patients(<40), the cancer rate was 2.2 events per 1,000 patient-years(95% CI 1.2, 3.7) which was more than twice that of the general population of this age (1 event per 1,000). The cancer rate in SLE after age 40 was 5 events per 1,000 patient-years, similar to the general population cancer rate for this age group. With very few hematological cancers observed in this inception cohort, the hematological cancer incidence in SLE was 2.6 cancers per 10,000 patient-years (95% CI 0.5, 7.6), which was a non-significant increase above the population rate of 2 per 1,000 person-years. Among other cancer types, only lung cancer was clearly increased versus the general population; the SLE incidence was 5.2 cases per 10,000 person years (95% CI 2-11), versus 1.7 cases per 10,000 person-years in the general population.

Conclusion: The cancer incidence rate in the cohort was 4 events per 1,000. Though higher than general population rates, it is still less than one-half percent per year. Comparisons of cancer in SLE versus the general population must be interpreted with caution, given differences in outcome ascertainment in the two populations. In our analyses, lung cancer was one of the most common cancers. The vast majority of these were smokers, supporting the belief that lung cancer risk in SLE (as in the general population) is largely driven by smoking.

Session Title: 2016 Rheumatology Research Foundation Edmond L. Dubois, MD Memorial Lectureship

Session Type: ACR Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: Registration trials for SLE therapeutics require large numbers of patients with active disease, which in turn necessitates the trials be multinational with many participating centers. While all patients meet ACR classification criteria for SLE, there is a range of disease activity at baseline that may influence response to treatment. To investigate this issue, we used objective molecular and biochemical parameters with high sensitivity (low false positive rate) to characterize patients as “SLE(+)” or “SLE(-)” and examined baseline demographics and disease characteristics to see if SLE(+) patients were distinct from SLE(-) patients.

Methods: Analyses are based on data from two phase 3 trials (n=2262) that evaluated the impact of an anti-BAFF antibody on SLE disease activity (1,2). ANA (≥ 1:80) and SLEDAI ≥ 6 was required at entry. Four dichotomous baseline parameters were used to categorize patients, IFN gene signature (high/normal), anti-dsDNA (+/-), C3 (low/normal) and C4 (low/normal). SLE(+) was defined by any of the following: IFN (high), anti-dsDNA (+), C3 (low) and/or C4 (low). SLE(-) required all of the following: IFN signature (normal), anti-dsDNA (-), C3 (normal) and C4 (normal). IFN gene signature was measured as previously described (3); anti-dsDNA, C3 and C4 were measured at a central lab.

Results: Baseline RNA transcript data were available for 1747 of 2262 patients, with 1318 (75%) of patients meeting the IFN (high) criteria. When IFN (high) was combined with the serology criterion, 1500 (86%) were classified as SLE(+) and 247 (14%) were classified as SLE(-). At baseline, SLE(-) patients had significantly lower mean SLEDAI scores (8.3) compared to SLE(+) (10.7 ; $p<0.001$). Baseline SLEDAI < 10 was observed in 72% of SLE(-) patients compared to 38% of SLE(+). SLE(-) patients had

83% less hematologic, 51% less renal and 70% less vascular organ system involvement at baseline compared to SLE(+) as measured by SLEDAI. Significantly fewer SLE (-) patients were on background medication at baseline. The proportion on corticosteroids at baseline was 49% in SLE(-) compared to 78% in SLE(+), and the proportion on immunosuppressants at baseline was 31% in SLE(-) compared to 44% in SLE(+). An evaluation of geographic distribution revealed that 22% of US patients were SLE(-) compared to 10% for Latin America, 7% for Europe, and 5% for ROW.

Conclusion: A subset of clinical trial patients was identified using biochemical and molecular markers with high sensitivity for SLE. Seronegative SLE patients with normal IFN gene signature represented 14% of the clinical trial population. These patients had lower disease activity and were taking less background medication at baseline, two factors which have been negatively associated with response to treatment in some previous trials. Further study is required to determine if seronegative/IFN normal patients in SLE trials represent a population of SLE patients that can confound the assessment of treatment benefit in SLE clinical trials.

In Systemic Lupus Erythematosus with Antiphospholipid Antibodies, Hypocomplementemia Associates with Thrombosis

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016

Session Title: 2016 Rheumatology Research Foundation Edmond L. Dubois, MD Memorial Lectureship

Session Type: ACR Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: Hypocomplementemia is a common phenomenon in systemic lupus erythematosus (SLE) and antiphospholipid antibody syndrome (APS). Robust mechanistic data implicate complement activation in antiphospholipid antibody related thrombosis. However, many questions remain unanswered regarding the clinical implications of hypocomplementemia in SLE and APS. Whether low complement should be considered a risk factor for thrombosis in this population is unknown. This work was undertaken to evaluate the relationship between hypocomplementemia and thrombotic outcomes in SLE patients with antiphospholipid antibodies.

Methods: As part of a longitudinal lupus cohort, thrombotic events were noted at inception and updated at each quarterly visit. Anticardiolipin antibodies and the lupus anticoagulant were measured quarterly. The statistical analysis included patients who were found on longitudinal follow up to have antibodies to cardiolipin or the presence of the lupus anticoagulant. Patients were then categorized according to the type of thrombotic event, the presence of hypocomplementemia (low C3, low C4 and both low C3 and low C4) and type of antiphospholipid antibody encountered. Those with low complement were compared to those without and the odds ratio for each thrombotic outcome was calculated.

Results: 2399 SLE patients were included in this analysis, 1140 (47.5%) had antibodies to cardiolipin and 624 (26.0%) were found to have had a positive lupus anticoagulant. The relationship between the antiphospholipid antibodies, thrombotic outcomes

and low C3, low C4 or both is outlined in Table 1. Low C3 and low C4 in combination associated with deep venous thrombosis and stroke in those with anticardiolipin antibodies. This relationship remained significant on multivariate analysis, controlled for ethnicity and gender. The lupus anticoagulant and low C3 and C4 in combination was also associated with stroke. An association was also demonstrated with digital gangrene and low C4 in the presence of the lupus anticoagulant.

Conclusion: Hypocomplementemia (both low C3 and low C4), in the presence of either the lupus anticoagulant or anticardiolipin antibodies, associates with stroke. Low complement, with antibodies to cardiolipin, also associated with deep venous thrombosis. These finding support the mechanistic data implicating the complement system in APS related thrombus formation and indicate that hypocomplementemia, in association with antiphospholipid antibodies may represent an addition risk factor for thrombosis.

Membrane-Type 1 Matrix Metalloproteinase Controls Osteo- and Chondrogenesis By a Proteolysis-Independent Mechanism Mediated By Its Cytoplasmic Tail

Session Title: Biology and Pathology of Bone and Joint
Session Type: ACR Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: We aimed to understand the mechanism by which membrane-type 1 matrix metalloproteinase (MT1-MMP, MMP-14) controls bone and cartilage homeostasis. MT1-MMP, a cell-membrane-bound proteinase with an extracellular catalytic site and a 20-amino acid cytoplasmic tail, plays a key role in postnatal bone formation. The genetic deficiency of MT1-MMP in the mouse causes dwarfism, osteopenia and severe arthritis. Deletion of MT1-MMP in bone marrow-derived mesenchymal progenitor cells (BM-MSC) recapitulates this phenotype, showing that MT1-MMP controls osteogenic differentiation in MSC. The phenotype of MT1-MMP$^{-/-}$ mice has been proposed to result from lack of MT1-MMP proteolytic activity. However, mounting evidence shows a variety of proteolysis-independent signaling functions of MT1-MMP. The unique tyrosine (Y573) in the MT1-MMP cytoplasmic tail is fundamental for the control of intracellular signaling.

Methods: We generated a mouse with the Y573D mutation in MT1-MMP (MT1-MMP Y573D) and characterized its skeletal phenotype by histological and microCT analyses. Isolated BM-MSC were induced to differentiate into osteoblasts, chondrocytes and adipocytes, using qRT-PCR to analyze gene expression. Mouse C3H10T1/2 MSC were transfected with MT1-MMP cDNA and analyzed for Wnt signaling by luciferase reporter assays.

Results: MT1-MMP Y573D mice had increased trabecular bone relative to wt littermates, marked thinning of articular cartilage with disorganized tissue architecture, clustering and cloning of chondrocytes, and pronounced decrease in bone marrow-associated and total body fat. We induced BM-MSC from wt and MT1-MMP Y573D littermates to differentiate into osteoblast and chondrocytes, and myeloid precursors into osteoclasts. The Y573D mutation dramatically increased MSC expression of osteoblast markers and strongly downregulated chondrocyte and osteoclast markers. These findings indicated that Wnt signaling is upregulated in MT1-MMP Y573D-expressing MSC. Therefore, we analyzed Wnt signaling. We transiently transfected C3H10T1/2 MSC cells in osteoblast medium with the cDNAs for wt MT1-MMP and MT1-MMP Y573D. As controls the cells were transfected with the empty vector (pcDNA) or with MT1-MMP E240A, a mutant devoid of proteolytic activity. MT1-MMP Y573D dramatically upregulated Wnt signaling relative to wt MT1-MMP and MT1-MMP E240A.

Conclusion: MT1-MMP controls Wnt signaling by a mechanism independent of extracellular proteolysis and mediated by its cytoplasmic tail. MT1-MMP is a bifunctional protein, with an extracellular proteolytic activity that promotes bone formation through ECM remodeling and a cytoplasmic tail that controls osteogenesis by interacting with a key pro-osteogenic signaling pathway.

Binding of Periostin to Discoidin Domain Receptor-1 (DDR1) Promotes Cartilage Degeneration By Inducing MMP-13 Expression

Yang Qing[1], Paolo Mignatti[2], Austin Ramme[3], Thorsten Kirsch[3], Jyoti Patel[4] and **Mukundan Attur**[4], [1]Medicine, New York University School of Medicine, New York, NY, [2]Medicine, New York University, New York, NY, [3]Orthopaedic Surgery, New York University, New York, NY, [4]Rheumatology Research, NYU - Hospital for Joint Diseases, New York, NY

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016

Session Title: Biology and Pathology of Bone and Joint

Session Type: ACR Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: We and others have previously shown that periostin (Postn) expression is dramatically elevated in cartilage and sub-chondral bone in OA patients and surgical models of OA (medial meniscectomy and anterior crucial ligament resection or PMX, partial meniscectomy) in rodents. *In vitro* Postn promotes collagen and proteoglycan degradation in human chondrocytes by

upregulating MMP-13 and ADAMTS4 expression. Postn controls gene expression in bone cells by interacting with avb3 integrin. However, the nature of periostin receptor(s) in chondrocytes is unknown. DDR1, a collagen-binding receptor tyrosine kinase highly expressed in chondrocytes, controls MMP-13 expression during chondrogenesis. Therefore, we hypothesized that the effect of Postn on chondrocytes is mediated by DDR1 and Postn-deficient mice (*Postn*$^{-/-}$) are protected from surgically-induced post-traumatic OA.

Methods: (*Postn*$^{-/-}$) mice were purchased from Jackson Laboratory (B6;129-Posttntm1Jmol/J Stock No: 009067). We subjected 3-months old littermates (*Postn*$^{+/+}$, *Postn*$^{+/-}$ and *Postn*$^{-/-}$) to partial medial meniscectomy (PMX) or sham surgery, and harvested the knee joints 8 week post-surgery for histological assessment of OA progression. Human OA chondrocytes cultures were incubated in the presence or absence of the DDR1 inhibitor DDR1-IN-1 dihydrochloridein (100-500 nM) for 2 h before addition of Postn (1 µg/ml) or control vehicle to the culture medium. MMP-13 levels were determined by ELISA 24 h post stimulation.

Results: We observed abundant expression of DDR1 mRNA in human chondrocytes and we found comparable levels of DDR1 in OA and normal cartilage. However, Postn expression was 3-4 times as high in OA than in normal cartilage. Pre-incubation of human cartilage explants or cultured chondrocytes with DDR1-IN-1 dihydrochloridein inhibited both constitutive and Postn-induced MMP-13 expression in a dose-dependent manner. In contrast, neutralizing antibody to αvβ3 integrin had no effect on Postn induction of MMP-13 expression. Co-immunoprecipitation experiments showed that Postn physically interacts with DDR1 in human chondrocytes. Furthermore, *Postn*$^{-/-}$ mice showed reduced PMX-induced cartilage degeneration and osteophyte formation, and both *Postn*+/- and *Postn*-/- mice had reduced subchondral bone thickening, relative to *Postn*+/+ mice.

Conclusion: *Postn*$^{-/-}$ mice are protected from surgically-induced post-traumatic OA, showing that Postn promotes cartilage degeneration. DDR1 mediates the stimulatory effect of Postn on MMP-13 expression. Further studies are in progress to investigate the potential of periostin as a druggable target for the treatment of OA.

Session Date: Tuesday, November 15, 2016

Session Title: Biology and Pathology of Bone and Joint

Session Type: ACR Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: Many osteoarthritis (OA) patients show synovial activation, which is thought to be involved in joint destruction. Previously, we described strongly increased expression of *Wnt2b* and *Wnt16* in the synovium of two experimental OA models. In addition, we found increased *Wisp1* expression, a protein induced by canonical Wnt signaling. Here, we determined whether there is a relation between synovial *WISP1* expression and OA progression in a cohort study of patients with early symptomatic OA. Furthermore, we elucidated whether WISP1 plays a role during experimental OA by inducing OA models in wild type (WT) and *Wisp1*$^{-/-}$mice.

Methods: Microarray analysis was performed on synovium from patients in the CHECK study, initiated to follow progression of early symptomatic OA patients. Expression data were correlated with progression of OA (defined as a decrease in joint space width of ≥1mm and progression of osteophyte formation of ≥4x in size) between baseline and the five-year follow-up measurement.

Human end-stage OA synovium was stimulated with WISP1. Joint pathology in WT or *Wisp1*$^{-/-}$mice was assessed by histology after induction of collagenase-induced OA (CIOA), destabilization of the medial meniscus (DMM) and anterior cruciate ligament transection (ACLT) experimental models of OA. The aggrecan neoepitope NITEGE was visualized using immunohistochemistry. Gene expression was evaluated using qRT-PCR.

Results: Microarray analysis of synovial tissue from patients in the CHECK cohort showed significantly increased WISP1 expression at baseline in OA progressors versus non-progressors. To determine the mechanism of how WISP1 might be involved in OA pathology, we stimulated human OA synovium with WISP1. This increased the expression of *MMP2/3/9/13* and *ADAMTS4/5*. Next, we determined the *in vivo* role of WISP1. First, we found that spontaneous cartilage damage was not different between WT and *Wisp1*$^{-/-}$ mice at 3, 6 and 12 months of age. Next, we assessed joint pathology 42 days after induction of CIOA. Cartilage damage was significantly decreased in the tibio-femoral joints of the *Wisp1*$^{-/-}$ mice as compared with the WT controls. In line, we found significantly decreased cartilage degeneration in the *Wisp1*$^{-/-}$ mice in the DMM and ACLT models, 56 days after induction. In addition we found decreased expression of *Mmp3/9* and the aggrecanases *Adamts4/5* in the synovium, 7 days after induction of CIOA in *Wisp1*$^{-/-}$ mice, in line with the increased expression of these factors after stimulation of human OA synovium with WISP1. Whereas *Wisp1*$^{-/-}$ mice showed decreased expression of the protease inhibitor *Timp1*, the expression of *Timp3*, an important inhibitor of ADAMTS4/5, was unaffected. Finally, the protease activity in the cartilage, as assessed by the staining of the neoepitope NITEGE, was decreased in the *Wisp1*$^{-/-}$mice.

Conclusion: Increased WISP1 expression may play an important role in OA pathology via increased synovial MMP/ADAMTS expression. Furthermore, because of the tight regulation and complexity of Wnt signaling and its role in many physiological processes, targeting WISP1 may more specifically target OA-related pathological events, while minimizing interference with physiological processes.

Session Title: Biology and Pathology of Bone and Joint

Session Type: ACR Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: Obesity is considered the primary preventable risk factor for OA, increasing the risk of developing OA in weight-bearing joints, especially the knee, as well as in non-weight-bearing joints, such as the hand. Obesity is associated with alterations in systemic inflammation as well as locally within the knee joint compartment. Saturated free fatty acids (FFA) in high fat (HF) diets induce pro-inflammatory cytokine production in a Toll-like receptor 4 (TLR4)-dependent manner. Therefore, we hypothesized that HF diet-induced OA is dependent on TLR4. To test this hypothesis, mice replete or deficient in TLR4, as well as DAP12-deficient mice, that have exuberant TLR4 responses, were treated with control or HF diet to induce obesity and OA.

Methods: 12-14 month old female WT (n=12-22), DAP12 KO (n=15-18) and TLR4 KO (n=10) mice were equally randomized to control (CON) or HF diets (10% or 60% kcal from fat, Research Diets) for 12 weeks. Body composition by DXA (Lunar PIXImus),

micro-computed tomography (microCT) of knee joints, and serum cytokine analysis was performed at baseline and 12 weeks. Two blinded graders evaluated OA pathology in the medial and lateral femur and tibia using a Modified Mankin OA scoring system. Synovium- infrapatellar fat pad samples and gonadal fat were collected for inflammatory gene expression and histology.

Results: HF diet induced obesity with increased fat mass in all mice independent of genotype compared to CON diet. HF diet significantly increased maximum OA scores in WT and DAP12 KO, but not TLR4 KO mice. Cartilage damage scores and tidemark duplications were significantly increased in HF diet WT and DAP12 KO but not TLR4 KO mice. Interestingly, chondrocyte hypertrophy was significantly suppressed in DAP12 KO mice independent of diet. Glucose intolerance was induced in HF diet WT and TLR4 KO but not DAP12 KO mice. All HF fed mice had increased serum leptin levels compared to their CON groups. Gonadal fat depots increased, adipocytes were significantly hypertrophied, and crown-like structures increased in WT and DAP12 KO but not TLR4 KO mice. However, HF diet failed to increase serum proinflammatory cytokines in any group. Infrapatellar fat pads (IFP) from HF diet WT mice increased in size while IFP from DAP12 KO mice had increased adipocyte hypertrophy and crown-like structures. Synovial thickening or macrophage infiltration was similar between groups independent of diet. IFP gene expression revealed significant changes between DAP12 KO and WT and surprisingly few changes between WT and TLR4 KO.

Conclusion: This study is the first to use middle-aged mice for a short term feeding to induce HF diet-induced OA progression. DAP12 KO and WT mice developed similar OA while TLR4 mice were protected from HF diet-induced progression of OA. HF-diet DAP12 KO mice developed distinct differences in their OA including significantly reduced hypertrophic chondrocytes and significantly increased IFP adipocyte hypertrophy. Our findings show that TLR4 is required for HF-diet induced progression of OA in middle-aged female mice. TLR4-inhibitors may be attractive targets for disease modifying osteoarthritis drugs.

Session Title: Biology and Pathology of Bone and Joint

Session Type: ACR Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: Intensive synovitis is a prominent feature that progressively aggravated excessive fibrosis reactions relative to joint stiffness in the pathogenesis of osteoarthritis (OA). MicroRNA-29a (miR-29a) is reported to modulate overabundant fibrotic matrix accumulation during tissue deterioration. This study is undertaken to verify whether miR-29a expression was linked to synovial fibrosis in end-stage knee OA and tested whether miR-29a signaling affected fibrogenic reactions in synovial fibroblasts and synovial remodeling and joint integrity during OA development.

Methods: Synovial tissues and fibroblasts were harvested from 20 patients with end-stage knee OA. For non-OA group, synovial specimens were biopsied from 10 patients with femoral neck fracture. Knee joints in mice that overexpressed miR-29a were subjected to superpatellar injection of collagenase to provoke OA. miR-29a and fibrogenic factor expression were quantified by RT-quantitative PCR and in situ hybridization. Synovial fibrosis and joint injury were analyzed by Masson's trichrome staining, immunohistochemistry and histomorphometry.

Results: Synovial tissues within end-stage knee OA exhibited 52% declines in miR-29a expression in conjunction with 2.1-3.3-

fold increases in fibrotic matrix deposition, capillary vessel formation, and membrane thickness compared to non-OA group. In vitro, miR-29a signaling interruption led to 1.8-2.6-fold increases in joint-deleterious factors collagen III, TGF-β1, MMP3, MMP9, ADAMTS5, and VEGF expression within synovial fibroblast cultures. Gain of miR-29a signaling enabled cell cultures to have 42-67% reductions in baseline expression of joint-deleterious factors. Of note, miR-29a transgenic mice exhibited moderate responses to the collagenase exacerbation of fibrosis, macrophage infiltration, and hypervascularization within synovial microenvironment. These synovium-protecting effects remarkably shielded knee joints from articular cartilage deterioration histopathology and gait irregularity. Likewise, exogenous miR-29a administration via intra-articular injection delayed the progression of excessive synovial angiogenesis, inflammation and fibrosis, a protective regime that improved joint damage and walking patterns of injured knees. Luciferase reporter analyses revealed that miR-29a directly targeted 3'-untranslated region (3'-UTR) of VEGF, which suppressed VEGF production and angiogenic activities in synovial fibroblasts cultures.

Conclusion: miR-29a deficiency is relevant to the occurrence of excessive synovial fibrosis within end-stage OA knees. miR-29a signaling is indispensable to fend off fibrogenic, angiogenic, and cartilage degradation factor expression in synovial fibroblast cultures. Gain of miR-29a function facilitates the maintenance of synovium homeostasis that alleviates OA knee pathogenesis. This study sheds a new light on the anabolic actions and therapeutic potential of miR-29a signaling to synovial integrity during OA progression.

Session Title: Biology and Pathology of Bone and Joint
Session Type: ACR Concurrent Abstract Session
Session Time: 2:30PM-4:00PM

Background/Purpose: Appreciation of the role of the gut microbiome in regulating vertebrate metabolism has exploded recently. However, the effects of gut microbiota on skeletal growth and homeostasis have only recently been explored.

Methods: To understand the effects of short-term and long-term colonization of microbiota on bone, we colonized sexually mature germ-free (GF) mice with gut microbiota from SPF mice. In complementary experiments, SPF mice were treated with antibiotics to deplete microbiota. Bone parameters were examined by micro-computed tomography (micro-CT) and histomorphometry 1 month after colonization. Micro-CT analysis was also performed 8 months after colonization. Serum C-terminal telopeptide (CTX), amino-terminal propeptide (P1NP) and insulin like growth factor 1 (IGF-1) were measured by ELISA.

Results: Reduced bone mass was observed one month after colonization, reflecting increases in bone resorption as measured by CTX. However, bone formation was significantly increased. Increased bone formation was demonstrated by both elevated bone formation rate measured by dynamic histomorphometry and increases in serum P1NP, a marker of bone formation. In addition, short-term colonized mice displayed a widen growth plate, suggesting that microbiota promotes longitudinal bone growth. In mice colonized for 8 months, increased bone formation and growth plate activity predominate, resulting in equalization of bone mass and increased longitudinal and radial bone growth. Serum levels of IGF-1, a hormone with known actions on skeletal growth, were substantially increased in response to colonization, with significant increases in liver and adipose tissue IGF-1 production. Antibiotic treatment of conventional mice, in contrast, decreased serum IGF-1 and inhibited bone formation, suggesting that skeletal effects of microbiota are mediated by IGF-1. Treatment with vancomycin, a non-absorbable antibiotic that only targets gram positive bacteria, was sufficient to decrease serum IGF-1 and inhibit bone formation, indicating that gram positive commensals are

sufficient for the regulation of bone formation by microbiota.

Conclusion: Colonization increases both bone formation and resorption, with the net effect of colonization varying with the duration of colonization. Long-term colonization with microbiota provides a net anabolic stimulus to the skeleton, which is likely regulated by IGF-1. Manipulation of the microbiome may afford opportunities to optimize bone health and growth.

Session Title: Orthopedics, Low Back Pain and Rehabilitation
Session Type: ACR Concurrent Abstract Session
Session Time: 2:30PM-4:00PM

Background/Purpose: Non traumatic osteonecrosis (ON) of the femoral head is characterized by epiphyseal necrosis leading to femoral head collapse and eventually hip replacement. The physiopathology of ON is multifactorial but it can be seen as a vascular, mesenchymal and bone cells disease. The treatment of early stages ON of the femoral head is still controversial. Core decompression using single or multiple drillings demonstrated contradictory results. Moreover core decompression associated with the implantation of bone marrow concentrate (BMC) containing mesenchymal stem cells (MSC) showed encouraging results in prospective and controlled trials. Indeed, it could delay ON of the femoral head progression to fractural stages and improve symptoms. Then, the possibility was raised that a cell-based medicinal product (PREOB®) consisting in a population of autologous osteoblastic cells (OB) could be more efficacious than BMC for the treatment of early stages ON of the femoral head. This study was undertaken to evaluate the efficacy of OB cells implantation in a randomized comparison with BMC implantation in early stages (prefractural ARCO stage 1 or 2) ON of the femoral head.

Methods: Patients with stage 1 or 2 ON were included in a randomized controlled single blind trial. Hips were randomized to receive a core decompression procedure followed by BMC or OB cells implantation. In the BMC group, 410.6 ± 84.9 ml of bone marrow (BM) was harvested from the iliac crest and concentrated to 41.8 ± 10.9 ml. In the OB group, MSC were isolated from BM aspirate (56.8 ± 36.3 ml), expanded and differentiated ex vivo under autologous conditions to obtain a population of OB cells with a target of 20 million of OB cells. Hip pain (as measured by visual analogue scale), WOMAC® score and ARCO stage (as assessed by X-Rays) were evaluated at 3, 6, 12, 24 and 36 months. For the final radiological evaluation, all radiographs were and given a random number. Four readers assessed all blinded radiographs for the progression of ON from non-fractural (stage 1 or stage 2) to fractural stage of ON (stage 3 or 4) by reference to ARCO-defined stages. The primary endpoint was the proportion of treatment responders at 24 months. A responder was defined as the absence of progression to fractural stage (stage 3 or 4) and a clinically significant pain improvement (i.e., at least the MCID, namely ≥10mm from baseline).

Results: From 72 hips randomized, 63 hips were treated, and 60 hips (30 hips per group) were assessable and analyzed as the efficacy cohort. Baseline demographic data such age (50.2 ± 13.1 years), gender, BMI, risk factors (corticosteroids, alcohol abuse and idiopathic ON), location and size of ON (more than 50% in each group were extensive C lesion; >30%) and symptoms (pain score and WOMAC® score subscales) were not statistically different between groups. At 24 months, 70.0% versus 36.7% of hips (p=0.011) and at 36 months, 60.0% versus 33.3% of hips in OB and BMC groups respectively were considered as treatment

responders. In post-hoc analysis, the rate of progression to stage 3 or 4 was in favor of the OB group: at 24 months, 20.0% versus 40.0% of hips and at 36 months, 20.0% versus 50.0% of hips in OB and BMC groups respectively progressed to stage 3 or 4 (corresponding to a 60% reduction in hip fracture; $p<0.05$). Over the 36-month period, the survival analysis showed a significant difference in the time to progression to stage 3-4 in favor of the OB group (Kaplan Meier; hazard ratio 0.37). In the OB group, the decrease in hip pain was clinically significant at all time points, and as early as 3 months, while no pain relief was observed in the BMC group. Finally, patients treated with OB cells demonstrated a decrease in joint symptoms at all time points according to the WOMAC® score. At 36 months, 3 hips in the OB group and 6 hips in the BMC group had undergone total hip replacement. Overall, 553 treatment emergent adverse events (TEAE) (226 in the BMC group and 327 in the OB group) were reported, of which 2.7% (15 TEAE) were possibly related to the procedure or the cell therapy products. 61.9% of subjects experienced at least one serious adverse event (SAE) during the study: 128 SAE (57 in the BMC group and 71 in the OB group) were reported in 39 hips (19 hips in the BMC group and 20 hips in the OB group).

Conclusion: This is the first trial studying the efficacy of a differentiated bone cell therapy product in ON of the femoral head. Compared to BMC, PREOB® is well characterized and its ability to form bone well defined which might explained its superiority to BMC. This study showed that OB cells implantation could be more efficacious than BMC treatment to delay the progression to subchondral fracture stage (ARCO stage 3) and to reduce pain in ON of the femoral head

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016

Session Title: Orthopedics, Low Back Pain and Rehabilitation

Session Type: ACR Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: Knee needle arthroscopy (KNA) is a minimally invasive procedure consisting in insertion of a thin fiber-optic needle system in the joint cavity, followed by inspection, tissue sampling, therapeutic lavage, and if needed, steroids injection after the procedure. It is usually performed in an office-based setting, requiring only local anaesthesia, as an out-patient procedure. KNA is of particular interest as it can be used for diagnosis (in case of undifferenciated arthritis), scientific purposes (synovial biopsies serving for histology, proteomics, and genomics), and can serve as a therapeutic tool (mainly articular lavage). Few data have been published regarding safety of KNA, and available studies deal with a relatively small number of patients. Objective: To determine the incidence of overall and serious, notably septic, complications, and identify patients at higher risk.

Methods: We retrospectively reviewed the records of all arthroscopies performed in the rheumatology department of our teaching hospital between July 2002 and December 2015. Patients, suffering from a rheumatic disease, and knee complains underwent a KNA, either for the diagnosis, or for clinical research reason. The procedure was performed in a dedicated room under sterile conditions (extensive local disinfection and draping of the leg) and local anaesthesia, by a senior rheumatologist. Of note, joint needle aspiration was performed before the incision. The fluid (if obtained) was then sent for routine laboratory analysis: cellularity, crystal detection and culture. The patient was allowed to walk immediately after the procedure. All patients signed an informed consent before the procedure.

Results: A total of 919 patients were included in the study. Two-thirds (65.4%) were female and mean age was 52 years. A total of 1,136 KNA were performed. Almost half of the patients suffered from rheumatoid arthritis (47%), 20.2% from osteoarthritis, 10.7% from spondylarthritis, 10.7% from undifferentiated arthritis, 4.9% from microcrystalline arthritis, 3% from connective tissue diseases, and 1.8% from idiopathic juvenile arthritis A few patients suffered from sarcoidosis, hemochromatosis, villonodular synovitis and polymyalgia rheumatica. Of note, a diagnosis of septic arthritis was suspected in 7 patients by joint inspection and confirmed by positive cultures. The overall rate of complications was 1.5% and the rate of infection was 0.79%. Minor complications included 2 cases of subcutaneous hematoma, 4 cases of delayed healing with persistent superficial wound, 1 case of local skin atrophy after glucocorticoids (GC) injection and 1 case of pancreatitis, also attributed to the injection of GC in a HIV positive patient, treated with antiretrovirals. We observed no cases of post-intervention hemarthrosis, bleeding or thrombo-embolic complications. All serious complications were infectious. We identified 7 cases of confirmed septic arthritis, 1 case of septic bursitis and 1 case of possible septic arthritis (no bacteriological proof). Patients were predominantly male (6/9), most of them with ≥2 comorbidities. 4 out of 9 patients were treated by oral GC and all patients received intraarticular glucocorticoids during the procedure. As expected, *Staphylococcus aureus*was the most frequent pathogen identified. On the 9 infected patients, 7 were hospitalized, treated with IV antibiotics and underwent a surgical arthroscopic lavage 24-48 hours following the admission. Clinical evolution showed improvement in all cases with no long-term morbidity.

Conclusion:

KNA is a safe, and well-tolerated procedure, with less than 1% of septic complications. It's slightly lower than conventional arthroscopy, with the additional advantages of local anaesthesia, fast recovery and lower cost. Special caution should be applied to patients with comorbidities, previous infection, or treated with GC.

Session Title: Orthopedics, Low Back Pain and Rehabilitation

Session Type: ACR Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: Low back pain of mechanical origin is a major cause of disability and surgical intervention. The lumbar computed tomography (CT)-guided steroid infiltration can accelerate the recovery process and sometimes avoid the surgery. Our aim was to review the indications, efficacy and complications of this technique in a wide series of unselected patients. In addition a comparative study of efficacy was performed according to the lumbar underlying pathology, type of steroid and approach of injection.

Methods: Study of lumbar CT-guided steroid injections performed in a University Hospital between January 2012 and June 2015. The minimum follow-up was 3 months. The procedure was performed in patients with low back pain refractory to standard medical therapy and Lumbar Spine Rehabilitation. Efficacy was assessed at 1 and 3 months according to a semiquantitative scale as the pain response as a) total response, b) partially c) no or d) worsening pain. A comparative study of the efficacy and safety was performed, regarding: a) underlying pathology, b) approach of injection and c) the different types of steroids used. Fisher's test and

Chi2 and the SAS System for Windows V program 9.2.were used for statistical analysis.

Results: During the study period 258 procedures were performed in 171 patients (132 men / 126 women) with a mean age ± SD of 58.24±13.45 years (range, 18-88). The indications for the injection were: a) disc herniation (44.57%), b) lumbar stenosis (34.11%), c) postoperative fibrosis and spondylolisthesis (20.15%) and d) facet joint synovial cysts syndrome (1.17%). Approaches used were: a) posterior epidural (24.42%), b) lateral recess (58.91%), and c) foraminal (16.67%). The chosen steroid was triamcinolone (74.81%), dexamethasone (23.64%) and methylprednisolone (1.55%). In a significant proportion of the procedures improvement in the patient´s sintomatology was reported at the first month, regardless of the indication, route of corticosteroid injection and steroid used (TABLE). Regarding the overall outcome, at 3 months 72.48% of the patients experienced clinical improvement. And only 21.71% of patients required a subsequent surgery. The clinical efficacy showed no statistically significant differences according to the indication of the procedure or the route used for the injection. However, the improvement of pain was significantly greater in patients treated with triamcinolone than those treated with dexamethasone (p = 0.01). Regarding safety there were 6 (2.3%) local complications (puncture of the thecal sac) and 3 (1.16%) systemic complications (allergic reaction). None of these complicationes were of clinical relevance and they were not associated with the corticosteroid used.

Conclusion: CT-guided corticosteroid injection is an effective and safe treatment in low back pain refractory to standard medical therapy in patients with spinal stenosis, disc herniation and postoperative fibrosis. Triamcinolone infiltration seems to be more effective than dexamethasone.

Session Title: Orthopedics, Low Back Pain and Rehabilitation

Session Type: ACR Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: Utilization of total knee arthroplasty (TKA) continues to grow. Recent literature has questioned the appropriateness of TKA for patients that are morbidly obese, citing the high risk of complications. Data on the impact of obesity on patient-reported outcomes following TKA remain sparse. We assessed the extent to which obesity level affects patient-reported outcomes in pain, function, and satisfaction with surgery following TKA.

Methods: We followed a cohort of TKA recipients 40 years or older with a primary diagnosis of osteoarthritis scheduled for TKA at four tertiary medical centers. We stratified patients into 5 groups using the World Health Organization categories for obesity based on body mass index (BMI). We assessed whether obesity category is associated with post-operative pain and function evaluated at 24 months, as well as baseline to 24 month changes in pain and function. We used a piecewise linear model with a knot at 3 months to determine covariates associated with early and late TKA recovery. Multivariable models adjusted for age, sex, race, diabetes, musculoskeletal functional limitation index, medication use and study site.

Results: 691 patients were enrolled across 4 centers, with 633 providing baseline BMI information and outcomes at one or more follow-ups. At baseline 19% were normal weight (BMI < 25), 32% were overweight (25 ≤ BMI <30), 27% were obese (30 ≤ BMI <35), 12% were morbidly obese (35 ≤ BMI <40) and 9% were severely obese (BMI ≥40). There were differences in baseline characteristics between BMI groups. Heavier subjects tended to be younger, were more likely to be female, non-White, and have diabetes. Study participants with higher BMI had worse preoperative WOMAC Pain and Function, with mean pre-operative pain score ranging from 34 in normal weight participants to 50 in severely obese participants, and mean pre-operative function score ranging from 35 in normal weight participants to 51 in severely obese participants. Patients in all BMI groups showed substantial improvement in pain (Figure). At 24 month follow-up there was no significant difference in WOMAC Pain between the BMI Groups. The results suggested that more obese patients had a steeper recovery slope from baseline to 3 months, and no difference in slope by BMI group between 3 and 24 months. Results were similar for WOMAC Function. All groups reported high satisfaction with the results of surgery, with 75% very satisfied at month 6 and 80% very satisfied at month 24.

Conclusion: Despite worse pain and functional status preoperatively, subjects in all BMI groups achieved similar pain relief and functional improvements following TKA. From the standpoint of patient reported outcomes, TKA is highly effective in obese patients. **Figure**. Adjusted Mean WOMAC Pain by BMI Group and Timepoint

SESSION INFORMATION
Session Date: Tuesday, November 15, 2016
Session Title: Orthopedics, Low Back Pain and Rehabilitation
Session Type: ACR Concurrent Abstract Session
Session Time: 2:30PM-4:00PM

Background/Purpose: Total knee arthroplasty (TKA) is an effective treatment for patients with end-stage knee osteoarthritis (OA); however, a growing body of evidence suggests that patients using opioids prior to TKA experience worse pain outcomes immediately following surgery. We evaluated the pain relief achieved from TKA in knee OA patients with and without opioid prescriptions pre-TKA.

Methods: We augmented patient-reported data from a longitudinal study of TKA outcomes with medical record-based information about opioid use. The study included patients >40 years old who underwent primary, unilateral TKA at a tertiary academic medical center. The Pain Catastrophizing Scale (PCS) and patient-reported outcomes, including the Western Ontario and McMaster Universities Arthritis Index (WOMAC), were assessed at baseline and 6 months post-TKA. Demographic and comorbidity information were collected at baseline via study questionnaire. We reviewed the electronic medical record of each subject to identify opioid use from two years pre- to one year post-TKA. We documented the dates of first and last opioid prescription and any additional surgeries done during the study period. We restricted our analyses to those who did not have additional surgery during the study period and who had no more than 2 comorbidities. To address confounding by indication we built a propensity score of opioid use based on age, PCS, comorbidities, and pain prior to TKA. The propensity score ranged from 10% to 75% likelihood of opioid use. The primary analysis included subjects with propensity scores from 20-75%. We compared WOMAC Pain scores (0-100, 100 worst) at 6 months after TKA in persons without opioid use to those with documented pre-TKA opioid use with a general linear model, adjusting for propensity score, PCS, and baseline pain.

Results: Our analytic cohort consisted of 134 patients with mean age 68 years (SD 8); 66% were female and mean pre-TKA WOMAC Pain was 43 (SD 16). Nineteen percent had at least one opioid prescription prior to TKA. Baseline WOMAC Pain scores were higher among those who used opioids pre-TKA (49 vs. 41, p=0.04). PCS was substantially greater among pre-TKA opioid users (18 vs. 12, p=0.004). Adjusted analyses showed that the opioid group had mean 6-month WOMAC pain of 18 points, while the non-opioid group had mean WOMAC Pain of 10 points (p = 0.0017). The adjusted difference in pain from pre-TKA to 6 month post-TKA was estimated at 25 WOMAC points among those who use opioids prior to TKR compared to 33 WOMAC points among those who did not use opioids (p=0.0017).

Conclusion: Patients with pre-TKA opioid use had higher levels of pain catastrophizing and WOMAC Pain at baseline, and, after adjusting for differences in baseline pain, pain catastrophizing, and likelihood of opioid use, had higher pain 6 months after TKA compared to patients without preoperative opioid use. With the substantial societal burden associated with opioid use, clinicians and policymakers may consider limiting the use of these analgesics prior to TKA to optimize the efficacy of the procedure.

The Choosing Wisely Initiative: Is It Complete?

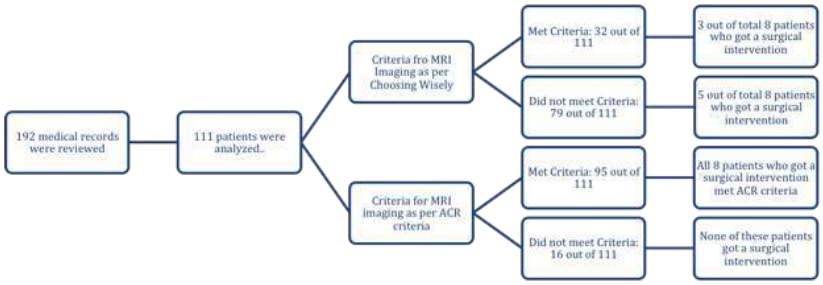
Navya Kuchipudi and Cathie-Ann Mancuso, Internal Medicine, Saint Peters University Hospital, New Brunswick, NJ
First publication: September 28, 2016

SESSION INFORMATION
Session Date: Tuesday, November 15, 2016

Session Title: Orthopedics, Low Back Pain and Rehabilitation
Session Type: ACR Concurrent Abstract Session
Session Time: 2:30PM-4:00PM

Background/Purpose: Low back pain is a highly prevalent problem affecting approximately 70-85% of Americans in their lifetime (1). American College of Physicians (ACP) has recommended in the Choosing Wisely Campaign by American Board of Internal Medicine (ABIM) in 2012, to avoid getting any radiological imaging in a patient complaining of non-specific lower back pain that cannot be attributed to a specific disease or spinal abnormality (2). The aim of this research is to compare the recommendations of the Choosing Wisely Campaign with American College of Radiology (ACR) in terms of evaluation of low back pain with MRI imaging.

Methods: This is a retrospective cross sectional study of all patients who had MRI of the lumbar spine from January 2013 to April 2015 for evaluation of low back pain. IRB approval was obtained. Indications as defined by the Choosing Wisely Initiative for MRI imaging in a patient with low back pain include history of fever, cancer, intravenous drug abuse, osteoporosis, focal neurological deficits or bowel/bladder incontinence, fever of 102 degrees and unexplained weight loss. In addition to above criteria, ACR also included age greater than 70 and pain persistent for more than 6 weeks after conservative measures as also indications for MRI imaging. We analyzed the data by calculating categorical subdivisions of different variables as percentages of the study group.



Results:

Mean age of the study group was calculated to be 59 with the majority being females (Females-59; Males-52).

Conclusion: Our study showed that 62.5% (5 out of 8 total patients with surgical intervention) of patients who were intervened surgically would not have received imaging in the initial evaluation, if choosing wisely recommendations were strictly followed. Although Choosing Wisely campaign was a great initiative to promote high value care in day to day practice, our study has showed that pain duration more than 6 weeks and age greater than 70, which were not clearly stated as indications for MRI imaging were risk factors by themselves necessitating MRI imaging and probable surgical intervention subsequently. This shows the requirement for clear-cut guidelines in the choosing wisely campaign as well as the need for larger studies comparing recommendations from various societies for MRI imaging in low back pain. **References:**

Session Title: Pediatric Rheumatology – Clinical and Therapeutic Aspects II: Juvenile Arthritis

Session Type: ACR Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: It is common view that macrophage activation syndrome (MAS) bears close similarities with primary hemophagocytic lymphohistiocytosis (pHLH). The resemblance of their clinical and laboratory manifestations may make it difficult to differentiate the two conditions, particularly when pHLH occurs at a later age or MAS develops at onset of systemic juvenile idiopathic arthritis (sJIA), when arthritis is not yet present. However, early recognition is important because pHLH is often more severe than MAS and the therapeutic approaches are different. The aim of our study is to develop and validate a diagnostic score that discriminates pHLH from sJIA-associated MAS

Methods: The clinical, laboratory and histopathologic features of 362 patients with sJIA-associated MAS and of 258 patients with pHLH were collected in a multinational collaborative project involving pediatric rheumatologists and pediatric hematologists. 80% of the study population was used to develop the score and the remaining 20% constituted the validation sample. The features with the strongest association with pHLH in univariate analyses (odds ratio > 5) were further scrutinized in multivariate logistic regression procedures. Each variable that entered the best fitting model was then assigned a score, based on its statistical weight. The MH score was made up with the individual scores of the selected variables. The cut-off in the MH score that discriminated best pHLH from MAS was calculated by means of ROC curve analysis. The sensitivity (SE), specificity (SP), area under the curve (AUC) and kappa value of the MH score were calculated for both the developmental and validation samples

Results: The following 6 variables entered the best fitted model of logistic regression analysis, that is, were most closely associated with a diagnosis of pHLH: age at disease onset ≤ 1.6 years, neutrophil count ≤ 1400/µl, fibrinogen ≤ 131 mg/dl, splenomegaly, platelet count ≤ 78000/µl, hemoglobin ≤ 8.3 g/dl. The MH score ranged from 0 to 123. Its median value was 97 (IQR 75-123) in pHLH patients and 12 (IQR 11-34) in MAS patients. The probability of a diagnosis of pHLH ranged from < 1% for a score < 11 to > 99% for a score ≥ 123. A cut-off value > 59 revealed the best performance in discriminating pHLH from MAS (SE=91%, SP=93%, AUC=0.92, kappa=0.85). The strong diagnostic power of the MH score was confirmed in the validation sample

Conclusion: The MH score is a powerful tool that facilitates timely discrimination of pHLH from MAS. Its application in routine clinical care may aid practitioners to identify those patients who are more likely to have pHLH and may, thus, deserve diagnostic confirmation with appropriate genetic and functional testing

Session Title: Pediatric Rheumatology – Clinical and Therapeutic Aspects II: Juvenile Arthritis

Session Type: ACR Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: Evidence in animals and humans points to a pivotal role of IFNγ in primary HLH. We have recently generated data in an animal model supporting a role for IFNγ also in MAS and reported high levels of IFNγ and of the IFNγ-related chemokines, CXCL9, CXCL10 in patients with MAS, during systemic JIA (sJIA) (1).

Methods: Circulating levels of sCD25, IL-18 and neopterin, as well as levels of IFNγ, CXCL9 and CXCL10 were measured by Luminex assay in 57 samples obtained, from 24 patients with active sJIA and in 37 samples from 20 patients with MAS at sampling at variable severity and treatments. We evaluated the correlation between serum levels of sCD25, IL-18 and neopterin, as well as levels of IFNγ of CXCL9 and CXCL10 with laboratory parameters of MAS severity in patients with active sJIA with or without MAS at sampling.

Results: Levels of IFNγ, CXCL9, CXCL10, sCD25, IL-18 and neopterin were significantly elevated in MAS compared to active sJIA without MAS at sampling (p-values <0.0001, except for IL-18 p=0.012). In patients with MAS, but not in patients with active sJIA without MAS at sampling, laboratory parameters of disease severity were significantly correlated with IFNγ, CXCL9, CXCL10, sCD25 and neopterin (Table1). No correlation with IL-18 was found (IL-18 levels were available only for a portion of the samples). Interestingly, during active sJIA without MAS at sampling, levels of CXCL9 (median 3889,IQR 965-7142), CXCL10 (764,323-1259) and IL-18 (4405,582-7122) were significantly higher in patients with a history of MAS compared to those of patients without a history of MAS (519,IQR 385-1168; 215,IQR 152-470; 439,312-824, respectively). **Table 1.**Correlation between cytokines and laboratory parameters in active MAS (N=37).

ALT (U/L)	0.012 (0.52)	0.0007 (0.68)	0.0005 (0.67)	0.008 (0.54)	>0.1 (0.38)	>0.1 (0.14)
Values are expressed as p value (r di Spearman).						

Conclusion: Levels of IFNγ, CXCL9, CXCL10, sCD25, and neopterin were higher during MAS and correlated with laboratory parameters of severity. IL-18 levels were not correlated with laboratory parameters of MAS severity and the observation that IL-18 levels are higher in patients with a history of MAS is consistent with the hypothesis that high levels of IL-18 may contribute to the

predisposition to MAS in sJIA as also suggested by Shimizu et al (2). Elevation of sCD25 is consistent with the presence of T cell activation in MAS. Elevation of neopterin and CXCL9, both of which reflects IFNγ production, and their correlation with laboratory parameters, supports the pathogenic role of IFNγ in MAS. Given the fact that circulating CXCL9 levels appear to reflect tissue IFNγ production, presence of high CXCL9 in patients with a history of MAS, but without MAS at sampling, suggests subclinical activation of the IFNγ pathway in these patients. **References.** 1. Session Date: Tuesday, November 15, 2016
Session Title: Pediatric Rheumatology – Clinical and Therapeutic Aspects II: Juvenile Arthritis
Session Type: ACR Concurrent Abstract Session
Session Time: 2:30PM-4:00PM

Background/Purpose: The management of SJIA with biological therapies is aimed to achieve and maintain clinical remission (CR), and accordingly taper corticosteroids (CS). Canakinumab (CAN) demonstrated high inactive disease (ID) rates in about 33% of patients (pts) in Day 15 and 30 respectively in previous studies[1]. However, little is known about high level response rates in SJIA pts using CAN long-term. The objective of this study was to evaluate the long-term treatment response in terms of safety and efficacy in CAN treated pts with active SJIA.

Methods: This was an open-label, non-comparative study of CAN-naïve SJIA pts (≥2 to <20 years) receiving subcutaneous CAN 4 mg/kg every 4 weeks. Efficacy was assessed every 3 months by the aACR (30/50/70/90/100) responses compared to baseline (BL), ID or CR (ID for >6 months) and changes in JADAS10-CRP scores over time. Safety was assessed by adverse events (AEs) and serious AEs (SAEs).The results are based on the observed data with imputations to carry the last observation forward.

Results: Of 123 pts with active SJIA, 70 (57%) had fever and 71 (57.7%) used corticosteroids at BL. Mean CRP was 117.8 mg/L (normal: 0-10 mg/L), and, on average, pts had 9.9 active joints and 8.9 joints with limited motion. A rapid response was observed at Day 15: 59 (51%) and 27 (26%) pts had aACR ≥70 and aACR 100 responses, respectively. These responses were maintained at subsequent time points (Table). At Month 6, CR was achieved in 52 (42.3%) pts. Overall, 33 (26.8%) pts had CR for at least 12

months. At BL, the median CRP score was 22.3, with median changes from BL of −12.0 at Day 15 and −16.8 at last assessment, respectively. At the last assessment, 59 (48.4%) pts had ID (JADAS10 ≤1); 14 (11.5%) had low disease activity (JADAS10 >1 and ≤3.8), while 14 (11.5%) had moderate and 35 (28.7%) had high disease activity. Overall, 24 (33.8%) pts were steroid-free at last assessment. In total, 108 (87.8%) pts had at least 1 AE. Overall, exposure adjusted AE and SAE rate was 8.22 and 54.8 events/pt-years (pyr) respectively, with 183.56 pyr exposure and 40 (32.5%) pts had SAEs; most commonly reported SAEs were disease flares or worsening of SJIA in 13 (10.6%) pts, macrophage activation syndrome in 6 (4.9%) pts, and fever in 4 (3.3%) pts. No deaths occurred in this study.

Conclusion: CAN treatment was associated with rapid response and sustained therapeutic effect over the long-term in the pts with active SJIA. The safety profile is consistent with other CAN studies. References: 1. Ruperto et al. *N Engl J Med*. 2012;367:2396-406.

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016

Session Title: Pediatric Rheumatology – Clinical and Therapeutic Aspects II: Juvenile Arthritis

Session Type: ACR Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: Although the recommended first line treatment for JIA, up to 50% of children will not respond to MTX. Currently, it is not possibly to identify at the start of therapy which children will not respond and thus initiation of effective therapies may be delayed. The aim of this analysis was to identify clinical factors measured at the outset of therapy associated with non-response to MTX with a view towards building an accurate multifactorial prediction model.

Methods: Children with JIA treated with MTX were identified from four large multi-centre UK observational studies participating in the Childhood Arthritis Response to Treatment (CHART) consortium: Childhood Arthritis Prospective Study, British Society for Paediatric and Adolescent Rheumatology Etanercept Cohort Study, Biologics for Children with Rheumatic Diseases Study, and Childhood Arthritis Response to Medication Study. Demographic, clinical and laboratory variables at start of MTX and at 6 (4-12) months following treatment start were extracted and combined using a common data model. Non-response at 6-months was defined as lack of achievement of the ACR Pediatric (ACR Pedi) 30 criteria or initiation of biologics due to MTX inefficacy. Patients stopping MTX prematurely (< 4 months) due to intolerance were excluded. Each potential predictor of non-response was evaluated

using logistic regression. Significant factors were taken into a multivariate logistic regression model and estimated using stepwise backward elimination approach. Missing data including outcome data was addressed using multiple imputations.

Results: A total of 2211 patients were included in this analysis, mean age at MTX start 8.4years, 68% female, 41% polyarthritis, 34% oligoarthritis, 7% psoriatic, 8% systemic onset, 4% undifferentiated and 6% enthesitis related arthritis. The non-response rate (95%CI) was 32.7% (30.2 – 35.0). In the multivariate model, only lower ESR, Physician global assessment (PGA), Parent's general evaluation of well-being (PGE), ANA negativity and use of oral MTX versus subcutaneous route were significantly associated with non-response (Table 1), AUC 66.6%.There was no significant association between age, gender, disease duration, BMI, JIA subtype, joint counts and CHAQ score and non-response to MTX at 6 months.

Conclusion: Although some routinely collected clinical and laboratory factors were associated with non-response in this large JIA cohort, overall, clinical factors alone could not predict non-response to MTX. The addition of biological or genetic factors to clinical factors may be able to identify a more robust model to predict non-response and divert children onto more effective therapies earlier in their disease course.

Parameters at the start of MTX therapy that were significant in univariate analysis	**Non-responders 32.7% (30.2 – 35.0)**	**Responders 67.3% (64.9 – 69.7)**	**OR (95% CI)**	**P value**

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016

Session Title: Pediatric Rheumatology – Clinical and Therapeutic Aspects II: Juvenile Arthritis

Session Type: ACR Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: Juvenile Idiopathic Arthritis (JIA) is the most common chronic inflammatory rheumatic diseases of childhood. Due to their long-term safety and efficacy, biologic disease modifying antirheumatic drugs (DMARD) are commonly necessary for control of polyarticular JIA (pJIA) patients (pts). The objective of this study is to evaluate 6-year (y) safety and 2 y effectiveness profile of Adalimumab with or without methotrexate (ADA±MTX) when used in current clinical practice for the treatment of moderately to severely active pJIA.

Methods: This is a 6 y interim analysis of an ongoing, multicenter, non-interventional, observational registry of pts with moderately to severely active pJIA with up to10 y safety follow-up. Included pts are treated with either ADA±MTX or MTX alone as part of their routine clinical care enrolled in the US, EU, and Australia. MedDRA observational adverse events (AEs) were recorded from the first day in the registry through last contact, irrespective of the duration of registry treatment. Effectiveness was assessed by 27-joint juvenile arthritis disease activity score (JADAS27), based on CRP.

Results: As of January 2014, enrollment was complete. As of June 1, 2015 cut-off date, 846 pts (543 in ADA±MTX and 303 in MTX groups) were treated in the registry. There were 39 pts who rolled over from the MTX to the ADA±MTX arm. At registry entry mean pJIA disease duration was 1.4 y and 3.7 y for MTX and ADA±MTX arms, respectively. At baseline (BL), mean AJC71 was 5.8 and 5.3 for MTX and ADA±MTX arms, respectively, and Childhood Health Assessment Questionnaire Disability Index (CHAQ-DI) was 0.6 for both arms. At data cutoff, the mean duration of study exposure was 1.81 y and 2.15 y for MTX and ADA ±MTX arms, respectively. Overall, 206 pts (68%) in the MTX and 216 pts (39.8%) in the ADA±MTX arms discontinued registry drug through 6 y. The main reasons for registry drug discontinuation for the MTX arm: pts required additional therapy (32.3%), other (11.9%), lack of efficacy (10.9%), AEs (8.3%), or pts achieved JIA remission (7.6%), and for ADA±MTX arm: lack of efficacy (16%), lost to follow-up (7.2%), other (5.9%), and AEs (5.3%). Frequencies and rates of treatment-emergent AEs were similar to those reported for observational AEs **(Table)**. There were no reports of deaths, malignancies, opportunistic infections, active TB, oral candidiasis, or CHF. Mean JADAS27(CRP) improved from 12.2 at BL to 9.7, 5.2, 4.4, 3.5, 2.2 at months 1, 6, and 12, 18, 24 for pts in the MTX and from 11.8 at BL to 7.0, 4.-2, 4.2, 3.6, 3.9 in the ADA±MTX arms, respectively (observed data).

Conclusion: Overall, ADA±MTX was well-tolerated in these pts with pJIA with no new safety signals. Discontinuations from the registry drug were relatively high through 6 y, but greater in the MTX only arm.

Table: Overview of Observational Adverse Events (AEs)

	MTX		ADA±MTX	
	N=303 n (%)	PYs=1014.6 E (E/100 PYs)	N=543 n (%)	PYs=1562.7 E (E/100 PYs)
Any AE	156 (51.5)	470 (46.3)	229 (42.2)	683 (43.7)
At least "possibly drug related" per the investigator	83 (27.4)	171 (16.9)	110 (20.3)	222 (14.2)
Severe AE	14 (4.6)	18 (1.8)	34 (6.3)	55 (3.5)
Serious AE	29 (9.6)	45 (4.4)	66 (12.2)	117 (7.5)
AE leading to discontinuation of study drug or study	25 (8.3)	33 (3.3)	35 (6.4)	56 (3.6)
Infectious AE	85 (28.1)	164 (16.2)	134 (24.7)	226 (14.5)
Serious infectious AE	12 (4.0)	15 (1.5)	26 (4.8)	36 (2.3)
Injection site-related AE	6 (2.0)*	8 (0.8)	28 (5.2)	37 (2.4)

*3 pts experienced injection site-related AEs with etanercept injections. During the registry, 47 (15.5%) pts in MTX arm and 38 (7.0%) pts in ADA arm started with biologic DMARD other than ADA. All except one pt in MTX arm had been documented as permanently discontinued registry drug or registry, at time of cut-off date for this analysis.

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016
Session Title: Pediatric Rheumatology – Clinical and Therapeutic Aspects II: Juvenile Arthritis
Session Type: ACR Concurrent Abstract Session
Session Time: 2:30PM-4:00PM

Background/Purpose: The data of the REMINDER study, a two-part, 48-week, randomized, placebo-controlled, double-blind withdrawal study on efficacy of etanercept (ETA) compared to placebo (PLC) in ERA patients is used to analyze the improvement of spinal symptoms (1).

Methods: Patients with active ERA received open-label ETA for 24 weeks. At week 24, patients with at least a JIA-ACR30 response entered a 24-week randomized (1:1 PLC or ETA), double-blind withdrawal period. Improvement was assessed by the number of active joints, the JIAACR30/50/70/90 and ACR remission criteria, the JADAS10, JADAS MDA and JADAS remission, the tender enthesitis points (TEP), and parameters of spinal involvement (BASDAI, BASFI and spinal pain (by VAS)).

Results: Forty-one patients (means for age: 13.4 years, baseline disease duration: 2.8 years, active joints count: 5.3, JADAS10: 15.8) were included and 39 received open-label ETA (0.8 mg/kg/week, max.50 mg/week) for 24 weeks. Two patients discontinued prematurely. Marked improvement was reached at week 24, the JIAACR30/50/70/90 response rates were 93%/93%/80%/56%. %. ACR remission was achieved by 23 patients (60.5%), respectively. JADAS MDA/remission was reached by 34 (87.1%)/23(60.5%) patients. The mean number of active joints decreased from 5.2+/-2.3 to 0.3+/-0.8. The mean BASDAI score decreased from 4.4+/-1.9 to 1.2+/-1.6 and the number of patients with a BASDAI of 0 increased from 0 to 26.3% (n=10). The mean BASFI improved from 2.7+/-2.4 to 0.36+/-0.68. 31(81.6%) of patients achieved an ASAS20 and 28 (73.7%) an ASAS40. Mean total spinal pain/spinal paint night also decreased from 5.2/2.9 to 1.5/0.5. The mean TEP count decreased from 1.8 [range 0-7] to 0.4 and the rate of patients with no tender enthesitis point more than doubled from 31.7% to 68.4%. Efficacy indicators were stable in patients receiving ETA in the double blind phase of the study, and worsened in part of the patients on PLC. Until week 48, 7/10 patients on ETA with BASDAI of 0 at week 24 remained with a BASDAI of 0. In all 3 cases with a JIA ACR30 flare, an increase of the BASDAI was noted (from 0 to 0.6, 1.1 and 7.6). All 7 patients randomized to placebo with a BASDAI of 0 at week 24 maintained a BASDAI of 0 until week 48 or until reset on ETA. Also 13/17 (76%) patients on ETA and 9 (69%) on PLC with no TEP at week 24 remained without TEP until week 48. A single uveitis event was reported in a patient randomized ETA at week 48.

Conclusion: In this placebo-controlled randomized study on ERA-JIA patients, ETA proved to be highly effective on peripheral disease as well as on spinal inflammation. A high rate of patients achieved JADAS remission, BASDAI 50, BASFI50, no spinal pain and no tender enthesitis points after 24 weeks of treatment. The study was underpowered to demonstrate differences between ETA and PLC cohort at week 48. (1) Horneff et al. Arthritis Rheumatol. 2015 Apr 17. doi: 10.1002/art.39145

Long-term Outcomes After Disease Activity Guided Tapering of TNF Inhibitors in Rheumatoid Arthritis: 3 Year Data of a Randomized Controlled Pragmatic Non Inferiority Strategy Study

Den Broeder AA[1], Bouman CAM[1], van den Hoogen FHJ[1,2], Fransen J[2], Van Vollenhoven RF[3], Bijlsma JWJ[4], van der Maas A[1], van Herwaarden N[1] [1]Department of Rheumatology, Sint Maartenskliniek, Nijmegen, the Netherlands [2]Department of Rheumatology, Radboud University Medical Centre, Nijmegen, the Netherlands [3]Amsterdam Rheumatology and Immunology Center ARC, Amsterdam, Netherlands. [4]Department of Rheumatology & Clinical Immunology, Utrecht University Medical Centre, Utrecht, the Netherlands

Background/Purpose: In a pragmatic, randomized, open label strategy study, non inferiority of a disease activity guided dose reduction (DR) strategy of adalimumab or etanercept compared to usual care (UC; non tapering tight control) was demonstrated after 18 months. Long term effects of this strategy are however unknown. We assessed whether the initial 18 months effects were sustained up to year 3 with regard to disease control, functioning, quality of life, radiographic outcome and cost (effectiveness).

Methods : In the intervention phase (months 0-18), patients were randomized to DR (stepwise TNFi interval increase until flare or discontinuation) or UC[1]. Consenting completers of this phase were included in the extension phase (months 18-36). Treatment in both groups converged to protocolized tight control and allowed dose optimization (Fig. 1). Intention-to-treat analyses were done on flare, medication use, disease activity (DAS28-CRP), functioning (HAQ-DI), quality of life (EQ5D-5L), adverse events (AE), radiographic progression (Sharp-Van der Heijde, SvdH), and costs.

Results : 172 (115 DR; 57 UC) were included in the extension phase (Fig. 2). Cumulative incidences of major flare were 10% and 12% (-2%, 95% CI -8 to 15) in the DR and UC group in the extension phase, and 17% and 14% (3%, 95% CI -9 to 13) from 0-36 month. In the DR group, 33/115 (29%, 95% CI 21 to 38%) still had successfully reduced their TNFi dose at 36 months, and 19/115 (17%, 95% CI 10 to 25%) discontinued TNFi at 36 months. In the UC group, 32/49 (65%, 95% CI 50 to 78%) attempted dose reduction in the extension phase of whom 19/49 (39%, 95%CI 25 to 54%) had successfully tapered and 7/49 (14%, 95% CI 1 to 27%) discontinued TNFi at 36 months. Mean DAS28-CRP, HAQ-DI, SvdH and EQ5D-5L remained stable over 36 months and did not differ significantly between groups (Fig. 3). Over 3 years, mean cost saving was −€13,451 (95% CI −€9,701 to−€17,198) per patient, which, with the small gain in QoL, resulted in a dominant cost-effectiveness ratio (€1.9 million savings per saved QALY).

Conclusion: Safety and efficacy of disease activity guided dose reduction of TNFi in RA patients are maintained up to three years. No difference in radiographic progression was found. Cost savings were considerable, no other benefits of tapering could be demonstrated. **Reference** Van Herwaarden N et al. BMJ 2015

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016
Session Title: Rheumatoid Arthritis – Clinical Aspects IV: Managing Patients in Remission
Session Type: ACR Concurrent Abstract Session
Session Time: 2:30PM-4:00PM

Background/Purpose: Tumor Necrosis Factor inhibitor (TNFi) free prolonged acceptable disease control in patients with rheumatoid arthritis (RA), in stable remission or low disease activity (LDA) during treatment with TNFi will benefit the balance between costs and effects. Therefore, using the data from the POET study, we evaluated the available potential clinical predictors of prolonged disease control after discontinuation of TNFi.

Methods: Data of 439 RA patients who were randomized to stop TNFi treatment in the POET study were analyzed post-hoc. The indicator of prolonged acceptable disease control over 12 months was: not restarting TNFi treatment. Available potential clinical predictors were: type of TNFi (antibody vs. receptor antagonist); concomitant conventional systemic DMARD; female sex; Younger age (<60 yrs.); short disease duration (<10 yrs.); RF positive; ACPA positive; erosive disease; normal weight (BMI 18.5 – 25); first TNFi; DAS28 deep remission (DAS28 ≤1.98) and MBDAscore ≤44, all at baseline. Associations between potential clinical predictors and disease relapse versus prolonged acceptable disease control were examined using univariate analysis and multivariate logistic regression.

Results: In the POET study 439 stable controlled RA-patients in remission or low-disease activity stopped their TNFi. During the following 12 months observation 50,1% of patients remained in low disease activity or remission. <span">Univariate analysis revealed an association of the following predictors: type of TNFi (antibody vs. receptor antagonist) OR: 2.26(1.53–3.34) p<0.0001; Short disease duration OR: 1.88(1.26–2.79) p=0.002; absences of erosions OR: 1.62(1.08–2.44) p=0.020 and MBDA score ≤44 OR: 2.32(1.32–4.05) p=0.003.Multivariate (backward deletion) of potential clinical predictors of prolonged acceptable disease control after TNFi discontinuation are: Type of TNFi (antibody vs. receptor antagonist) OR:2.39(1.57 – 3.65) p<0.0001; Short disease duration (<10 yrs.) OR 2.02 (1.34 – 3.05) p=0.001; and MBDA ≤44 OR: 2.01 (1.11 – 3.65) p= 0.022.

Conclusion: This post hoc analysis in well-controlled RA patients stopping their TNFi during participations in the POET study suggests that patients characterized by the use of an TNFi antibody (predominatly adalumimab but including infliximab, golumimab and certoluzimab) with a short disease duration and a low MBDA score are likely to remain well-controlled (remission or low disease activity) during the following 12 months. Their littermates using a receptor antagonist (etanercept) with a longstanding disease and a high MBDA are most likely to flare. These data allow the well-controlled RA-patient using a TNFi and their attending physician to make an educated shared decision on continuation or stopping this expensive treatment.

Session Date: Tuesday, November 15, 2016
Session Title: Rheumatoid Arthritis – Clinical Aspects IV: Managing Patients in Remission
Session Type: ACR Concurrent Abstract Session
Session Time: 2:30PM-4:00PM

Background/Purpose: Dose tapering in patients in remission has previously proven promising in randomized controlled trials. However, systematic implementation in clinical practice is lacking. A new guideline in the Capital Region of Denmark required that RA patients in sustained remission on biological therapy must attempt dose reduction according to a predefined algorithm. We aimed to 1) report the 1-year results of the implementation of the guideline and 2) investigate potential clinical baseline predictors of flare during the 1st year.

Methods: Patients with disease activity score (DAS28, 4 variables, CRP-based) ≤2.6 for ≥1 year and no radiographic progression the previous year were included. According to the algorithm, dosing of biological drug was to be reduced to 2/3 of standard dose at baseline, to ½ of standard dose after 4 months, and discontinued after 8 months. Patients who flared stopped tapering and were escalated to the previous dose to regain remission. Flare was defined as 1) DAS28≥2.6 AND DDAS28≥1.2 since baseline, or 2) erosive progression based on X-ray and/or magnetic resonance imaging (MRI). The relapse-free time since start of tapering stratified by gender and by median disease duration (11 years) was presented as Kaplan-Meier curves (time to flare). Breslow test was applied to test for significant difference between men and women and disease duration.

Results: A total of 143 patients from 5 departments of rheumatology were included as part of the implementation of the guideline. Baseline characteristics and medication are shown in table 1. During the 1st year, 101 (71%) patients flared and stopped tapering. All patients who flared were re-escalated and regained remission. At 1 year, 49 (34%) were on full dose, 28 (20%) patients were on 2/3 dose, 36 (25%) on half dose, and 30 (21%) had discontinued biological treatment. Median time to flare was 273 days (IQR:

247-299). According to figure 1 female sex and longer disease duration were associated with an increased risk of flare.

Conclusion: One year after initiating dose tapering in RA patients in remission in routine clinical practice, 66% of patients had been able to reduce the dose. Flares during tapering occurred in >70%, but were reversed by re-escalating patients to the previous dose. Female sex and longer disease duration were associated with increased risk of flare.

Session Date: Tuesday, November 15, 2016
Session Title: Rheumatoid Arthritis – Clinical Aspects IV: Managing Patients in Remission
Session Type: ACR Concurrent Abstract Session
Session Time: 2:30PM-4:00PM

Background/Purpose: Treatment with biologicals is based on the principle of 'one size fits all' without taking differences into account for dosing schemes, patients' characteristics and pharmacokinetics. The aim of this study is to compare disease activity after 26 weeks between adalimumab dose interval prolongation and continuation of the regular dose in rheumatoid arthritis (RA) patients with high adalimumab serum concentration[1] .

Methods: In this open randomized controlled trial, patients with an adalimumab concentration >8 mL/L were randomly (1:1) assigned to continuation of 40 mg adalimumab every other week (continuation group) or prolongation of the dosage interval to once every 3 weeks (tapering group). This was independently of disease activity score in 28 joints (DAS28). Before the study, patients were treated with adalimumab 40 mg subcutaneous every other week for at least 28 weeks. Visits were scheduled at baseline, 13 and 26 weeks thereafter. The change in DAS28 (deltaDAS28) after 26 weeks compared to baseline was taken as outcome measurement. A clinical relevant difference was defined as a deltaDAS28 >0.6. Based on an intention to treat analysis, an independent t-test was used to compare mean deltaDAS28 between the two groups. A total of 102 patients was calculated as a priori sample size.

Results: Fifty-three patients out of 142 screened patients (37%) had adalimumab concentrations >8 mL/L and were included in the study. All patients completed follow up. Twenty-six patients were assigned to continuation group and 27 to tapering group. Baseline characteristics did not differ significantly between the two groups. After 26 weeks, mean deltaDAS28 did not meet the criteria for a clinically relevant difference in both continuation group (0.29 ± 0.58 standard deviation (SD)) and tapering group (-0.06 ± 0.58 SD) (see figure). The groups were not significant different (p=0.06). Six patients in the continuation group developed active inflammation (defined as an increase of ≥ 1 swollen joint compared to baseline) during follow-up. In the tapering group, two patients developed active inflammation of whom one returned to standard dose of adalimumab. Despite the absence of inflammatory signs, eight other patients in the tapering group returned to standard dose on request of patient or treating rheumatologist.

Conclusion: This study shows that disease activity remains stable in RA patients with adalimumab concentrations > 8 mL/L who prolonged their dose interval to once in the three weeks compared to patients who continued adalimumab every other week.

Session Date: Tuesday, November 15, 2016

Session Title: Rheumatoid Arthritis – Clinical Aspects IV: Managing Patients in Remission

Session Type: ACR Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: Rheumatoid arthritis (RA) is characterised by the presence of a progressively destructive joint inflammation. Even in times of modern therapeutics, a subgroup of patients continues to be refractory to numerous consecutive therapeutic interventions with regards to control of inflammation and joint damage. **Objective:** To explore the characteristics and causes of refractory RA in 2016.

Methods: We defined refractory RA as patients who had experienced ³3 treatment courses (with at least one biological) over a minimum of 18 months since diagnosis without reaching the treatment goal of low disease activity or remission (defined by a Simplified Disease Activity Index, SDAI, ³11). From our clinicÕs ongoing longitudinal data set we identified 64 refractory patients out of 737 RA outpatients. This is an interim report of the first 30 of these patients, who were prospectively included in our study (figure 1). Radiographic images were obtained prospectively, and were retrospectively scored by an experienced reader using the modified Sharp/van der Heijde (SvH) method. Average changes in SvH scores of ³3 per year were considered as progressive. After enrolment, we performed ultrasound examination of the hands among these refractory patients and semi-quantitatively scored them for signs of Greyscale and Power Doppler.

Results: 15 out of 30 (50.0%) patients showed radiographic progression (figure). In this group, almost every patient (86.7%) also showed signs of ultrasound activity (Power Doppler signs grade 2 or 3). Radiographic progressive patients showed significantly fewer tender joints than patients being non-progressive (p=0.032) (table). Of the 15 non-progressive refractory patients, 8 were diagnosed with fibromyalgia by the ACR 2010 fibromyalgia diagnostic criteria, and accordingly had failed their treatment target

due to high patient global scores and tender joint counts. The remaining seven had active synovitis, which was confirmed in five patients by ultrasound. Regardless of radiographic or sonographic state, patients evaluate their state of disease activity the same (Patient Global Assessment, PGA: 57.3 vs 62.2, p=0.502; or 59.9 vs 59.1, p=0.925; respectively).

Conclusion: There a several different types of patients being referred as ÒrefractoryÓ. Whereas almost all radiographic progressing patients also show signs of active synovitis by ultrasound, most non-progressing patients do not and are mainly classified as refractory due to pain components. Here, our clinical composite indices fail.

Session Title: Rheumatoid Arthritis – Clinical Aspects IV: Managing Patients in Remission

Session Type: ACR Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: The original Disease Activity Score (DAS) was derived from clinicians' therapeutic decisions[1], which may have been influenced by patient-subjective factors such as general health status and joint tenderness. Modern imaging allows accurate measurement of synovitis and provides an objective standard against which to derive an updated DAS. We aimed to identify alternative forms of the DAS28 that are more strongly associated with ultrasound (US) measures of synovial inflammation than existing definitions.

Methods: Patients were included from 2 observational early RA cohorts [Inflammatory Arthritis CONtinuum (IACON n=433) and Pathobiology of Early Arthritis Cohort (PEAC n=117)], and a clinical trial (IDEA n=89); all satisfied ACR 1987 and/or ACR/EULAR 2010 criteria for RA. Data were available at repeated time-points [weeks 0, 26, 52, 78, 104 (IACON); 0, 26 (PEAC); 0, 50, 78 (IDEA)]; US scan was within 1 week of clinical exam. In IACON and IDEA US grey scale and power Doppler scores (0-3) for bilateral wrists, knees, MCPs 2&3, PIPs 2&3 and MTPs 1-5 were combined into a global GSPD score with Rasch analysis. In PEAC global GSPD was GS+PD in bilateral MCPs 1-5. Using linear mixed models with random intercepts for within-patient clustering we modelled the association in each cohort between GSPD and: original 4-component (4C) DAS28CRP score, a 2-component (2C) score with weights for SJC28 (0.15) and lnCRP+1 (0.49) from an existing MRI-based equation[2], and DAS28CRP components [SJC28, CRP or TJC28, SJC28, CRP, general health VAS (GH)]. We compared models using restricted maximum likelihood deviance. Multiple imputation addressed missing data. Analyses used R v3.2.5.

Results: Models included 843, 237 and 183 visits from IACON, IDEA and PEAC respectively. Using DAS28 scores, deviance differences favoured 2C-DAS28 for IACON (2C-4C: -31) and PEAC (-16) but original 4C-DAS28 in IDEA (8). Nevertheless, using individual components, in all 3 studies only SJC28 and CRP were associated with GSPD. Coefficients from models using individual components are presented in Table 1. Despite differences in joints measured and methods of creating GSPD, the ratio of coefficients in the 2C models (SJC:CRP) were consistent: IACON 2.2, IDEA 2.1, PEAC 2.5.

Conclusion: Using a more objective measure of synovial inflammation, US-derived GSPD, the subjective elements of the DAS28 equation (TJC28, GH) can potentially be removed without loss of association with underlying synovitis and their removal may even improve the association. A 2-component DAS28CRP would simplify clinical examination and reduce the likelihood of missing data in clinical studies. This has the potential to improve patient care by targeting escalation of therapy to those with synovitis. Additional modelling will determine optimal weights for a 2-component DAS28CRP.

Session Title: Rheumatoid Arthritis – Human Etiology and Pathogenesis I

Session Type: ACR Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: The initial site of anti-citrullinated protein antibody (ACPA) generation in RA has been proposed to be a mucosal site. We have previously demonstrated ACPA elevations (characterized by anti-CCP) in the lung of individuals at-risk of future RA and with established RA using induced sputum (*Willis 2013*). In recent pilot work, we found that anti-CCP-IgG and CCP-IgA are elevated in 25% of first-degree relatives (FDR) of RA patients who are at-risk of RA development based on familial risk. However, it is unknown what factors may trigger anti-CCP production in the lung. Neutrophil extracellular trap (NET) formation is

one mechanism that can externalize citrullinated proteins (e.g. cit-histones) and potentially trigger anti-CCP. Prior studies identified enhanced peripheral NETosis in patients with established RA; however the relationship between NETosis and mucosal anti-CCP production is unknown. To better understand anti-CCP development in the lung, we sought to evaluate NET levels in sputum associated with anti-CCP.

Methods: From the Studies of the Etiology of RA cohort, we evaluated 51 FDRs without inflammatory arthritis (IA). Induced sputum was tested by ELISA on a CCP3 substrate using isotype-specific IgA and IgG secondary reagents (Inova, for research only). In sputum, *in-vivo* NET levels were measured using a sandwiched ELISA for DNA-myeloperoxidase (MPO) complexes, and total citrulline level was quantified using colorimetric assays. A subset of 35 FDRs also had total neutrophils (per mL) quantified in sputum using cytocentrifugation. Analyses included SpearmanÕs correlation.

Results: FDRs had a mean age of 52 ± 13, and were 71% female and 33% ever-smokers. Sputum anti-CCP-IgG and CCP-IgA levels significantly correlated with sputum level of NETosis (Figure). Using linear regression, this correlation remained significant after adjusting for smoking. When considering only FDRs who were serum anti-CCP-IgG and IgA negative (n=40), these correlations also remained significant. In addition, sputum anti-CCP-IgG and IgA correlated with sputum total neutrophil cell count (Figure) and total citrulline level (for CCP-IgG, r=0.33, p=0.02; for CCP-IgA, r=0.52, p<0.01).

Conclusion: We identified a strong correlation between sputum anti-CCP-IgG and IgA levels and NET-associated biomarkers in RA-free FDRs that was independent of smoking and serum anti-CCP positivity. Sputum anti-CCP also correlated with neutrophil cell count and total citrulline levels. In aggregate, these data suggest that in the lung, in the setting of elevated neutrophils, NETosis may be a source of externalized citrullinated protein that can trigger sputum anti-CCP-IgA and anti-CCP-IgG production locally. Since these findings are in subjects without RA, longitudinal studies are needed to determine the relationships between these mucosal biomarkers, the development of systemic RA-related autoimmunity and progression to classifiable RA.

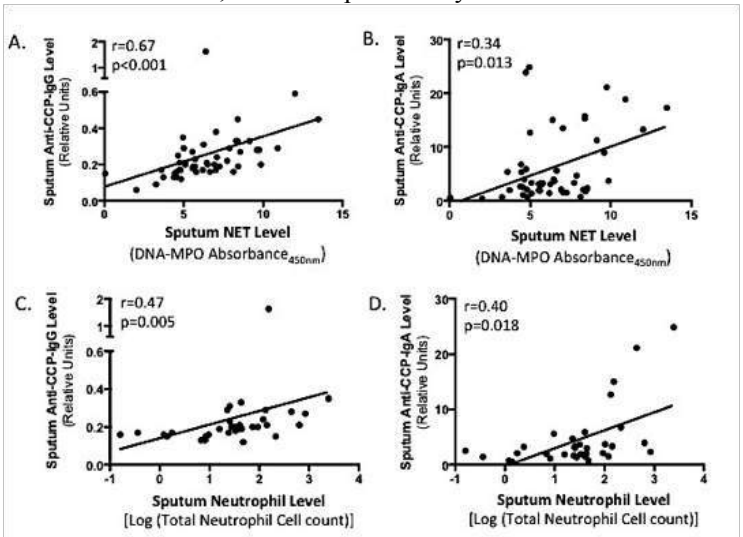

Figure. Correlations of Sputum Anti-CCP, Neutrophil Extracellular Trap (NET) and Neutrophil Levels in First Degree Relatives (FDRs). The correlation between sputum anti-CCP (Y axis) and NET levels (X axis) are depicted in Panels A (for anti-CCP-IgG) and B (for anti-CCP-IgA). The correlation between sputum anti-CCP (Y-axis) and neutrophil levels (log of total neutrophil count, X-axis) are depicted in Panels C (for anti-CCP-IgG) and D (for anti-CCP-IgA).

Session Title: Rheumatoid Arthritis – Human Etiology and Pathogenesis I
Session Type: ACR Concurrent Abstract Session
Session Time: 2:30PM-4:00PM

Background/Purpose: Although various genetic factors have been implicated in susceptibility to rheumatoid arthritis (RA), environmental factors including smoking, periodontal disease and hormones are also necessary for the disease manifestations. We speculate that gut microbiota is one such environmental factor that may be correlated with the development of RA. Previous reports have demonstrated that RA patients have altered composition of gut microbiota. However, it remains unclear whether the altered composition of intestinal microbiota observed in RA patients causes the disease onset.

Methods: We first examined whether RA patients have particular patterns of microbiota. All the patients were diagnosed according to the American College of Rheumatology/European League Against Rheumatism 2010 classification criteria for RA. We collected human fecal samples from 17 untreated new-onset RA patients (disease duration 1.0±0.7 years, mean±SD) and 13 healthy volunteers to investigate the microbiota by 16S rRNA-based deep sequence technique. We further analyzed the correlation between bacterial counts of intestinal microbiota and disease activity in 50 treated RA patients (disease duration 9.6±9.0 years, mean±SD) by quantitative reverse transcription PCR (RT-qPCR) method. We also inoculated human fecal samples from new-onset RA patients or healthy controls into germ free SKG mice (intestinal microbiota-humanized mice) and analyzed for the severity of arthritis and immune responses. We next evaluated whether *Prevotella copri* (*P. copri*) has an ability to induce Th17-related cytokines *in vitro*. Bone marrow-derived DCs were stimulated with intestinal bacteria and analyzed for the production of Th17-related cytokines. Finally, we inoculated *P. copri* into germ free SKG mice and analyzed severity of arthritis.

Results: Six out of 17 new-onset RA patients showed high abundance of *Prevotella.* Especially, *P. copri* was dominant OTU in the RA patients. None of the healthy controls harbored increased abundance of *Prevotella.* The bacterial counts of *Prevotella* were positively correlated with the disease activity of treated 50 RA patients ($r = 0.36$, $P<0.01$). SKG mice harboring *Prevotella*-dominated microbiota from new-onset RA patients (RA-SKG mice) showed severe arthritis in the presence of zymosan injection. Increased number of Th17 cells in the regional lymph nodes and large intestine was observed in RA-SKG mice. *P. copri* induced high production of IL-6 and IL-23, indicating that *P.copri* has an ability to enhance Th17-biased immune responses. Mono-colonization of *P. copri* into germ free SKG mice also showed arthritis.

Conclusion: *Prevotella*–dominated gut microbiota may contribute to the development of arthritis both in human RA patients and SKG mice.

Session Title: Rheumatoid Arthritis – Human Etiology and Pathogenesis I

Session Type: ACR Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: Multiple studies demonstrate that ACPAs are elevated in the serum years prior to the onset of seropositive RA during a preclinical period of autoimmunity. Importantly, the mechanisms and site of development ACPAs as well as their initial antigen targets in the preclinical period are unknown, although data suggest that initial production may occur at a mucosal site such as the lung. Therefore, we sought to explore ACPAs in the lung of subjects with RA and at-risk of future RA.

Methods: From the Studies of the Etiology of RA cohort, we included 17 established RA subjects, 45 subjects At-Risk of RA and 16 healthy Controls. RA subjects were all serum anti-CCP3.1 positive (IgG/IgA, Inova). At-Risk subjects were without RA, were at-risk of future RA based on familial (i.e. first-degree relative of RA patient) or serologic (i.e. serum anti-CCP3.1 positive identified in clinics or health fairs) risk, and included 19/45 (42%) who were serum anti-CCP3.1 positive. Paired serum and induced sputum were tested using a bead-based ACPA array for IgG reactivity to 29 individual citrullinated proteins/peptides and quantified by fluorescent intensity. A separate cohort of 22 healthy controls were used to set ACPA positive cut-off levels at a level that was positive in <5% of these controls. For analysis, At-Risk subjects were stratified as Serum ACPA(+) and Serum ACPA(-) based on our array results.

Results: Subject demographics are listed in the Table. Compared to Controls, positivity of ≥1 sputum ACPA was higher in RA (71%, $p<0.01$) and At-Risk subjects (40%, $p=0.01$). The median number of positive sputum ACPAs was higher in RA ($p<0.01$) and Serum ACPA(+) At-Risk subjects ($p<0.01$) compared to Controls. Several individual sputum ACPAs were more prevalent in RA and At-Risk subjects compared to Controls (Table footnotes 5-7). Of interest, antibodies to citrullinated fibrinogen, fibronectin and apolipoprotein E were more prevalent in Serum ACPA(-) and Serum ACPA(+) At-Risk subject compared to Controls. In RA, antibodies to citrullinated fibrinogen and fibronectin peptides were more prevalent than in Controls.

Conclusion: In this pilot study, we found ≥1 sputum ACPA in 71% of RA and 40% of At-Risk subjects. These data support our prior finding of elevated sputum anti-CCP-IgG in At-Risk and RA subjects by ELISA testing (*Willis 2013*). Furthermore, 25% of Serum ACPA(-) At-Risk subjects were sputum ACPA positive supporting these ACPAs may originate in the lung. In particular, citrullinated fibrinogen, fibronectin and apolipoprotein E may be early antigenic targets in the lung during preclinical phases of RA. Finally, the number of sputum ACPAs positive increased from Controls to Serum ACPA(+) At-Risk to RA subjects suggesting that epitope spreading likely occurs in the lung during phases of RA development. Additional longitudinal studies are needed to confirm and extend these findings as well as evaluate non-citrullinated protein reactivities in the lung.

Session Title: Rheumatoid Arthritis – Human Etiology and Pathogenesis I
Session Type: ACR Concurrent Abstract Session
Session Time: 2:30PM-4:00PM

Background/Purpose: Inhibitor of DNA binding-1 (Id1) is a nuclear transcription factor that regulates cell growth and differentiation via selective binding and sequestering of other transcription factors. We have shown Id1 is primarily fibroblast derived with elevated expression in rheumatoid arthritis (RA) synovial fluids (SFs) and functions as a potent angiogenic factor. We have found that in vitro citrullination of Id1 exhibits heterogeneity in the number of modified arginines observed, leading to remarkable differences in autoantigenicity and autoantibody formation in vivo. In this study, we investigated how targeted citrullination affects the potential autoantigenicity of citrullinated Id1 and autoantibody formation in RA.

Methods: RA SFs were immunodepleted of Id1 and measured by ELISA using anti-modified citrulline (AMC) antibody for total citrullinated antigens. RA synovial tissues (STs) were homogenized and immunoprecipitated of Id1 for Western blot analysis using anti-Id1 or AMC antibodies. In vitro citrullination was performed by incubating recombinant human (rh) PAD4 or rabbit PAD with the target protein. Liquid chromatography-tandem mass spectrometry (LC-MS/MS) was performed to localize the sites of citrullination. To test the presence of anti-citrullinated protein antibodies (ACPAs) to citrullinated Id1, normal (NL) and RA patient peripheral blood (PB) sera as well as SFs, immunodepleted of rheumatoid factor, were analyzed using immunodot blot (IDB).

Results: Immunodepletion of Id1 from RA SFs significantly reduced the levels of total citrullinated antigens in RA SFs by as much as 64%, with an average reduction of 31%, as measured by ELISA. Similarly, immunoprecipitated Id1 from homogenized RA STs was also significantly citrullinated as shown by Western blots. IDB analyses revealed antibodies to citrullinated Id1, but not native Id1, which were detected in RA sera and SFs, but not in NL sera. By a series of LC/MS-MS and immunoassays, we determined the citrullination sites of modified Id1. Of the 10 available arginines (R) in Id1, the critical arginines for autoantigenicity were located at positions R33, R52 and R121. Citrullinated Id1 protein lacking modified arginines at those residues did not bind to AMC antibody, did not migrate as citId1 on acrylamide gels due to charge differences, and were not recognized by ACPAs to citId1 in IDBs. In contrast, we observed a robust change in autoantigenicity of epithelial-derived neutrophil-activating peptide-78 (ENA-78)/CXCL5 modified with rabbit PAD, showing that a single modification at R48 converts it so that it is recognized by ACPAs in patient sera and SFs.

Conclusion: We identify key arginines in Id1 that may be an autoantigenic target for ACPA development in RA. Our findings also show that targeting select arginines for citrullination conversion can produce dramatic changes in autoantigenicity. The degree of citrullination of Id1 may alter the natural folding pattern and immune properties of Id1, leading not only to autoantigenicity, but potentially also to functional changes in this molecule. These findings could explain putative disease-associated properties of Id1: increased severity of certain cancers and perpetuation of inflammatory disease.

Session Title: Rheumatoid Arthritis – Human Etiology and Pathogenesis I
Session Type: ACR Concurrent Abstract Session
Session Time: 2:30PM-4:00PM

Background/Purpose: Anti-citrullinated peptide antibodies and/or rheumatoid factor (RF) in the setting of arthralgia ("seropositive arthralgia") has been associated with a high risk of development of rheumatoid arthritis (RA). Models of the risk of imminent RA have used arthralgia as an inclusion criterion. The significance of arthralgia in an unselected population of first-degree relatives (FDR) and controls, with or without seropositivity, is not known. We recruited a high-risk group, FDR of indigenous North American (INA) people with RA, in addition to INA population controls, with or without arthralgia. The goal of this analysis is to describe the prevalence of arthralgia at baseline and the association of arthralgia, seropositivity, and other RA risk factors with development of RA.

Methods: INA FDR and healthy unrelated controls were recruited from two populations in Canada and the United States. Data collected at the baseline visit included demographic features, habits and environmental exposures, and self-reported joint symptoms. Sera were tested for the presence of anti-cyclic citrullinated peptide (CCP) antibodies and rheumatoid factor IgM by ELISA. Risk of future RA was estimated based on a previously reported risk model for imminent RA. Participants have been followed longitudinally for development of RA.

Results: 961 participants were included in the analysis (620 FDRs and 341 controls). The mean age at baseline was 36.0 years. The cohort was 62.2% female, with 74.4% residing in rural communities. Arthralgia of any joint was present in 51.3% of the cohort (58.4% of FDRs and 35.5% of controls, $p<0.0001$). Arthralgia of both the hands and other joints was present in 31.9% overall. Seropositive arthralgia was present in 128 participants (27.7% of those with arthralgia). Seropositivity for RF and/or CCP was associated with reduced odds of arthralgia at the baseline visit (OR 0.59 (95%CI 0.44-0.80)). The majority of those with arthralgia (91.2%) fell into the low-risk category for RA development based on the imminent RA prediction model. Participants who developed RA during the follow-up period (n=14) were no more likely to have arthralgia at baseline than those who did not develop RA ($p=0.9$). Those who developed RA were less likely to fall in the low risk group at baseline ($p<0.001$) and more likely to be seropositive for RF ($p=0.07$) and CCP ($p<0.001$) and to have seropositive arthralgia ($p=0.001$).

Conclusion: Although arthralgia is more common in FDRs than in controls, arthralgia is not associated with seropositivity or with development of RA in a healthy population. In contrast, both seropositivity and seropositive arthralgia are associated with RA development.

Autoantibodies to Peptidylarginine Deiminase 2 Protect Against Radiographic Progression in Patients with Rheumatoid Arthritis

Erika Darrah[1], Jon T. Giles[2], Ryan Davis[1], Pooja Naik[1], Maximilian Konig[1] and Felipe Andrade[1], [1]Department of Medicine, Division of Rheumatology, The Johns Hopkins University, Division of Rheumatology, Baltimore, MD, [2]Columbia University, College of Physicians and Surgeons, Division of Rheumatology, New York, NY

SESSION INFORMATION
Session Date: Tuesday, November 15, 2016
Session Title: Rheumatoid Arthritis – Human Etiology and Pathogenesis I
Session Type: ACR Concurrent Abstract Session
Session Time: 2:30PM-4:00PM

Background/Purpose: The mechanisms that drive clinical heterogeneity and outcomes in patients with rheumatoid arthritis (RA) are poorly understood, but precise biomarkers may identify clinically unique subgroups with distinct underlying disease

mechanisms. In a subset of patients with RA, autoantibodies that activate the peptidylarginine deiminase (PAD) 4 enzyme have been identified. These antibodies are associated with severe joint and lung disease, highlighting the potential importance of functional autoantibodies in disease pathogenesis. The PAD enzymes are central players in RA due to their ability to generate the citrullinated targets of anti-citrullinated protein antibodies (APCAs). Although PAD4 has garnered the most attention, PAD2 is also strongly implicated in RA pathogenesis, but antibodies to PAD2 have not been reported.

Methods: In this study, sera from 184 patients in the ESCAPE RA cohort and 37 healthy controls were screened for the presence of antibodies to human PAD2 by ELISA. The frequency of anti-PAD2 antibodies and associated clinical features were determined.

Results: The frequency of anti-PAD2 antibodies in patients with RA was 18.5%, compared with 5.4% of healthy controls ($p=0.001$). Interestingly, the clinical characteristics of anti-PAD2 positive patients were distinct from those previously observed for anti-PAD4 antibodies. While antibodies to PAD4 are associated with APCAs, the *HLA-DRβ1* shared epitope (SE), and severe joint and lung disease, anti-PAD2 antibodies were negatively associated with SE ($p=0.014$) and swollen joint count ($p<0.05$) and were not associated with APCAs ($p=0.94$). Significantly higher anti-PAD2 antibody titers were observed in RA patients who were female ($p=0.013$) or on biologic therapies ($p=0.036$), while significantly lower antibody titers were observed in patients with SE ($p=0.02$) or interstitial lung disease ($p=0.039$). In a multi-variable model adjusted for C-reactive protein, adiponectin, and baseline radiographic joint damage, anti-PAD2 antibodies were significantly protective against radiographic progression with a 9% lower odds of progression per log unit of anti-PAD2 antibody (OR=0.91; $p=0.021$) (Figure).

Conclusion: Anti-PAD2 antibodies represent a novel biomarker in RA that is not associated with the traditional risk factors linked to disease severity such as SE and ACPAs. Instead, patients with antibodies to PAD2 are protected against radiographic progression and have less interstitial lung disease. This novel biomarker has potential implications for disease monitoring and highlights an unappreciated role of PAD2 in RA pathogenesis. The less aggressive disease phenotype observed in patients with anti-PAD2 antibodies suggests that they may target a pathogenic function of PAD2 in patients with RA. The effect of anti-PAD2 antibodies on PAD2 enzyme activity is currently under investigation.

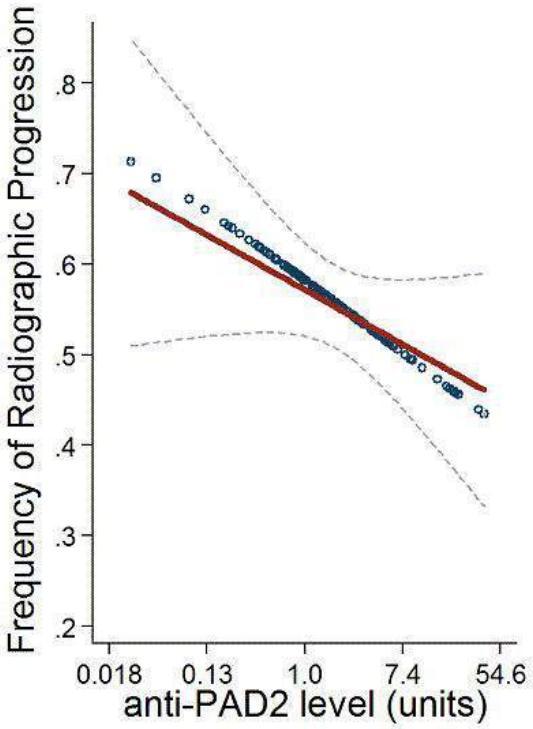

Figure. Crude and Adjusted Frequency of Radiographic Progression Over Three Years According to anti-PAD2 Level. The open circles represent the unadjusted average probability function derived from logistic regression. The solid line with its dashed 95% confidence interval represent the adjusted average probability function, adjusted for average CRP, baseline radiographic damage (i.e. Sharp van der Heidje Score), and average adiponectin level (OR=0.91; p=0.016)

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016
Session Title: Rheumatoid Arthritis – Small Molecules, Biologics and Gene Therapy III: Small Molecules and Early Intervention
Session Type: ACR Concurrent Abstract Session
Session Time: 2:30PM-4:00PM

Background/Purpose: In patients with active RA an increase in lipid analytes has been observed after treatment with janus kinase inhibitors and other disease-modifying antirheumatic drugs.[1] The molecular mechanisms underlying these lipid changes are under active investigation.[2]

Methods: Data were analyzed from Phase 2 and Phase 3 studies of 4 mg oral baricitinib (bari) administered once daily in patients with moderately to severely active RA. The effect of statin therapy on lipid levels was evaluated in a subgroup of Phase 3 patients. In 1 Phase 3 study, the lipoprotein particle size and number were evaluated with nuclear magnetic resonance (NMR) at baseline and Week (Wk) 12.

Results: Treatment with bari was associated with increased levels of total cholesterol, triglycerides (TG), low density lipoprotein cholesterol (LDL-C), and high-density lipoprotein cholesterol (HDL C) with a stable LDL C/HDL C ratio. The lipid elevation plateaued after Wk 12 (Table 1). By NMR, bari did not significantly affect total LDL particle number while the small, dense potentially more atherogenic LDL particle numbers decreased. Bari significantly increased HDL-C, the total number of HDL particles, all HDL subfractions, and TG-rich lipoproteins. The magnitude of lipid change from baseline was not significantly different between baseline statin users and nonusers (Table 2). In bari patients who initiated statin therapy before Wk 24 (N=18), the increased levels of total cholesterol and LDL-C decreased to baseline levels by Wk 24, while HDL-C levels remained elevated after statin therapy (Figure 1). Similar results in lipids changes and response to initiation of statin therapy were observed for apolipoprotein A1 and apolipoprotein B corresponding to HDL-C and LDL-C.

Conclusion: These analyses showed that bari was associated with increased LDL-C, HDL-C, and TG levels, with a stable LDL-C/HDL-C ratio. The magnitude of lipid change was not significantly different between baseline statin users and nonusers. In patients who initiated statin therapy during the study, the elevation in total cholesterol, LDL-C, and TG decreased to pretreatment levels in response to statin therapy, while HDL-C remained elevated with statin therapy. **References:**

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016

Session Title: Rheumatoid Arthritis – Small Molecules, Biologics and Gene Therapy III: Small Molecules and Early Intervention

Session Type: ACR Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: RA patients (pts) are at increased risk of myocardial infarction (MI) and stroke that cannot be completely explained by traditional cardiovascular (CV) risk factors. Tofacitinib is an oral Janus kinase inhibitor for the treatment of RA. Tofacitinib treatment may increase total cholesterol (TC), LDL-c and HDL-c in some pts. We evaluated major adverse CV event (MACE) risk factors in tofacitinib-treated RA pts in the clinical development program.

Methods: Data were pooled from pts with moderately to severely active RA receiving ≥1 tofacitinib dose in 6 Phase 3 and 2 long-term extension (LTE) studies (1 LTE study ongoing, data cut-off: March 2015). MACE was defined as any MI, stroke, or CV death (coronary, cerebrovascular, cardiac). Cox proportional hazard models evaluated associations between baseline (BL) values and time (BL to first tofacitinib dose) to first MACE. Changes (BL to Week [wk] 24) in MACE predictors and time to future MACE (first occurrence after 24 wks) were evaluated after adjusting for age, BL values and time-varying tofacitinib dose. Hazard ratios (HR) and 95% confidence intervals (CI) were calculated.

Results: 52 MACE cases occurred over 12,873 pt-years (py) of exposure in 4076 pts (incidence rate: 0.4 pts with events/100 py). Table 1 shows BL characteristics for pts with/without MACE. In univariate analyses, traditional CV risk factors, corticosteroid and statin use were associated with BL MACE risk. BL disease activity and inflammation measures were not associated with MACE risk (Table 2). Increases in HDL-c ($p<0.001$) and decreases in TC/HDL-c ratio ($p<0.05$) after 24 wks of tofacitinib therapy were significantly associated with decreased risk of future MACE (Figure). In contrast, increases in ESR may be associated ($p=0.09$) with increased future MACE risk. Changes in TC or LDL-c or other disease activity measures were not associated with future MACE risk.

Conclusion: In pooled analyses of tofacitinib-treated pts (age and BL value adjusted), increases in HDL-c and decreases in the TC/HDL-c ratio after 24 wks of tofacitinib therapy were associated with reduced future MACE risk. Increases in ESR after 24 wks may be associated with increased future MACE risk. Increases in LDL-c and TC after 24 wks of tofacitinib therapy were not associated with future MACE risk. More data are needed to confirm these findings.

Table 1. Baseline demographics and disease characteristics

Parameter Mean ± SD	Adjudicated MACE (N=52)	No MACE (N=4024)

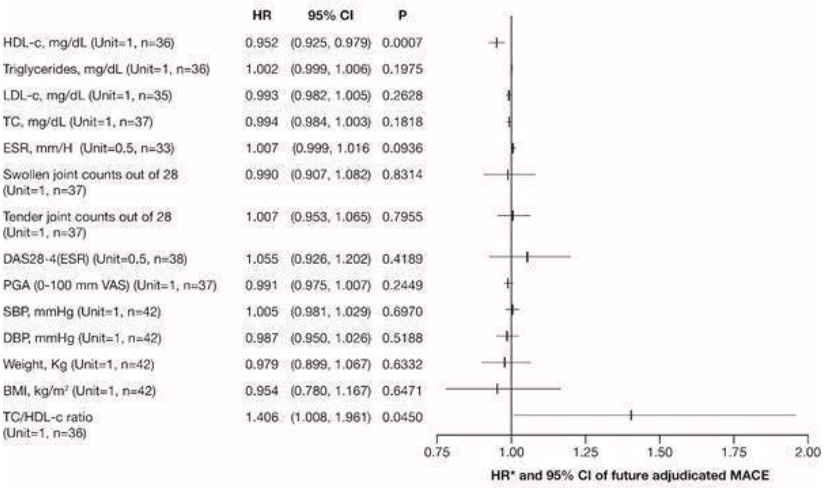
Diastolic blood pressure (mmHg, n=51)	1.04*	(1.01, 1.07)
History of cardiac disorders (Y/N, n=52)	1.85	(0.67, 5.14)
History of diabetes (Y/N, n=52)	2.56*	(1.20, 5.43)
History of hypertension (Y/N, n=52)	2.86***	(1.65, 4.96)

*p<0.05; **p<0.01; ***p<0.001

BMI, body mass index; CI, confidence interval; CRP, C-reactive protein; DAS28-4, disease activity score in 28 joints; ESR, erythrocyte sedimentation rate; HDL-c, high-density lipoprotein-cholesterol; HR, hazard ratio; LDL-c, low-density lipoprotein-cholesterol; MTX, methotrexate; NSAID, non-steroidal anti-inflammatory drug; TC, total cholesterol.

n represents number of patients with MACE (uncensored) analyzed for each variable.

Figure. Age-adjusted and baseline parameter-adjusted association of change from baseline to Week 24 in lipid levels, inflammation parameters, and RA disease activity measures with future MACE



BMI, body mass index; CI, confidence interval; DAS28-4(ESR); Disease Activity Score 28(ESR); DBP, diastolic blood pressure; ESR, erythrocyte sedimentation rate; HDL-c, high-density lipoprotein cholesterol; HR, hazard ratio; LDL-c, low-density lipoprotein cholesterol; MACE, major adverse cardiovascular event; PGA, patients global assessment; RA, rheumatoid arthritis; SBP, systolic blood pressure; TC, total cholesterol
These data show results from a cox regression model: showing age-adjusted and baseline parameter-adjusted association of changes from baseline to Week 24, for future MACE risk.
*For each variable listed, a cox regression model was fit, with change in variable at Week 24, the variable at baseline and age at baseline and time varying dose as predictors. In this model, only patients with exposure after the tofacitinib-week 24 are considered (ie, patients who had MACE before tofacitinib-week 24 or who had withdrawn or completed the study by tofacitinib-week 24 are excluded.) Additionally, patients with missing data for a tofacitinib-week 24 variable are excluded from the analysis of that variable (no imputation method). The HR corresponds to increased risk MACE per 1-unit increase in the parameter. 'n' is the number of patients with future MACE for each predictor.

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016

Session Title: Rheumatoid Arthritis – Small Molecules, Biologics and Gene Therapy III: Small Molecules and Early Intervention

Session Type: ACR Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: Filgotinib (GLPG0634) is a novel oral, potent and selective JAK1 inhibitor that showed rapid and sustained improvements of signs and symptoms of active rheumatoid arthritis (RA) in patients with inadequate response to methotrexate (MTX) in two 24-week Phase 2B studies, with an acceptable safety profile. The effect of filgotinib add-on to MTX or monotherapy on patient-reported outcomes (PROs) is presented here.

Methods: In DARWIN 1 (add-on to MTX) and DARWIN 2 (monotherapy), patients with active RA were randomized in a double blinded manner to placebo (PBO) or one of the three daily doses of filgotinib (50mg, 100mg or 200mg) for 24 weeks. In DARWIN 1, once (qd) and twice daily (bid) regimens were assessed. At week 12, patients on PBO (in DARWIN 1) and 50mg daily dose (in DARWIN 1 and DARWIN 2) whose tender and swollen joint counts did not improve by at least 20% were reassigned to 100mg

daily dose. In DARWIN 2, all patients on PBO were reassigned to 100mg daily dose. Assessed PROs were patient evaluation of disease activity & pain, physical function, fatigue and HRQoL-SF36. This presentation reports results of the Phase 3 filgotinib doses, 100mg and 200mg qd.

Results: In total 594 and 283 patients were randomized and dosed in DARWIN 1 and DARWIN 2, respectively. Mean HAQ-DI baseline value was 1.74 and 1.81, respectively, indicating severe impairment. Filgotinib was associated with rapid and statistically significant improvement in PROs (patient assessment of disease activity and pain, physical function, fatigue and HRQoL-SF36) in both studies. The 200mg daily dose showed statistically significant effects as early as week 1-2 on HAQ-DI and patient VAS for global disease and pain, and from week 4 for FACIT and SF-36-PCS. With the 100mg qd dose, patient global assessment significantly improved from week 1-2 and FACIT from week 4 in both studies. SF-36 PCS improved from week 4 in DARWIN 2. After week 12, these responses were maintained or continued to improve through 24 weeks. At week 24, the clinical effect was comparable between filgotinib 100mg qd and 200mg qd and between add-on and monotherapy (between study comparison). Table 1. PRO responses for the 100mg and 200mg once daily doses

Mean change from baseline (LOCF)		Patient's VAS disease activity	Patient's VAS pain	HAQ-DI	FACIT	SF-36 PCS	SF-36 MCS

The Efficacy and Safety of Low Dose IL-2 Therapy in over-Treated Patients with Rheumatoid Arthritis: A Preliminary Study

Sheng-Xiao Zhang[1], Miao Miao[2], Xiao-Qing Liu[2], Xiao-Wen Ma[2], Xiao-Yan Wu[2] and Xiao-Feng Li[1], [1]Rheumatology, The Second Hospital of Shanxi Medical University, Taiyuan, China, [2]The Second Hospital of Shanxi Medical University, Taiyuan, China

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016

Session Title: Rheumatoid Arthritis – Small Molecules, Biologics and Gene Therapy III: Small Molecules and Early Intervention

Session Type: ACR Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: Current therapy for rheumatoid arthritis (RA) often leads to excessive immunosuppression induced by glucocorticoids and DMARDs. Low-dose Interleukin 2 (IL-2) has been showed to induce Treg cell expansion and activation, which is expected to control the development of RA. We studied the clinical efficacy and safety of IL-2 treatment in RA.

Methods: Total 41 RA patients with low Treg cells, who had been treated with glucocorticoids and DMARDs for over 6 months, were divided into two groups randomly. Patients in Non-IL-2 group (n=15) were still given traditional glucocorticoids and DMARDs treatment. Patients in IL-2 group (n=26) were not only given traditional treatment, but also injected subcutaneously IL-2 at 50 WIU per day for a 5 day course. The demographic features, clinical manifestations and laboratory indicators were compared before and after the treatment.

Results: There was no difference between Non-IL-2 group and IL-2 group in gender, age and course of the disease ($P>0.05$). The ratios of Th1/Th2 and Th17/Treg were significant correlated with ESR, the number of tender or swollen joints and DAS28-ESR ($P<0.05$) in all two groups of patients. After IL-2 treatment, the number of Th17 cells (16.51±19.06 vs 19.00±11.38, P=0.01) or Treg cells (18.67±14.08 vs 78.55±44.67, P=0.001) were significantly increased. Due to increased Treg cells were much more than the Th17, leading to a decrease in their ratio (1.36±1.49 vs 0.28±0.20, P=0.024). Before the IL-2 treatment, there was no difference in clinical manifestations between two groups ($P>0.05$), but in IL-2 group, there was a significantly decrease after the treatment in the number of tender joints (3.73±2.79 vs 0.94±1.00, P=0.001) or swollen joints (1.40±1.64 vs 0.42±0.70, P=0.011) and DAS28-ESR (3.60±0.96 vs 2.85±0.67, P=0.005). There was no difference in blood routine, liver and renal functions both before and after the treatment between two groups ($P>0.05$).

Conclusion: IL-2 can effectively up-regulate the level of Treg as well as that of Th17 to some degree and maintain the balance of Th17 and Treg cells. IL-2 subcutaneous injection combined with traditional antirheumatic drugs may help for RA patients' symptoms remission without over-treatment and evaluated side effect. IL-2 could be used as a novel therapeutic candidate for RA treatment but long term benefits of IL-2 therapy are required to further study.

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016

Session Title: Rheumatoid Arthritis – Small Molecules, Biologics and Gene Therapy III: Small Molecules and Early Intervention

Session Type: ACR Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: Compared to the general population, RA patients (pts) have an increased risk of herpes zoster (HZ) due to their disease and various DMARD therapies including JAK inhibitors.[1] The aim of this analysis was to evaluate HZ in RA pts treated with baricitinib (bari), an oral JAK1/JAK2 inhibitor in development for treatment of RA.[2,3]

Methods: Data were pooled from completed Phase (Ph) 1, 2, and 3 studies, and an ongoing long-term extension (LTE) study of bari in RA pts (data cutoff January 1, 2016). HZ events were identified using MedDRA preferred terms related to HZ. The incidence of HZ was evaluated for all RA pts who ever received bari (any dose, including LTE data), pts in the 6 randomized, placebo [PBO]-controlled studies (0-24 weeks, DMARD-inadequate responders), and pts in individual active-controlled studies with MTX (DMARD-naive: RA BEGIN) and adalimumab (ADA; MTX-inadequate responder: RA BEAM). Incidence rate (IR) was calculated as the number of pts with an HZ event per 100 patient-years of observation (PYO) with exposure censored at event date. The Mantel-Haenszel method was used for between treatment group comparisons, controlling for the study effect.

Results: In the All Bari group (1 Ph 1, 3 Ph 2, 4 Ph 3, and 1 ongoing LTE; 3492 pts, 5141 PYO), treatment-emergent HZ was reported in 170 pts (IR=3.3) (Figure 1). In the PBO-controlled studies HZ rates for bari 4 mg were significantly increased compared to PBO (IR difference [95%CI]: 3.2 [1.0, 5.4]) but were comparable to ADA in RA-BEAM. The majority of HZ events (95%) were reported as mild or moderate in severity; few were disseminated or complicated (7 distributed beyond primary or adjacent cutaneous dermatomes, 2 associated with facial nerve palsy, no visceral events). Rates appeared higher in Japan and in patients with advancing age, but not with longer RA duration, or corticosteroid use (Tables 1 and 2), and decreased with prolonged exposure.

Conclusion: In these integrated analyses, treatment with bari was associated with an increased risk of HZ compared to PBO, with an overall IR of 3.3/100 PYO in patients with RA. Rates appeared to diminish with prolonged exposure. **References:** [1]Smitten AL et al. *Arthritis Rheum* 2007;57:1431-1438. [2]Dougados M et al. *Ann Rheum Dis* 2015;74(S2):79. Session Title: Rheumatoid Arthritis – Small Molecules, Biologics and Gene Therapy III: Small Molecules and Early Intervention

Session Type: ACR Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: The development of clinical signs and symptoms of seropositive rheumatoid arthritis (RA) is often preceded by a phase of systemic autoimmunity. This offers a window of opportunity to delay or prevent the development of clinically manifest arthritis.This could represent a paradigm shift from treatment to prevention[1]. B cells could be a good target as they play a key role in the pathogenesis of the disease. The purpose of this study is to explore the effects of a single infusion of the anti-CD20 antibody rituximab on the onset of clinically manifest arthritis in individuals at risk of developing autoantibody positeve RA.

Methods: Eighty-two subjects with arthralgia and positive serology for both anti-citrullinated protein antibodies (ACPA) and rheumatoid factor, who never had clinically manifest arthritis and never used disease-modifying antirheumatic drugs were included in the PRAIRI study, a multicentre, randomised, double-blind, placebo-controlled clinical trial. Subjects were randomized to receive a single infusion of either 1000 mg rituximab or placebo after all receiving 100 mg methylprednisolone premedication. Subjects were prospectively followed to assess development of clinically manifest arthritis and change in biomarkers. Kaplan-Meier survival analysis, Cox regression analysis and Treatment*Time Cox proportional hazard ratios were used to determine the treatment effects.

Results: Eighty-one individuals (52 females; mean age 53 (IQR 13.5) years) received treatment, which was generally well tolerated. One patient withdrew before treatment. The median follow up was 29.0 months (0-54), during which 30 subjects developed arthritis: 16/40 (40%) in the placebo group and 14/41(34%) in the rituximab group, after a median period of 11.5 (interquartile range [IQR] 12.5) months in the placebo group versus 16.5 (IQR 19.0) months in the rituximab group. Rituximab decreased the risk with 55% (HR (95%CI) 0.45 (0.154-1.322) at 12 months follow up compared to the observed risk of developing arthritis in the placebo group of 40%. At the 25% quartile (75% free of arthritis) of the cumulative arthritis-free survival there was a delay in the development of arthritis of 12.0 months (12 months versus 24 months in the placebo vs rituximab group, respectively). As expected, this effect attenuated over time. Treatment*Time Cox proportional hazard analysis showed that the beneficial effect of rituximab was highly statistically significant (P<0.0001). Biomarkers were measured over time shedding light on the potential mechanism underlying the delay in arthritis development.

Conclusion: A single infusion of 1000 mg rituximab significantly delays the development of arthritis in subjects at risk of developing RA. This is the first study evaluating the effects of a biopharmaceutical in this population, and the results support the rationale for future clinical trials aimed at prevention of RA by a targeted intervention. **References**[1] *Gerlag DM, Norris JM, Tak PP. Session Title: Sjögren's Syndrome I: Clinical Insights
Session Type: ACR Concurrent Abstract Session
Session Time: 2:30PM-4:00PM

Background/Purpose: Ultrasonography of major salivary glands (sUS) is applied in the diagnostic work-up of primary Sjögren's syndrome (pSS). This study aims to assess (i) the validity of sUS compared to salivary gland biopsy, sialometry and serology and (ii) the alignment of sUS with classification criteria in patients suspected for pSS.

Methods: 103 consecutive outpatients clinically suspected for pSS underwent sUS of both parotid and submandibular salivary glands between October 2014 and November 2015. Parenchymal echogenicity, homogeneity, hypoechogenic areas, hyperechogenic reflections and clearness of the salivary gland posterior border were scored. Ultrasound total score (UTS) was calculated as the sum of these domains (range 0-48), according to the Hocevar scoring system.(1) All patients underwent a complete diagnostic work-up. For the present analyses, UTS was compared to parotid (n=70) and labial (n=54) gland biopsy outcomes (focus score ≥1), sialometric data (unstimulated (UWS) and stimulated (SWS) whole saliva; n=99), presence of anti-SSA antibodies (n=103) and AECG, ACR and proposed ACR-EULAR classification criteria (n=98/99). ROC analysis with area under the curve (AUC) was performed to define the optimal cut-off point of UTS to predict positive salivary gland biopsy or fulfilling classification criteria.

Results: Of 103 included patients, median age was 51 years (range 18-82), 90% were female and median UTS was 12 (range 3-43). Accuracy of sUS outcomes to predict positive parotid gland biopsy (AUC 0.833) and labial gland biopsy (AUC 0.816) was good. The optimal cut-off point of UTS was 15 for parotid and 14 for labial gland biopsies. Agreement between positive UTS and positive parotid (κ=0.580, sensitivity 70%, specificity 88%) and labial (κ=0.556; sensitivity 70%, specificity 85%) gland biopsy was moderate. UTS showed high negative predictive value for parotid gland biopsy and high positive predictive value for labial gland biopsy. Accuracy of sUS outcomes to predict abnormal UWS (AUC 0.696) was poor and to predict abnormal SWS (AUC 0.731) was fair. There were fair reversed associations of UTS with UWS (ρ=-0.336) and SWS (ρ=-0.371). Accuracy of sUS outcomes to predict presence of anti-SSA antibodies (AUC 0.803) and agreement between positive UTS and anti-SSA antibodies (κ=0.633) were both good. Accuracy of sUS outcomes to predict AECG classification (AUC 0.804) and ACR classification (AUC 0.839) was good and to predict ACR-EULAR classification (AUC 0.782) was fair. The optimal cut-off point of UTS was 14 for AECG and 15 for both ACR and ACR-EULAR. Agreement between positive UTS and AECG (κ=0.573, sensitivity 73%, specificity 85%) and ACR-EULAR classification (κ=0.512, sensitivity 61%, specificity 93%) was moderate and agreement between positive UTS and ACR classification (κ=0.636, sensitivity 71%, specificity 92%) was good.

Conclusion: In our prospective inception cohort derived from daily clinical practice, sUS outcomes showed moderate agreement with salivary gland biopsies, poor to fair agreement with sialometry, good agreement with serology and moderate to good agreement with classification criteria in patients suspected for pSS. **References:** (1) Hocevar et al. Evidence of Inflammasome Activation in the Peripheral Blood and Salivary Gland Tissues of Primary Sjögren's Syndrome Patients: Correlation with Clinical Indices of Severe Disease and Lymphoma Development

Session Date: Tuesday, November 15, 2016

Session Title: Sjögren's Syndrome I: Clinical Insights

Session Type: ACR Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: Inflammasomes are intracellular multiprotein complexes that sense pathogenic microorganisms, as well as danger signals released following tissue injury. Such activation of inflammasome leads to the upregulation of various inflammasome-related molecules and the release of pro-inflammatory cytokines, namely interleukin-1β (IL-1β) and interleukin-18 (IL-18). In this study, we sought to investigate the inflammasome activation status in the peripheral blood and the salivary gland (SG) tissues of SS patients and its relationship with indices of disease activity and severity.

Methods: PBMC mRNA expression of inflammasome-related molecules NLRP3, AIM2, ASC, pro-caspase-1, IL-1β, IL-18 as well as the interferon type I signature genes MX1 and IF44L was evaluated by RT-PCR. Serum expression of inflammasome proteins ASC, IL-1β and IL-18 was evaluated by ELISA. SG biopsies were examined for the presence of inflammasome-related proteins by confocal microscopy.

Results: Compared to healthy controls (n=20), SS patients exhibited significantly higher serum levels of ASC (n=56; p=0.002), IL-1β (n=37; p=0.003) and IL-18 (n=33; p<0.0001). The serum levels of ASC protein were significantly higher in SS patients at high risk for lymphoma development (SS-type I; n=17) and in SS patients with lymphoma (n=28), compared to SS patients with low risk for lymphoma development (SS-type II; n=11, for p=0.030 and p=0.004, respectively). In SS patients, the serum levels of ASC and IL-18 correlated positively with the total cumulative ESSDAI score values (p=0.005 and p=0.006, respectively), whereas ASC levels correlated with the presence of C4 hypocomplementemia (p=0.002), rheumatoid factor (p=0.02) and purpura (p=0.02). In addition, compared to healthy controls (n=16), the PBMC of SS patients expressed significantly higher levels of ASC, NLRP3, IL-1β, IL-18 and pro-caspase-1 transcripts (n=39, p<0.05). The calculation of the NLRP3-inflammasome score in PBMC indicated an optimal discrimination between SS clinical subgroups (AUC=0.915) and positively correlated with interferon type I expression (Spearman r=0.443, p= 0.0006, n=37). In the SG tissues of SS patients, CD68+ macrophages and epithelial cells manifested high expression of ASC protein that was localized in perinuclear aggregates (specks), suggesting inflammasome activation. Co-localization experiments showed significantly increased ASC expression in CD68+ macrophages in SS (p<0.0001), compared with non-SS control patients.

Conclusion: Our findings indicate that SS patients manifest evidence of inflammasome activation in both peripheral blood and the SG tissues. Several indices of inflammasome activation correlated with the presence of severe disease, as well as lymphoma development and may constitute valuable clinical biomarkers for these patients.

Session Title: Sjögren's Syndrome I: Clinical Insights

Session Type: ACR Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: Primary SjšgrenÕs Syndrome (pSS) is a chronic autoimmune rheumatic disease causing a wide-range of symptoms including dryness, pain and fatigue. Individual patient experiences of pSS vary resulting in a heterogeneous patient population. We use patient reported symptoms to identify distinct clinical pSS phenotypes and use these to explore underlying biological differences.

Methods: We used Patient Reported Outcome Measures (PROMs) to clinically phenotype 594 patients on the United Kingdom Primary SjšgrenÕs Syndrome Registry. Phenotype patterns were identified using hierarchical cluster analysis of patient reported rating scales for pain, fatigue, dryness, anxiety and depression. Non-parametric analysis of variance was used to evaluate biological differences between these clusters. We then used the same PROMs to phenotype 463 pSS patients from Norwegian and French cohorts, in order to validate these four phenotypes independently.

Results: We identified four phenotypic clusters, which we refer to as Low Symptom Burden (LSB), High Symptom Burden (HSB), Dryness Dominant (DD) and Low Anxiety and Depression (LAD) – with marked differences in health status and quality of life (TTO p <0á0001, EQ-5D VAS p <0á0001). Furthermore, there were significant differences on clinical measures of disease activity (ESSDAI p=0á039), and objective dryness measures (salivary flow p=0á007, SchirmerÕs p=0á014). In addition, there were marked differences in biological parameters (IgG p<0á0001, lymphocytes p=0á0005, ESR p=0á003, IL-17 p=0á0174 and TNFα p=0á0133) between clusters, suggesting possible distinct underlying endotypes. Significant biological and clinical differences in IgG, Lymphocytes, ESR, ESSDAI, and Salivary Flow remained across the four phenotypes in our validation cohorts.

Conclusion: We have identified and independently validated four distinct pSS clinical phenotypes with associated biological

differences. There are marked differences in the potential health gains for these four clusters with important implications for clinical management, trial design and therapeutic development for pSS.

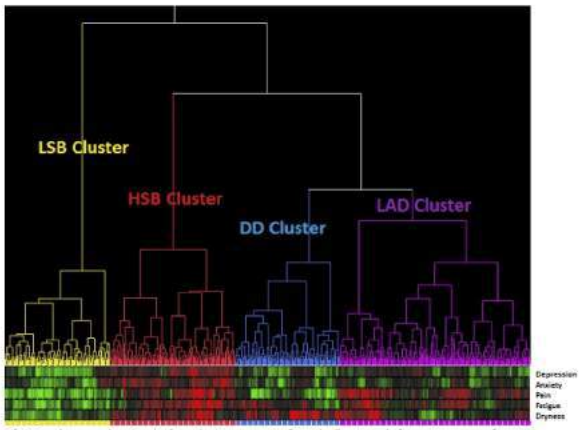

Fig1: Dendrogram showing the four clusters emerging from the 'heat map' of symptom scores for pain, fatigue, dryness, anxiety and depression below. Green is a low score, while black is middling and red is high.

Table 1: Clinical and biological differences across phenotypes. Median values in bold, 25th and 75th centile below, with UKPSSR cohort in white and the two validation cohorts shaded in grey.

Session Title: Sjögren's Syndrome I: Clinical Insights

Session Type: ACR Concurrent Abstract Session
Session Time: 2:30PM-4:00PM

Background/Purpose: Very limited data is available regarding predictors of systemic disease activity in primary Sjögren's syndrome. The ESSDAI, the international systemic disease activity score of the disease, is mainly used in clinical trials, as an inclusion criteria and primary end point. The ESSDAI takes into account some routine laboratory parameters included in the haemotological (disease-related anemia, lymphopenia, neutropenia and thrombocytopenia) and biological domain (IgG levels, monoclonal component, cryoglobulinemia, complement levels). We therefore investigated whether abnormalities of either the haematological or the biological domain could predict the evolution of systemic disease activity.

Methods: The ASsessment of Systemic complications and Evolution in primary Sjögren's Syndrome (ASSESS) cohort is a prospective ongoing cohort of 395 patients. All patients have a medical examination every year by a trained physician, who notably collects the ESSDAI (Eular Sjögren's Syndrome Disease Activity Index), which scores systemic disease activity and clinical ESSDAI (clin ESSDAI), which scores systemic disease activity without the biological domain of the ESSDAI.

Results: At enrollment, 1, 2, 3 and 4 years of follow-up, 55%, 44.3%, 48.1%, 46.9%, and 46.5% had at least one biological abnormality (i.e. a positive biological domain of the ESSDAI), respectively. The mean (SEM) ESSDAI 1 year after: at 1, 2, 3, 4 and 5 years of follow-up were 5.0 (0.4), 5.3 (0.4), 6.2 (0.5), 5.6 (0.5), and 5.4 (0.5), respectively, compared to 3.9 (0.4), 3.7 (0.3), 3.7 (0.4), 3.5 (0.4), and 3.4 (0.3), in patients with no biological abnormality, respectively. Overall, mean (SEM) ESSDAI the year after, in patients with at one least biological abnormality the year before ESSDAI assessment, was 5.5 (0.2) compared to 3.6 (0.2) in patients with no biological abnormality ($p< 0.0001$). Significant associations were also observed between biological abnormalities and clinESSDAI the year after (clinESSDAI of 4.7 (0.2) with a positive biological domain the year before and 3.9 (0.2 without, $p= 0.007$) as well as between hypergammaglobulinemia, a frequent abnormal parameter in the biological domain, and ESSDAI and clinESSDAI the year after (5.8 (0.3) and 4.8 (0.3) versus 4.1(0.1) and 4.0 (0.1) in patients without hypergammaglobulinemia, $p<0.0001$ and $p= 0.002$, respectively). At enrollment, 1, 2, 3 and 4 years of follow-up, 26.7%, 25.3%, 24.2%, 25.7%, and 24.1% had at least haematological abnormality (i.e a positive haematological domain of the ESSDAI), respectively. The mean (SEM) ESSDAI 1 year after: at 1, 2, 3, 4 and 5 years of follow-up were 5.6 (0.6), 5.9 (0.6), 7.0 (0.7), 6.6 (0.9), and 6.5 (0.7), respectively, compared to 4.1 (0.3), 3.8 (0.3), 4.0 (0.3), 3.7 (0.4), and 3.6 (0.3), in patients with no haematological abnormality, respectively. Overall, mean (SEM) ESSDAI the year after in patients with at one least haematological abnormality the year before ESSDAI assessment, was 5.7 (0.3) compared to 3.7 (0.1) in patients with no haematological abnormality ($p< 0.0001$). Significant associations were also observed between haematological abnormalities and clinESSDAI the year after (5.7 (0.3) versus 3.7 (0.1) in patients with no haematological abnormality, $p< 0.0001$) and between lymphopenia, a frequent abnormal parameter in the haematological domain, and ESSDAI and clinESSDAI the year after (6.5 (0.3) and 5.9 (0.4) vs 3.9 (0.1) and 3.8 (0.1) in patients without lymphopenia, $p< 0.0001$ and $p< 0.0001$, respectively).

Conclusion: Abnormalities in the biological or haematological domain of the ESSDAI, prevalent in nearly one half or one fourth of patients, predict a significant increase in systemic disease score the year after. Therefore, in pSS, some routinely assessed parameters, such as serum IgG levels or lymphocyte blood count, can be considered, not only as part of this systemic disease activity score, but also as relevant biomarkers of future systemic disease activity in common practice.

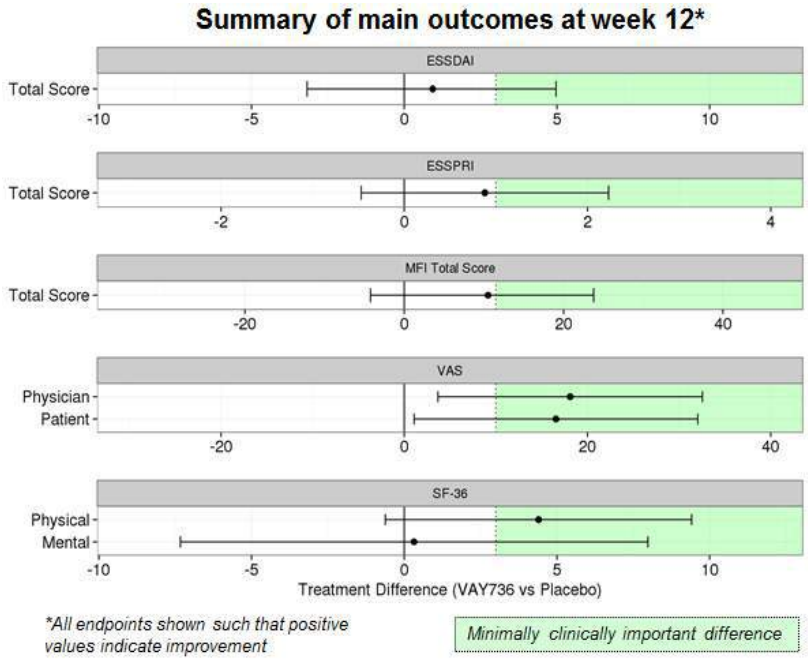
Session Title: Sjögren's Syndrome I: Clinical Insights
Session Type: ACR Concurrent Abstract Session
Session Time: 2:30PM-4:00PM

Safety and efficacy of single dose VAY736 (anti-BAFFR mAb) in patients with primary Sjögren's syndrome (pSS) T Dörner[1], M Posch[2], F. Wagner[2], A Hüser[2], T Fischer[1], L Mooney[3], O Petricoul[3], P Maguire[3], P Pal[3], J Doucet[3], M Cabanski[3], E Kamphausen[3], R Kazma[3], S Oliver[3] [1]Charité Hospital, Berlin; [2]Charité Research Organisation, Berlin; [3]Novartis Institutes for Biomedical Research, Basel

Background/Purpose: VAY736 is a novel, defucosylated, human IgG1 mAb targeting the receptor for B cell activating Factor of the TNF family (BAFF-R), providing both enhanced antibody-dependent cellular cytotoxicity-mediated depletion of B cells and blockade of BAFF:BAFF-R signaling that drives B cell differentiation, proliferation and survival. We evaluate here safety and efficacy of the dual mechanisms of action of VAY736 in patients with pSS, a highly BAFF-driven, systemic autoimmune disease involving lymphocytic infiltration and progressive dysfunction of exocrine glands along with various extra-glandular manifestations.

Methods: A single center, randomized, parallel group, double-blind, placebo-controlled trial recruited 27 seropositive pSS patients with EULAR Sjögren's Syndrome Disease Activity Index (ESSDAI) ≥6 over a 10-month period for treatment with intravenous VAY736 at either a single high dose, (n=12), a single lower dose (n=6), or with placebo (n=9). Outcomes were measured at baseline and at weeks (w)6, 12 and 24. The primary outcome was change in ESSDAI at w12. Secondary outcomes included the EULAR Sjögren's Syndrome Patient Reported Index (ESSPRI), Short Form-36 (SF-36), Multidimensional Fatigue Inventory (MFI), physician/patient global VAS assessments, salivary flow rate, Ocular Staining Score (OSS), high resolution salivary gland ultrasound (US) de Vita scores/perfusion and elastography, serum markers of B cell hyperactivity and flow cytometry-determined lymphocyte subsets.

Results: Analyses to w24 included all 27 patients. VAY736 was safe and well-tolerated with no drug-related SAE, drop outs or discontinuations. Mean age was 50.5 years with 4 males, 2 in placebo and 1 in each treated arm. Baseline mean ESSDAI scores (range) were 11.5 (6-18), 14.5 (6-31) and 11.1 (6-19) in the high dose, lower dose and placebo arms, respectively. Target engagement was confirmed by serum BAFF levels and rapid, profound depletion of circulating B cells in all VAY736-treated patients; up to 99% by 24h and remaining so to 12-24w and beyond. The primary endpoint of ESSDAI was reduced within 12w but did not reach clinical or statistical significance versus placebo. However, improvements for VAY736-treated subjects were seen across clinical secondary outcomes, particularly for patient and physician global assessments and SF-36 physical. Reductions in parotid gland stiffness by US suggest early signs of salivary gland improvement. B cell hyperactivity markers were also reduced in treated patients. There were no consistent changes in salivary flow rate or OSS.



Conclusion: Despite a limited, single infusion, VAY736 achieved in this early phase trial trends for improvement in the primary outcome and across all secondary outcomes. Thus, this treatment was safe and suggests a positive therapeutic effect for this dual mechanisms of action in pSS that warrant further evaluation.

Session Title: Sjögren's Syndrome I: Clinical Insights

Session Type: ACR Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: Interferon(IFN) signatures are upregulated in patients with primary Sjogren's syndrome (pSS) and interferons are considered to play a pathogenic role in pSS. Therefore, Janus kinase (JAK) which mediates interferon signaling pathway may be a good therapeutic target. We set out to investigate whether a selective JAK1 inhibitor, filgotinib would ameliorate disease-related parameters in non-obese diabetic (NOD) mice, an animal model SS.

Methods: Filgotinib (1.5mg/kg) or vehicle (saline) was intraperitoneally injected three times per week from 8 weeks after birth. Salivary flow rate (SFR) was addressed on 8, 12, 16 and 20 weeks. Histologic analysis was performed on 20 weeks. The effect of filgotinib on the expressions of B cell activating factor (BAFF), IFN signature genes and chemokines (CXCL10 [IP-10], CXCL3 [fractalkine], CCL-2 [MCP-1]) in human salivary gland epithelial cell (SGEC) line or primary epithelial cells of patients with pSS was determined *in vitro*.

Results: The SFR of NOD mice in both groups decreased over time. Of note, SFRs of filgotinib-treated mice were greater than those of controls. Histologic evaluation of the salivary gland revealed that the lymphocytic infiltration of salivary gland was markedly reduced in the mice treated with filgotinib. Filgotinib suppressed STAT1 phosphorylation in IFN-treated SGECs. In addition, IFN-induced BAFF and chemokine production of SGECs or primary epithelial cells were abrogated by filgotinib treatment.

Conclusion: Filgotinib suppresses SFR decrease and lymphocytic infiltration of salivary glands of NOD mice by inhibiting inhibiting IFN signaling pathway, thus suppressing BAFF and chemokine production of salivary gland epithelial cells. JAK inhibition may be a novel therapeutic approach for SS.

Session Title: Spondylarthropathies Psoriatic Arthritis – Pathogenesis, Etiology I

Session Type: ACR Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose:

Psoriatic arthritis (PsA) is an inflammatory joint disease that affects over 650,000 Americans. Bone damage occurs in half of these patients within the first 2 years of disease, which impacts the quality of life and function. Dysregulation of osteoclasts (OC), the only cells known to erode bone, is responsible for bone damage in PsA. Our study is centered on DC-STAMP, a transmembrane signaling protein essential for OC development. DC-STAMP-/- osteoclast precursors (OCP) fail to fuse and develop into mature OC with bone erosion activity. Although DC-STAMP is preferentially expressed by monocytes, intriguingly, we identified a unique DC-STAMP+ T cell subset in a small cohort of PsA patients but not in healthy controls. Given that Th17 and FoxP3(+) Treg T cell subsets are known to promote or suppress OC differentiation, respectively, we hypothesize that DC-STAMP+ T cells are a specialized T cell subset in PsA with Th17- or Treg-like properties.

Methods:

We analyzed the frequencies of DC-STAMP+ populations by 12-color cell lineage-specific flow cytometry, and determined OCP frequency by TRAP-based OC enumeration on 102 psoriasis (Ps), 41 PsA patients and 25 healthy controls (HC). The Spearman correlation analysis was performed to test the correlation between the frequencies of OCP and DC-STAMP+ T cells.

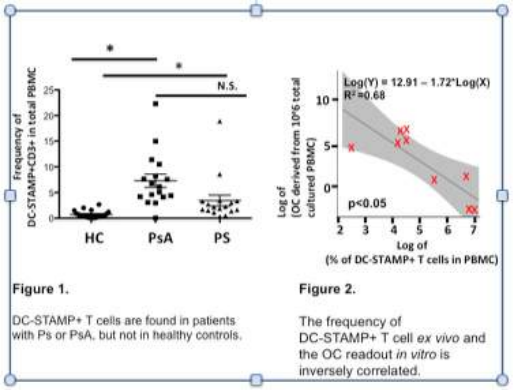

Figure 1.

DC-STAMP+ T cells are found in patients with Ps or PsA, but not in healthy controls.

Figure 2.

The frequency of DC-STAMP+ T cell *ex vivo* and the OC readout *in vitro* is inversely correlated.

Results:

Data from 143 patients (102 Ps & 41 PsA) and 25 HC demonstrated that DC-STAMP is primarily expressed by CD14+ monocytes in HC, whereas its expression on T cells was only observed in 22% of the Ps & PsA patient cohorts (21/67, 6/44 and 5/32 respectively in 3 separate clinical studies). DC-STAMP+ T cells were significantly elevated in Ps and PsA patients than HC (Figure 1). Flow cytometry analysis revealed that DC-STAMP+ T cells were CD3+CD4+CD8-CCR4-CCR6+ T cells, and 68% of circulating DC-STAMP+CD3+ T cells had detectable intracellular IL-4 expression *ex vivo*. An inverse correlation between the frequency of DC-STAMP+CD3+ T cells (*ex vivo*) and OC frequency (*in vitro*) (the correlation between OC and 1/ (T cell frequency) was 0.73, p=0.04) was confirmed by Spearman analysis (Figure 2).

Conclusion:

The presence of DC-STAMP+ T cells in Ps or PsA patients but not in HC suggests that this T cell subset is induced to proliferate in the inflammatory conditions of psoriatic disease. An inverse correlation between the *ex vivo* frequency of DC-STAMP+CD3+ T cells and *in vitro* OC generation together with detectable intracellular IL-4 expression *ex vivo* suggest that DC-STAMP+ T cells suppress OCP differentiation *in vitro* and *in vivo*. Modulating T cell activities toward OC-promoting Th17-like or OC-suppressive Treg-like properties remains an attractive option for the treatment of psoriatic disease.

IL-22 Is Dysregulated in Psoriatic Arthritis and Acts to Limit IFN-γ Driven Inflammatory Chemokine Production

Amara Ezeonyeji[1], Helen Baldwin[2], Milica Vukmanovic-Stejic[3] and Michael R. Ehrenstein[4], [1]Rheumatology, Medicine, University College London, London, United Kingdom, [2]Rheumatology, Centre for Rheumatology Research, University College London, london, United Kingdom, [3]Infection & Immunity, University College London, london, United Kingdom, [4]Medicine, University College London, London, United Kingdom

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016

Session Title: Spondylarthropathies Psoriatic Arthritis – Pathogenesis, Etiology I
Session Type: ACR Concurrent Abstract Session
Session Time: 2:30PM-4:00PM

Background/Purpose: IL-22 is an IL-10 family cytokine with both pro-inflammatory and anti-inflammatory effects and its dysregulation is associated with the development of autoimmune disease including psoriasis, rheumatoid arthritis and Crohn's disease. The purpose of this study was to characterize the role of IL-22 production from CD4 T cells in psoriatic arthritis (PsA).

Methods: Whole PBMCs from PsA patients and healthy controls (HCs) were stimulated with anti-CD3/CD28 (αCD3/28) and cultured for 3 or 5 days. CD4+ T cell populations were analysed for surface expression of CCR6, CXCR3, CCR4 and CCR10 and intracellular production of IL-22, IFN-γ and IL-17 measured by FACS. The percentage of IL-22+IL-17- cells within CD4+ T cells after 5 days culture were correlated with percentage naïve (CD27CD45RA+), central memory ($CD27^+$ $CD45RA^-$), and effector memory (CD27- CD45RA-). CD4 T cell subsets were isolated, and IL-22 and IFN-γ production from HCs and PsA patients measured by FACS and the concentration in the T cell supernatants quantified by ELISA. The effects of IL-22 and IFN-γ were investigated using the HaCaT keratinocyte cell line as a model of inflammation.

Results: In the peripheral blood of untreated PsA patients, there was an overall decrease in the percentage $IL\text{-}22^+CD4^+$ T-cells compared to HCs (p=0.0075). This was associated with a switch from an IL-22-producing central memory cells in HCs, towards effector memory cells capable of accumulating at sites of inflammation in PsA. Paradoxically, we found a significant increase in IL-22 (p=0.026) and IFN-γ (p=0.001) production by naïve T cells from patients with PsA upon stimulation associated with increased proliferation (p=0.01) compared to healthy controls. This aberrant control of IL-22 and IFN-γ in the naïve T cell subset was restored in adalimumab treated patients. $IL\text{-}22^+$CD4+ T-cells in HCs expressed CCR6 whereas there was a significant loss of CCR6 expression in CD4 T cells in untreated PsA patients (p=0.0027) but not adalimumab treated patients. Supernatants from anti-CD3/28+/-IL-21 stimulated naïve T cells from untreated PsA patients, but not patients treated with adalimumab, induced high levels of the T cell chemoattractant CXCL-9 in HaCaT cells compared to HCs (p=0.0079) in an IFN-γ dependent manner. Moreover, blockade of IL-22 in supernatants from anti-CD3/28 +IL-21 activated naïve T cells from untreated PsA patients enhanced the production of CXCL-9 from HaCaT cells (p=0.01), suggesting an ability of IL-22 to negatively regulate IFN-γ.

Conclusion: IL-22 and IFN-γ production is dysregulated in PsA. IL-22+ CD4+ T cells switch to an effector memory phenotype and show an altered migratory phenotype which may promote accumulation of these cells at sites of inflammation. Furthermore IL-22 can act to suppress pathogenic responses triggered by IFN-γ suggesting that IL-22 may play a protective role in PsA. Modulation of this axis may therefore be a potential target for therapy in in PsA.

SESSION INFORMATION
Session Date: Tuesday, November 15, 2016
Session Title: Spondylarthropathies Psoriatic Arthritis – Pathogenesis, Etiology I
Session Type: ACR Concurrent Abstract Session
Session Time: 2:30PM-4:00PM

Background/Purpose: SKG mice exhibit features of spondyloarthropathy (SpA) and inflammatory bowel disease (IBD). Their SpA-like phenotype is induced by a beta-glucan, curdlan, via the Dectin-1 pathway, residing upstream of TNFα, IL23 and IL17. In SpA, the mechanism for enthesial bone formation and ankylosis is not well understood. Currently, no treatment can reverse this

process, although recent evidence suggests that TNF inhibitors may prevent bone formation if initiated early. The goal of this study was to discover genes and pathways that lead to axial/enthesial inflammation and bone formation. SKG mice were chosen for this purpose as they were previously reported to develop axial bone formation within 12 weeks of curdlan injection.

Methods: Nine week old SKG or control BALB/c mice were injected intraperitoneally with curdlan. Histology and microCT were perfomed at various time points to evaluate axial bone formation. Laser capture microscopy was performed on formalin-fixed paraffin-embedded (FFPE) tissue sections. Samples were obtained from entheseal sites near tail vertebrae at early inflammation, 3 weeks after injection. These were compared with identical anatomical sites in non-arthritic BALB/c mice. RNA collected from these tissues was extracted using the Qiagen RNeasy FFPE kit. Gene expression was analyzed using Affymetrix mouse transcriptome assay 1.0 (MTA 1.0).

Results: SKG mice developed clinical inflammation scores similar to those reported in published studies, with findings of skin and eye inflammation, arthritis, enthesitis, colitis/ileitis and weight loss when compared to control mice. We found that inflammation at axial sites developed earliest at the base of the tail. Contrary to previous reports, we did not observe axial bone formation, but rather significant erosion of vertebral bodies, and laxity of tendons leading to tail base deformity, as late as 24 weeks post injection. Early axial inflammatory tissue captured via laser was found to express S100a8 and S100a9 at 23-fold and 35-fold higher, respectively, when compared to control. Upregulation of S100A8 protein was confirmed by immunohistochemistry. Pathway analysis demonstrated enrichment of bone related pathways including endochondral ossification, TGF-beta receptor signaling and the Wnt signaling pathway. S100A8/9 (or the heterodimer, calprotectin) are antimicrobial peptides (AMPs), secreted by activated phagocytes, that act as endogenous activators of TLR4, upstream of TNFα, to induce a proinflammatory response. Studies show that calprotectin serum levels are elevated in SpA, correlate with disease activity and decrease with TNF inhibition. Recently, it has been shown that Dectin-1 stimulation upregulates expression of S100A8. Our results suggest that S100a8/9 are highly upregulated, likely via Dectin-1 in axial sites, and may drive inflammation and axial erosion in SKG mice.

Conclusion: Our whole transcriptome analysis revealed that S100a8/9 are the most highly upregulated genes in inflamed axial sites in SKG mice. We hypothesize that these play a role in axial inflammation and bone erosion in SKG mice.

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016

Session Title: Spondylarthropathies Psoriatic Arthritis – Pathogenesis, Etiology I

Session Type: ACR Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: In an IL-23 overexpression animal model of spondyloarthropathy (SpA), primary entheseal disease is driven by innate like lymphocytes at peripheral and spinal enthesis with these cells being reported in the enthesis soft tissue-bone interface. We previously described that the normal human entheseal soft tissue (EST) also had a populations of innate lymphoid cells (ILCs) (Cuthbert *et al* ACR abstract 2015). However, in human SpA the earliest imaging changes may occur in peri-entheseal bone (PEB) with such bone changes, rather than soft tissue changes, being harbingers of eventual joint ankylosis. The purpose of this work was to define PEB ILCs, to examine ILC3 transcriptional profiles and test entheseal responsiveness to IL-23 stimulation in comparison to other ILC3 sources.

Methods: Human PEB and EST was harvested from normal spinous process in patients undergoing elective spinal orthopaedic procedures. Interspinous EST was dissected from PEB and enzymatically digested. Knee joint synovial fluid cells from active SpA were also collected as a comparator source of ILCs from an inflammatory environment. ILC3s were isolated for RNA analysis by FACS sorting using accepted phenotypic cell surface markers. For cytokine stimulation unsorted PEB digest was incubated for 48 hours in the presence of IL-1β and IL-23. In all cases TaqMan genes expression assays (Applied Biosystems) were used to measure transcripts of interest.

Results: Bone adjacent to interpinous process attachment sites contained ILCs including ILC3s ($6.1x10^{-3}$%). RORγt and IL-23R were significantly increased in PEB ILC3 isolates compared to unsorted mononuclear cells (p=0.032 and p=0.033 respectively). Expression of immunomodulatory transcripts IL-10 and TGFβ were comparable in ILC3s isolated from all tissues. STAT3 expression was elevated in ILC3s isolated from PEB (p=0.048) compared to both EST and synovial fluid ILC3s as was TNFα. IL-17A and IL-22 expression was not detected in EST but both were detected in PEB and synovial fluid ILC3s. IL-1β/IL-23 stimulation of PEB resulted in 47-fold induction of IL-17A, 43-fold induction of IL-17F and 51-fold induction of IL-22 transcript.

Conclusion: This is the first study to define the presence of type 3 ILCs in normal peri-entheseal bone. ILC3s from this location exhibit occasional IL17 gene transcripts which increased substantially following priming. This work adds to the emerging data on ILCs resident populations in the SpA associated target tissues.

Session Title: Spondylarthropathies Psoriatic Arthritis – Pathogenesis, Etiology I

Session Type: ACR Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: Secukinumab, a monocloncal antibody to IL-17A, suppresses signs and symptoms as well as inflammation in ankylosing spondylitis and psoriatic arthritis, and inhibits bone and cartilage destruction in psoriatic arthritis. As to new bone formation, a distinct form of structural damage in spondyloarthritis (SpA), a 2-years Secukinumab study in AS showed that mean progression of new bone formation was low (0.3 mSASSS points) and that 80% of patients did not show any progression at all (Baraliakos X. et al [abstract] Arthritis Rheum 2015; 67 suppl 10). As formal demonstration of an effect of anti-IL17A on new bone formation in human SpA requires long term data and the inclusion of an appropriate control group, we aimed to assess the potential impact of anti-IL17A on new bone formation in a validated animal model of SpA.

Methods: SpA-like arthritis and spondylitis was induced in HLA-B27/huβ2m tg rats (23-1x283-2) by immunization with low dose heat-inactivated *M. tuberculosis*/IFA. The animals were treated with 15 mg/kg anti-mouse/rat IL-17A antibody versus IgG2a isotype control weekly or, alternatively, with 10 mg/kg anti-TNF (Etanercept) versus PBS twice weekly in both prophylactic and therapeutic experiments for a period of 5 weeks. Arthritis and spondylitis were scored clinically and hind paw swelling was measured by plethysmometry. At the end of the study rats were sacrificed for skeletal analysis by micro-CT (low density bone volume as a measure for new bone formation) and histology.

Results: Prophylactic treatment with anti-IL-17A or anti-TNF showed a significant delay in arthritis and spondylitis when compared to their control groups. In addition, arthritis was significantly less severe in the anti-IL-17A or anti-TNF treatment groups as assessed by clinical scoring as well as by hind paw swelling. Therapeutic treatment with anti-IL-17A showed a significant reduction in arthritis score and hind paw swelling compared to the control group, spondylitis incidence remained stable after treatment. In contrast, treatment with anti-TNF in a therapeutic setting did not affect arthritis severity and spondylitis incidence continued to increase over time. Micro-CT analysis after therapeutic treatment revealed low density/newly formed bone present in both control groups. Treatment with anti-IL-17A significantly reduced levels of low density bone in the ankle joints, when compared to the IgG2a treated controls, and were even comparable to healthy age matched HLA-B27/huβ2m tg rats. In the axial joints new bone formation was present in 11 vertebrae from 5/9 control rats and 9 vertebrae from 3/9 anti-IL-17A treated rats. Coloring by bone density suggests less new bone formation in the anti-IL-17A treated group. In contrast, therapeutic treatment with anti-TNF did not affect new bone formation in both peripheral and axial joints.

Conclusion: These data show that, although the model is dependent on both IL-17A and TNF, only blockade of IL-17A affects clinical symptoms in a therapeutic setting. Strikingly, micro-CT analysis indicates that anti-IL-17A but not anti-TNF can halt pathological new bone formation in a therapeutic treatment setting.

Session Date: Tuesday, November 15, 2016

Session Title: Spondylarthropathies Psoriatic Arthritis – Pathogenesis, Etiology I

Session Type: ACR Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: Uncontrolled migration of Th17 cells into the skin and joints is a major driver in the pathogenesis of psoriatic arthritis (PsA). Modulation of T cell migration is thus an attractive option in order to reduce inflammation and restore immune tolerance. Th17 cells and regulatory T cells (Treg) both express CCR6, and migrate into the site of inflammation in response to CCL20. Importantly, maintenance of the correct Treg: effector T cell (Teff) ratio via appropriate control of cell migration is critical in the establishment of immune homeostasis. Dysregulation of Teff migration leads to their accumulation within inflamed tissue, and a resultant imbalance in the Treg: Teff ratio at the inflammatory site, thereby perpetuating disease. Here, we investigated the ability of Treg to modulate Th17 migration, in order to understand whether Treg can control Th17 migration in healthy individuals, and whether this axis in perturbed in PsA patients.

Methods: IL-17 production and association with CCR6 within $FoxP3^+$ and $FoxP3^-$ cells was measured in healthy and PsA peripheral blood mononuclear cells (PBMC) and synovial fluid (SF). Modulation of Th17 cell migration by Treg was investigated using a transwell model of CCR6-mediated migration towards CCL20. Sorted $CD4^+$Treg ($CD25^{high}CD127^{low}$) were mixed with Cell Trace Violet (CTV)-labelled Teff ($CD25^{low}CD127^{high}$). The number of CTV^+Teff migrated towards CCL20 in the presence or absence of Treg was enumerated by FACS using counting beads.

Results: $CD4^+IL\text{-}17^+$ cells were significantly increased in the peripheral blood (PB) (p=0.03*) and synovial fluid (SF) (p<0.0001***) of PsA untreated/DMARD patients compared to healthy controls and Adalimumab (Ada) treated PsA patients. We also observed an increase in IL-17 within $CD4^+$ $FoxP3^+$ synovial fluid Treg compared to HC PBMC (p=0.05*). Overall, the percentage of $FoxP3^+$ Treg in PsA untreated/DMARD PBMC was significantly reduced compared to HC PBMC (p=0.007**) and Adalimumab treated PsA patients (p=0.02*). We found a 3-fold increase in the percentage of $CCR6^+$ Teff ($FoxP3^-$) cells within PsA SF compared to paired PsA PBMC (p=0.0026**). There was a small (1.5 fold), but significant (p=0.02*) increase in $CCR6^+$ Treg ($FoxP3^+$) in PsA SF compared to paired PsA PBMC. Co-culture of healthy Treg with healthy Teff down-regulated CCR6-mediated migration towards CCL20 (p=0.03*) but PsA untreated/DMARD Treg enhanced CCR6 mediated migration of PsA untreated/DMARD Teff (p=0.02*). PsA Treg could down-modulate healthy CCR6 mediated Teff migration, whereas healthy Treg were unable to decrease migration of PsA Teff towards CCL20

Conclusion: These data reveal an accumulation of $CCR6^+$Th17 cells within the synovial fluid of PsA patients, potentially due to an enhancement of Th17 migration by Treg. In contrast, healthy Treg suppress Th17 migration towards CCL20. We hypothesise that paradoxically, Treg may drive Th17 migration into the skin and joints in PsA, leading to accumulation of Th17 cells at the site of inflammation and propagation of disease. Modulation of this axis may provide an attractive future therapeutic target for patients with PsA.

Session Date: Tuesday, November 15, 2016

Session Title: Vasculitis III: Pathogenic Mechanisms

Session Type: ACR Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: Advancing age is the strongest risk factor for GCA, a disease that exclusively affects individuals >50 years of age. The immune system undergoes dramatic restructuring with aging, but aging-related cellular and molecule defects that predispose to GCA have remained undefined. In general, immune aging is associated with the declining ability to generate antigen-specific immune responses and the increasing propensity for inflammatory activity. Here, we have examined whether patients with GCA lack anti-inflammatory regulatory mechanisms in the adaptive immune system, rendering them susceptible to unopposed inflammation and tissue damage.

Methods: Patients with biopsy-positive GCA and age-matched healthy controls were enrolled into the study. Immunosuppressive T regulatory cells (Treg) in the CD4 and CD8 compartment were quantified by phenotypic and functional analysis. Expression of the lineage-determining transcription factor FoxP3 and the immunosuppressive NADPH oxidase 2 (NOX2) was determined by flow cytometry. Immunosuppression was measured by monitoring the pool of phosphorylated signaling molecules (pZAP70) in stimulated target cells.

Results: Frequency of $CD4^+FoxP3^+$ Tregs was maintained in GCA patients compared to controls (p=0.207). To assess the

population of $CD8^+FoxP3^+$ Tregs, we defined the phenotype of such cells as $CD39^+$, $CD26^-$ and $CCR7^+$ and identified the oxidase NOX2 as their functional element. $CD8^+CCR7^+NOX2^+$ Tregs were distinctly low in patients with GCA ($p<0.001$). By comparing untreated and treated patients, we found that anti-inflammatory therapy did not restore this functional T cell subset ($p=0.591$). Comparative studies in patients with other inflammatory conditions (e.g. small vessel vasculitis, psoriatic arthritis) indicated that the defect was selective for GCA. Understanding the functional implications of CD8 Treg deficiency required definition of the molecular mechanism underlying their suppressive activity and their distribution in the immune system. CD8 Tregs were positioned in the T-cell zones of secondary lymphoid tissues and suppressed the activation of CD4 T cells by the targeted release of NOX2-containing microvesicles ($p<0.001$). Exosomes generated from CD8 Tregs were able to mediate the suppressive function and limited the activation of CD4 T cells ($p<0.001$). In healthy individuals, CD8 Tregs lost NOX2 expression with progressive age ($p<0.001$). This age-related loss of Treg function was markedly accelerated in GCA patients ($p<0.001$).

Conclusion: In humans, CD8 Treg cells function by packaging the enzyme NOX2 into microvesicles and transferring them onto neighboring CD4 T cells, to effectively suppress their clonal expansion. In healthy aging, $CD8^+NOX2^+$ Tregs decline with age. In patients with GCA, such $CD8^+NOX2^+$ Tregs are reduced to minimal frequencies. With the loss of $CD8^+NOX2^+$ Tregs, GCA patients lack an immunoinhibitory principal, exposing them to uncontrolled expansion of proinflammatory CD4 T cells. Recovering the function of $CD8^+NOX2^+$ Tregs in GCA may allow for reparative instead of immunocompromising therapy.

First publication: September 28, 2016

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016

Session Title: Vasculitis III: Pathogenic Mechanisms

Session Type: ACR Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: The vasculitic lesions in GCA are filled with differentiated effector T cells that sustain granuloma formation, vessel wall restructuring, neoangiogenesis and intimal hyperplasia. Persistent T cell effector functions are counterregulated by inhibitory immune receptors, such as programmed cell death-1 (PD-1), and $PD\text{-}1^+$ T cells have been identified as the mediators of immune exhaustion in chronic viral infection and anti-tumor immunity and are the target of novel immunotherapy to unleash tumor-destroying immune responses. Conversely, failure to upregulate PD-1 may perpetuate chronic immune reactivity and could contribute to the relentless inflammation in GCA

Methods: Patients with biopsy-positive GCA and age and sex-matched controls were enrolled. GCA-affected temporal artery tissues were examined for the expression of PD-1 on T cells. Dynamics of PD-1 expression following T cell activation were examined ex vivo in CD4 T cells from GCA patients and healthy controls. $PD\text{-}1^+$ and $PD\text{-}1^-$ CD4 T cells were sorted and examined for T cell effector functions (expression of the lineage-determining transcription factors RORγt, T-bet, GATA-3 and FoxP3, and intracellular cytokine stores).

Results: Frequencies of circulating $PD\text{-}1^+$ CD4 T cells were significantly reduced in GCA patients ($p<0.01$). No PD-1–expressing cells were identified in normal, noninflamed human arteries, but in GCA affected temporal arteries almost all tissue-infiltrating T cells were positive for PD-1. In inflamed arteries, PD-1 expression on tissue-residing T cells was predictive for the thickness of

the intimal layer ($p<0.05$) and correlated with the tissue expression of the proinflammatory cytokines IFN-γ ($p<0.05$) and IL-17 ($p<0.01$). Ex vivo, sustained PD-1 expression could be induced in CD4 T cells from GCA patients ($p<0.05$). PD-1^+ and PD-1^- CD4 T cells populations from healthy controls and GCA patients were sorted and compared for the expression of lineage-determining transcription factors, and the effector cytokines IFN-γ, IL-17 and IL-4. PD-1^+ $CD4^+$ T cells from GCA patients expressed higher levels of Th1 ($p<0.05$) and Th17 related genes ($p<0.01$).

Conclusion: In patients with GCA, T cells expressing the inhibitory immune receptor PD-1 are highly enriched in the vascular lesions. However, such PD-1^+ T cells are not exhausted and, to the opposite, display strong immune-stimulatory functions, including remodeling of the vascular wall. In GCA the immunoprotective effects from PD-1–mediated downregulation of chronic immunity are lost, depriving the patient of the beneficial effects of the PD-1–dependent immune checkpoint.

Session Title: Vasculitis III: Pathogenic Mechanisms
Session Type: ACR Concurrent Abstract Session
Session Time: 2:30PM-4:00PM

Background/Purpose: Behçet's disease is a chronic relapsing inflammatory disease characterized by recurrent mucocutaneous involvement. We performed dense genotyping in immune related loci in a large multi-ethnic cohort of Behçet's disease patients and controls to further characterize the genetic basis of this disease.

Methods: We studied 5 independent cohorts of Behçet's disease patients and controls consisting of 1253 patients and 5799 controls from Turkey, Italy, Spain, Japan, and Korea. Genotyping was performed using the Immunochip platform (Illumina), which includes ~200,000 genetic variants in immune-related genetic loci. Genetic association analysis in each cohort and a meta-analysis were performed to identify genetic susceptibility loci for Behçet's disease. Additional genetic variants were imputed up to the 1000 Genomes Project density. Conditional genetic analysis and functional mapping using epigenetic marks of enhancer regions and expression quantitative trait loci (eQTL) analyses were performed to further characterize the genetic effects identified.

Results: We identified and fine-mapped genetic associations for Behçet's disease with a GWAS level of significance in a lncRNA near *QSOX2* (OR= 1.82, P= 1.08E-8), *RASIP1*/*FUT2* (OR= 1.41, P= 3.57E-09), and *IL12A-AS1* (OR= 1.71, P= 4.19E-08). The genetic association within the *RASIP1*/*FUT2* locus is located within an active enhancer region as indicated by H3K27 acetylation marks. The disease risk variant in this locus is associated with mRNA expression changes of multiple transcripts within this locus, including significantly increased expression of *RASIP1* and decreased expression of *FUT2* in mucocutaneous tissues, frequently a target in Behçet's disease. The association in the *QSOX2* genetic locus can be localized to genetic variants within WI2-1959D15.1, which is a 1235bp lncRNA, and is associated with increased expression of this transcript. Several previously identified susceptibility loci for Behçet's disease were also replicated.

Conclusion: We performed dense genotyping in immune-related genes in a multi-ethnic cohort of Behçet's disease patients and controls, and identified a novel genetic susceptibility locus in a lncRNA near *QSOX2*, a genetic association with a functional genetic variant within an enhancer region in *RASIP1*/*FUT2*, and replicated the recently reported association in *IL12A-AS1*.

Session Title: Vasculitis III: Pathogenic Mechanisms
Session Type: ACR Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: Giant cell arteritis (GCA) is a vascular inflammatory disease involving large and medium sized arteries, particularly the cranial vessels. Inflammation-induced vascular remodeling leads to vascular occlusion and ischemic symptoms and complications including partial or complete visual loss and, in some cases, stroke or other symptoms of vascular insufficiency. Pathogenic mechanisms contributing to this process are incompletely understood although vascular smooth muscle cell (VSMC) acquisition of a myofibroblastic phenotype might be involved. Over-expression of endothelin-1 (ET-1) and its receptors ET_AR and ET_BR in GCA lesions as well as increased serum concentrations of ET-1 in patients with ischemic complications has been previously reported (Lozano E et al Ann Rheum Dis 2010). The most investigated function of ET-1 in VSMC is vascular tone regulation. In recent years, it has been shown that ET-1 may contribute to myofibroblast differentiation of fibroblasts, a crucial step in lung and skin fibrogenic diseases. Whether ET-1 has similar effects on VSMC contributing to vascular occlusion has not been investigated. The aim of this study is to investigate if ET-1 induces a migratory myofibroblastic phenotype in human temporal artery (TA) -derived VSMC which might contribute to vascular remodeling and ischemic complications.

Methods: *Ex vivo* culture of TAs into three-dimensional matrix, migration assays using primary cultures of TA-derived VSMC, co-culture of TA-derived VSMC with peripheral blood mononuclear cells. Immunofluorescence and confocal microscopy of TA, qRT-PCR, immunoassay and western-blot.

Results: In GCA lesions ET-1 was mainly produced by inflammatory cells whereas VSMC overexpressed ET-1 receptors which enhanced their ability to respond to ET-1. ET-1 promoted a spread morphology in cultured VSMC and stimulated their migration by inducing focal adhesion kinase (FAK) phosphorylation at Y397 permitting the association with p85 subunit of PI3Kinase which co-localized with FAK at the cell protrusions of migrating cells. Accordingly, inhibition of both FAK and PI3K abrogated ET-1 induced migration. Interestingly, ET-1 treatment of cultured non pathological TAs promoted the disorganization of the artery layers as a consequence of VSMC migration towards the intima layer. Consistently, blockade of ET_AR and ET_BR with BQ123 and BQ788 antagonists inhibited ET-1 induced VSMC migration and VSMC outgrowth from cultured GCA-arteries as well as reduced Y397FAK phosphorylation *in vitro* and *ex vivo*.

Conclusion: ET-1 may be involved in GCA vascular occlusion by promoting VSMC migration towards the intimal layer, a mechanism involving either ET_AR or ET_BR._Suported by SAF 2014/57708-R, PIE 13/00033 and FEDER.

Session Title: Vasculitis III: Pathogenic Mechanisms

Session Type: ACR Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: Mounting an inflammatory response requires immune cells to undergo major changes in metabolism. Mediators such as cytokines can specifically alter the metabolism of different immune cell populations, thereby influencing the inflammatory response. This study characterized global patterns of immunometabolic response in renal tissue from patients with ANCA-associated vasculitis (AAV).

Methods: The study population consisted of patients with AAV (granulomatosis with polyangiitis and microscopic polyangiitis) recruited from the European Renal cDNA Bank (ERCB) cohort (n=80), patients with nephrotic syndrome recruited from the ERCB (n=61), patients from a North American based cohort (n=126); and healthy living kidney donors (n=37). Kidney biopsies performed as routine clinical care were micro-dissected into glomerular and tubulointerstitial compartments. Whole genome gene-expression profiling across the two tissue compartments was conducted on Affymetrix microarray platforms. 104 genes representing the critical enzymes of glucose metabolism and 26 genes related to specific immune cell populations were selected for analysis. Differential gene expression was compared between patients with AAV and both living donors and patients with nephrotic syndrome. Correlation analyses were performed to study potential relationships between genes related to metabolic response and genes related to immune response. A false discovery rate (FDR) of <0.05 defined statistical significance.

Results: Every enzyme in the pentose phosphate pathway (e.g. G6PD) and key regulatory genes of glycolysis (e.g. enolases, hexokinases) were significantly upregulated in the glomerular and tubulointerstitial compartments from patients with AAV compared to controls and patients with nephrotic syndrome. Glucose transporter receptor expression significantly differed among patients with AAV and comparators. Genes related to the Krebs cycle, glutaminolysis, and fatty acid oxidation were significantly downregulated in kidney samples from patients with AAV. Several immune response genes were differentially upregulated in kidney biopsies from patients with AAV, most strikingly macrophage-related markers (e.g. CD14, CD68, CD163). Strong correlations ($r= 0.45\text{-}0.82$; $p<1.0E^{-07}$) were observed in the glomerular compartment between specific pentose phosphate pathway enzymes (G6PD, TKT), enzymes that regulate glycolysis (PKM, PFKFB3), and macrophage-related markers (CD14, CD68).

Conclusion: Distinct alterations in cellular metabolism are observed in the renal transcriptome from patients with ANCA-associated glomerulonephritis, reflective of metabolic reprogramming. Global patterns of gene expression suggest increased utilization of glucose and decreased oxidative phosphorylation in patients with AAV relative to comparators. The strong correlation between markers of glycolysis and macrophage-related markers suggest that altered immunometabolism may play a role in the pathophysiology of kidney disease in AAV. Modulation of glucose metabolism may offer a novel approach to treatment of AAV.

Session Title: Vasculitis III: Pathogenic Mechanisms

Session Type: ACR Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: Clinical trials in rare diseases typically test therapeutic efficacy in one disease defined by a particular clinical phenotype. Improved understanding of the molecular mechanisms of disease may identify shared pathways across different clinical diseases that could be leveraged to develop stratified approaches to treatment and enable novel disease classification strategies based upon molecular rather than clinical phenotyping. An unbiased analysis of kidney diseases suggests many rare kidney diseases share common molecular profiles (Martini et al., 2014). To expand on these findings, we explored shared transcriptional responses in patients with ANCA-associated vasculitis (AAV) and nephrotic syndrome (NS) to identify common targetable disease mechanisms.

Methods: Patients with various forms of NS (minimal change disease, focal segmental glomerulosclerosis and membranous nephropathy) were recruited from the NEPTUNE cohort (n=126) and the European Renal cDNA Bank (ERCB, n=61). Patients with AAV (granulomatosis with polyangiitis (GPA) and microscopic polyangiitis (MPA)) recruited from the ERCB cohort (n=80) and healthy living donors (n=37) were also studied. Patients with NS and AAV underwent standardized diagnostic kidney biopsies performed as routine clinical care. Biopsy material was micro-dissected into glomerular and tubulointerstitial compartments. Transcriptomic profiles across the two tissue compartments were generated on Affymetrix U133 and ST2.1 microarray platforms. Differential gene expression across the transcriptome was compared between patients with NS and AAV versus living donors, and shared transcriptional responses were assessed relative to living donors. Functional networks were interrogated for cross-cutting disease mechanisms, upstream regulators and potential therapeutic targets shared between both diseases.

Results: Overall, 5%-25% of expressed transcripts were differentially regulated compared to living donor in both NS and AAV in the glomerular and tubulointerstitial compartments (fold change ≥ 1.3, FDR<0.05). Findings were replicated and cross-validated across the different microarray platforms. There was significant overlap in shared directionality of change of differentially expressed genes between patients with AAV and NS in both tissue compartments (FDR<0.05). Functional analysis identified conserved, therapeutically targetable transcriptional networks in the glomeruli from patients with NS and AAV including activation of Tec kinase, IL-8 signaling, TNF, IFNG, TGFB1, and NFkappaB, while alpha catenin and retinoid-related signaling were suppressed. Transcripts causally downstream of TNF were used to develop a TNF pathway activity score across diseases, and increased TNF-related inflammatory signaling was observed in specific subsets of patients.

Conclusion: AAV and NS, two rare kidney diseases, share common intra-renal transcriptional profiles that can be readily mined to identify shared molecular targets. Shared molecular targets can be leveraged for drug development and repurposing efforts in these rare kidney diseases.

Session Title: ARHP V: Epidemiology and Public Health

Session Type: ARHP Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: Individuals with specific comorbid conditions have increased risk of having hip osteoarthritis (OA). Some of these conditions are also associated with increased risk of premature death. In this study, we explored diabetes (DM) and body mass index (BMI) as modifiers of the association between hip OA measures and all-cause death.

Methods: We analyzed data from the Johnston County Osteoarthritis Project to investigate the association between baseline radiographic hip OA (rOA) and all-cause death, stratified by DM and BMI. Analyses were carried out using baseline data from 2,381 individuals with hip radiographs, including men aged 45 or older and women over 50 who entered the cohort during the original study enrollment (1990-1997; n=1,817) and those with their baseline assessment during the cohort enrichment (2003-2004; n=564). Vital status was assessed using National Death Index records to capture date of death. Person-years of follow-up were accrued from baseline assessment to the date of death, loss to follow-up or December 31, 2014, whichever came first. Hip rOA was defined as a Kellgren-Lawrence (KL) grade of ≥2 in either hip at baseline clinical assessment. Symptomatic rOA (sxOA) is a subset of those with rOA who also had symptoms of pain in the same joint. We used multivariable Cox proportional hazards regression models to estimate hazard ratios and 95% confidence intervals for the risk of all-cause mortality. Interactions by BMI group (<25, 25-<30, ≥30) and self-reported DM (yes/no) at baseline were assessed at the p=0.1 level.

Results: At baseline, the mean age was 61.1 years; 55.9% were women, 31.5% African American, 33.3% did not complete high school, 23.8% were smokers. There were 12.0% with DM and 33.4% had a BMI≥30. Mean follow-up time was 14.2 (SD=5.7) years. Adjusted HRs for the association of hip rOA and sxOA with death were higher among individuals with DM at baseline (Table). We observed interactions on the multiplicative scale for hip rOA with a KL grade ≥2 (interaction p=0.015) where those with DM and hip OA were 45% more likely to die than those without hip OA, whereas we observed no association between hip rOA and death among those without DM. A similar association was observed among those with hip sxOA (interaction p=0.018). Further, among those with a BMI≥30, we observed a 50% increase in hazards for the association of hip sxOA on mortality, no association with BMI 25-<30 and reduced hazards for BMI<25 (interaction p<0.001).

Conclusion: The associations between hip OA measures and mortality were increased among those with DM and higher BMI at baseline. These associations were particularly strong among those with symptomatic disease and were independent of other comorbidities and sociodemographic measures. Our results suggest roles for DM and BMI in the link between hip OA and mortality, findings that merit further investigation into potential mechanisms and clinical attention.

Pain Severity As a Mediator of the Effect of Depressive Symptoms on Physical Performance in Knee Osteoarthritis

Alan Rathbun[1], Michelle Shardell[2], Michelle S. Yau[3], Mona Baumgarten[4], Elizabeth Stuart[5] and Marc Hochberg[6], [1]Epidemiology and Public Health, University of Maryland School of Medicine, Baltimore, MD, [2]Translational Gerontology Branch, National

Session Date: Tuesday, November 15, 2016

Session Title: ARHP V: Epidemiology and Public Health

Session Type: ARHP Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: Depression is a significant comorbidity of knee osteoarthritis (OA) that occurs in approximately 20% of OA patients. Depressive symptoms are associated with both subsequent increases in knee pain and decreases in physical performance. It is hypothesized that depression leads to exacerbations in pain severity which, in turn, results in a decreased ability to perform the activities of daily living. The study aim was to determine whether the effect of depressive symptoms on physical performance is mediated by pain severity in knee OA.

Methods: Eligible participants (N=1,487) were enrolled in the Osteoarthritis Initiative, a multi-center natural history study of persons with or at risk for knee OA, who had radiographic disease (Kellgren-Lawrence grade of 2 or 3) at study baseline (time *t*). Depressive symptoms were measured using the Center for Epidemiological Studies Depression (CES-D) scale at the first annual follow-up visit (time *t*+1). Knee pain severity was assessed using the Western Ontario and McMaster Universities Arthritis Index pain subscale at the second annual follow-up visit (time *t*+2). Physical performance was evaluated with timed 20-meter walking speed (meters per second (m/sec)) at the third annual follow-up visit (time *t*+3). Potential confounders of the exposure-outcome or mediator-outcome relationship were measured at time *t* or *t*+1 and included age, sex, race, marital status, health insurance, employment, smoking, alcohol consumption, history of knee injury, comorbidity, analgesic use, baseline knee pain, and baseline physical performance. Marginal structural models that use inverse probability weighting were used to estimate the total, indirect (mediated), and direct (unmediated) effect of depressive symptoms at time *t+1* mediated by knee pain severity at time *t*+2 on physical performance at time *t*+3 (**Figure 1**).

Results: Depressive symptoms were significantly associated with slower 20-meter gait speed. For each one-unit increase in CES-D score, a subjects' gait speed would be expected to decrease by -0.0039 m/sec (95% CI: -0.0065, -0.0013; P Value=0.004). Effect decomposition yielded statistically significant direct and indirect effects of -0.003 (95% CI: -0.0057, -0.0004; P Value=0.024) and -0.0009 (95% CI: -0.0013, -0.0004; P Value=<0.001), respectively, suggesting that approximately 25% (-0.009/-0.0039) of the effect of depressive symptoms on physical performance is mediated by knee pain.

Conclusion: Depressive symptoms in subjects with knee OA are associated with significantly worse physical function, and this adverse effect is mediated, in part, by knee pain. However, the larger direct effect of depressive symptoms on physical performance implies there are multiple mediators of this relationship. Given that depression negatively affects physical function, it may also result in greater structural disease progression in persons with knee OA.

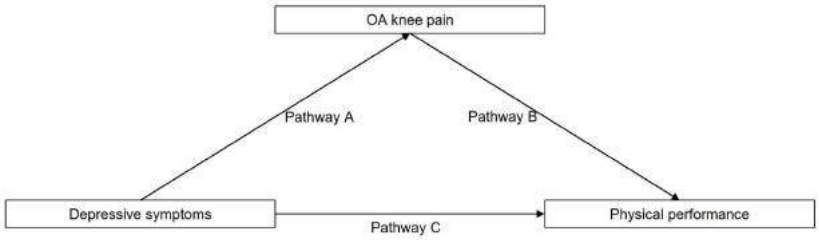

Figure 1. Model of mediation of the pathway between depressive symptoms and physical performance by OA knee pain. The C pathway shows the direct effect of depressive symptoms on physical performance. Pathways A and B show the indirect effects of depressive symptoms and OA knee pain on physical performance. The combined effects of pathways A, B, and C represent the total effect.

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016

Session Title: ARHP V: Epidemiology and Public Health

Session Type: ARHP Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: In the US, over 86 million adults have pre-diabetes; physical activity is recommended to reduce the high risk of developing diabetes. Arthritis is a common comorbid condition among persons with diabetes that is associated with reduced physical activity, presumably because of joint pain and swelling. Arthritis may have the same effect among adults with pre-diabetes, but population-based estimates of arthritis prevalence among adults with pre-diabetes are unknown.

Methods: We used the 2009-2014 National Health and Nutrition Examination Survey (NHANES) to estimate the prevalence of arthritis among adults with pre-diabetes, overall and by various sociodemographic characteristics, as well as those with diabetes or neither condition. NHANES is a nationally representative sample of the US non-institutionalized adult population with both interview and examination components. We limited our sample to adults aged ≥20 years with a fasting plasma glucose (fpg) measurement; unweighted sample sizes were 2,787 in 2009-2010; 2,471 in 2011-2012, and 2,574 in 2013-2014. Pre-diabetes was defined as glycated hemoglobin A1c (HbA1c) level of 5.7% to <6.5%, or a fasting plasma glucose (fpg) level of 100-125 mg/dL. Diabetes was defined as an HbA1c level of ≥ 6.5%, or fpg level of ≥ 126 mg/dL or a “yes” response to the questions “other than during pregnancy has a doctor or other health professional ever told you that have diabetes or sugar diabetes?” Arthritis was defined as a "yes" response to the questions "Has a doctor or other health professional ever told you that have arthritis?" For comparisons, estimates were age-standardized to the projected 2000 U.S. population; and pairwise comparisons were evaluated using a t-test with a Bonferroni-Holm correction for multiple comparisons.

Results: During 2009-2014, the prevalence (number) of adults with arthritis among those with pre-diabetes was 30% (27.9 million). The age-standardized prevalence of arthritis among adults with pre-diabetes (25.5%; 95% CI: 23.5-27.7%) was significantly (p-value=0.022) higher when compared with adults without diabetes (21.6%; 95% CI: 19.2-24.3%), but similar (p-value=0.182) to those with diabetes (28.6%; 95% CI: 24.8-32.7%) (Figure). Among adults with pre-diabetes, older adults (age ≥ 65 years), women, and those with <college degree had the highest age-standardized prevalence of arthritis.

Conclusion: Nearly 28 million adults in the US have pre-diabetes and arthritis, which may impact the physical activity recommended to prevent diabetes. Health care and public health professionals can address arthritis-specific barriers to physically activity among adults with pre-diabetes by promoting evidence-based physical activity, including programs such as EnhanceFitness and Walk with Ease, that reduce joint pain, which in turn may increase physical activity and reduce progression to diabetes.

Session Date: Tuesday, November 15, 2016

Session Title: ARHP V: Epidemiology and Public Health

Session Type: ARHP Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: There is little information regarding maternal post-partum complications in women with inflammatory arthritis conditions and none on persons with juvenile arthritis. Our objective was to evaluate the frequency of post-partum complications including depression in new mothers who had juvenile arthritis and to assess whether these differ from mothers who never had juvenile arthritis.

Methods: Our cohort study used data from physician billing and hospitalizations covering Québec, Canada. We identified all females with juvenile arthritis with a first-time birth between 01/01/1983 and 12/31/2010, and assembled a control cohort of first-time mothers without juvenile arthritis from the same administrative data source, matching 4:1 for date of first birth, maternal age and area of residence. Using a combination of physician billing codes and hospital codes and procedures, we compared the following post-partum complications: major puerperal infection, thromboembolic events, anaesthetic complications, post-partum haemorrhage, obstetrical trauma, complications of obstetrical surgical wounds, and depression in the first year following delivery, in the juvenile arthritis versus non-juvenile arthritis groups, using univariate and multivariate logistic regression analyses (adjusting for maternal age, education, caesarean delivery, hypertension, diabetes, birthweight, and adverse birth outcome).

Results: Mean age at delivery was 24.7 years in the juvenile arthritis group (n=1681) and 25.0 for the non-juvenile arthritis group

(n=6724). Mothers with juvenile arthritis were more likely to be diagnosed with depression in the first year post-partum (29.8% vs 6.7%, p<0.0001), and more had post-partum hemorrhage (10.0% vs 6.1%, p<0.0001) compared to the matched group of non-juvenile arthritis mothers. On the other hand those with juvenile arthritis had fewer major puerperal infections (1.6% vs. 2.5%, p=0.03) and less obstetrical trauma (4.3% vs. 7.2%, p<00001). In multivariate analyses, mothers with juvenile arthritis were more likely to experience depression in the first year post-partum (adjusted Risk Ratio (aRR): 4.25 95% Confidence Interval (CI) 3.78,4.77) and post-partum hemorrhage (aRR: 1.65, 95% CI 1.39,1.96). Mothers with juvenile arthritis were less likely to have a thromboembolic event (aRR 0.79, 95% CI 0.65,0.96) or obstetrical trauma (aRR 0.60, 95% CI 0.47,0.77) compared to mothers without juvenile arthritis.

Conclusion: Mothers with a history of juvenile arthritis were more likely to be diagnosed with depression in the first year post-partum and with post-partum hemorrhage. Possible explanations for the greater tendency towards depression might be higher pre-existing depression in juvenile arthritis or more frequent post-partum follow-up by physicians. Further research on these factors, and others (such as co-morbidity and medications) is warranted.

Is Frailty a Relevant Concept in Systemic Lupus Erythematosus (SLE)?

Patricia P. Katz[1], James Andrews[2], Edward H. Yelin[1] and Jinoos Yazdany[1], [1]Medicine/Rheumatology, University of California, San Francisco, San Francisco, CA, [2]Rheumatology, University of Washington, Seattle, WA

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016

Session Title: ARHP V: Epidemiology and Public Health

Session Type: ARHP Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: Frailty, a syndrome of weight loss, weakness, slowness, exhaustion, and inactivity, has been examined primarily in geriatric cohorts and is associated with poor health outcomes, including mortality. Components of the frailty syndrome are relevant to SLE, but frailty has not been examined in SLE.

Methods: In an in-person research visit (2008-2009), frailty components defined by Fried[1] were assessed: unintentional weight loss, slow gait (based on 4-meter walk using sex and height criteria), weakness (grip strength, gender and BMI criteria), exhaustion (2 specific questions), and inactivity (physical activity questionnaire). Accumulation of 3+ deficits classifies an individual as "frail," one or two deficits as "pre-frail," and none as "robust." Outcomes examined were physical function, cognitive function, and mortality. Physical function was measured with the SF-36 Physical Functioning subscale (score range 0-100) and the Valued Life Activities (VLA) disability scale (range 0-3). Cognitive functioning was measured with a 12-test battery. Scores on each test below -1.0 SD of age-adjusted population norms were considered "impaired." Subjects were classified as cognitively impaired if they were impaired on ≥1/3 of indices completed. Mortality was determined as of December 2015. Differences in function and two-year changes in function were examined using multiple regression analyses controlling for age, SLE duration, race/ethnicity, glucocorticoid use, obesity, self-reported SLE activity and damage, and, for longitudinal analyses, baseline function. Analyses include women (n=138).

Results: Mean age was 48 (±12) years, mean SLE duration 16 (±9) years. 65% were white, non-Hispanic. 24% of the sample was classified as frail, and 48% as pre-frail (Table 1). Frail women had significantly worse physical function than robust and pre-frail women and were more likely to have cognitive impairment (Table 2). Frail women were also more likely to experience declines in function and onset of cognitive impairment. Mortality rates were significantly higher in the frail group (frail 16.7%; pre-frail 4.1%; robust 2.3%). Odds (95% CI) of death for frail women were elevated, even after adjusting for age, SLE duration, and baseline disease damage (5.1 [0.5, 51.3]).

Conclusion: Prevalence of frailty in this sample of women with lupus was more than double the prevalence in older adults. Frailty was associated with poor physical and cognitive function, functional declines, and mortality. [1] Fried J et al. *Gerontol A Med Sci* 2001; 56A:M146-M156

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016

Session Title: ARHP V: Epidemiology and Public Health

Session Type: ARHP Concurrent Abstract Session

Session Time: 2:30PM-4:00PM

Background/Purpose: Information on causes of death can assist in monitoring health trends and discovering health gaps. Our aim was to determine the primary causes of death among RA patients and to ascertain whether there are patterns in causes of death that differ from the general population.

Methods: We performed a population-based study using Ontario health administrative databases from 2000 to 2013. We identified an inception cohort of 28,322 RA patients (aged 66 years or older) using a validated algorithm (requiring 3 diagnostic codes over a 2 year period, with at least one provided by a specialist). To each RA patient we matched four non-RA general population comparators according to age, sex and region of residence. RA patients and comparators were followed for 142,534 and 502,823 person years, respectively. Vital statistics were used to identify the date and primary cause of death, which we tabulated according to International Classification of Disease Chapter. All-cause, cause-specific, and excess mortality rates were estimated.

Results: During a median follow-up of 4 years, 8,812 (31%) RA patients and 27,139 (24%) comparators died, with corresponding mortality rates of 61.8 (95%CI 60.6-63.1) and 54.0 (95%CI 53.3-54.6), per 1,000 person years, respectively (Table). Mortality rates were highest among males in both groups. The leading causes of death were similar in both groups, with circulatory system diseases, cancer, and respiratory diseases being the most frequent causes of death. Excess mortality rates in RA were observed for circulatory, respiratory, musculoskeletal, and digestive diseases, as well as infections.

Conclusion: Our findings corroborate previous studies illustrating that circulatory system diseases, cancer, and respiratory diseases (including pneumonia) remain the leading causes of mortality in RA. While we observed similar patterns of the leading primary causes of death in RA and comparators from the general population, the excess cause-specific mortality in RA warrants further investigation in order to identify modifiable factors in reducing inequalities in survival.

Cartilage Loss Primarily Occurs in the Most Affected Tibiofemoral Compartment with No Evidence of a Ceiling Effect Among Advanced-Stage Disease: A Two-Year Longitudinal Study of Data from the Osteoarthritis

Ming Zhang[1], Lori Lyn Price[2], Amanda R. Canavatchel[1], Jeffrey B. Driban[3], Puwei Yuan[4], Grace H. Lo[5] and Timothy E. McAlindon[6], [1]Tufts Medical Center, Boston, MA, [2]Clinical Care Research, Tufts Medical Center, Boston, MA, [3]Rheumatology, Tufts Medical Center, Boston, MA, [4]the Fourth OA Department, Shaanxi University of Chinese Medicine, Xian Yang, China, [5]Immunology, Allergy, Rheumatology, Baylor College of Medicine, Houston, TX, [6]Division of Rheumatology, Tufts Medical Center, Boston, MA

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016

Session Title: ACR/ARHP Combined Abstract Session: Orthopedics and Rehabilitation

Session Type: ACR Concurrent Abstract Session

Session Time: 4:30PM-6:00PM

Background/Purpose: Cartilage morphometry on magnetic resonance images (MRIs) is an important outcome measure for clinical trials among individuals with knee osteoarthritis (KOA). However, it remains unclear if investigators should measure both the affected (index) and less affected tibiofemoral compartments. If the less affected compartment shows little change over time then investigators may focus solely on the index compartment and reduce the burden involved with measuring both tibiofemoral compartments. Hence, we calculated the sensitivity to change of cartilage loss in the medial and lateral tibiofemoral compartments among knees selected to represent the full range of medial and lateral tibiofemoral KOA.

Methods: We selected 100 knees with baseline and 24-month MRIs stratified by medial joint space narrowing (mJSN, 25 knees in

each mJSN grade, 90 knees lateral JSN = 0) and 100 knees stratified by lateral joint space narrowing (lJSN, 25 knees in each lJSN grade, 94 knees medial JSN = 0) from the Osteoarthritis Initiative (OAI). One reader (MZ) used a customized software to measure the tibiofemoral cartilage damage index (CDI) on both the medial and lateral compartments of all 200 knees. The tibiofemoral CDI, which is a parsimonious articular cartilage assessment that focuses on areas where cartilage defects often develop, is based on 36 informative locations within medial and lateral tibiofemoral compartments (Figure 1, yellow stars) and adjusted by height. We calculated the mean percent of CDI change (MC %, the mean two-year change of CDI divided by the mean baseline CDI) for medial, lateral, and total (medial + lateral) tibiofemoral.

Results : Four knees (2 in mJSN and 2 in lJSN) were excluded because of image quality. The MC % value of medial CDI in the medial disease cohort are 5 to 17 times greater than MC % value of lateral CDI (table 1). The MC % value of lateral CDI in the lateral disease cohort are 4 to 15 times greater than MC % of medial CDI (Table 1). Even among knees with advance-stage disease (JSN=3) there was 29% and 19% cartilage loss in the index tibiofemoral compartment (medial and lateral, respectively), which was 5 and 15 times the change in cartilage within the other compartment.

Conclusion: The majority of the cartilage loss happens in the index compartment of the knee. We believe investigators could focus on cartilage loss in the index compartment, which would reduce the burden of measuring articular cartilage loss. Furthermore, adults with advance-stage disease should not be excluded from trials based on a fear that they will not progress during a 2-year period.

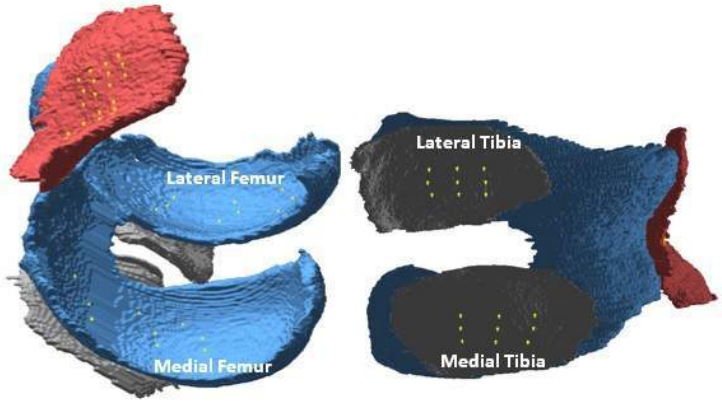

Figure 1. 3D femur and tibia cartilage images informative locations (yellow stars)
3D animation is available at http://canhelp2007.blogspot.com/

Table 1. The cartilage loss happens mostly at the index compartment

98 knees selected based on medial joint space narrowing (mJSN)

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016
Session Title: ACR/ARHP Combined Abstract Session: Orthopedics and Rehabilitation
Session Type: ACR Concurrent Abstract Session
Session Time: 4:30PM-6:00PM

Background/Purpose: Obesity is a common risk factor for knee osteoarthritis (KOA). While it is intuitive that bariatric weight loss improves knee pain, it is not clear how much is due to decreased mechanical load vs metabolic changes.

Methods: Patients were screened for knee pain prior to sleeve gastrectomy, gastric bypass, or laparoscopic gastric banding. We required pain for ≥15 days/month and VAS pain ≥ 30, excluding lupus, inflammatory arthritis, crystal disease, psoriasis, and bilateral knee replacement. Enrolled patients took standing knee xrays for Kellgren-Lawrence (KL) grading. We measured BMI and used the Knee Injury and Osteoarthritis Outcome Score (KOOS) questionnaire at baseline and 1, 3, 6 and 12 months, calculating % excess weight loss (%EWL) and ΔKOOS. We collected blood at baseline and followup to study biomarkers for predicting KOOS scores.

Results: Of 536 patients considering bariatric surgery, we found 308 with knee pain and enrolled 176 (91.5% female; BMI 43.6 kg/m^2±7, 32-61; age 42 ±11, 18-73) well distributed in xray severity (KL0-4). For the 150 patients who had surgery, knee improvement paralleled weight loss at the followups. At 1 year, %EWL correlated well with ΔKOOS pain (R = .262, n = 114, p = 0.005), similar to other intervals and to other KOOS measures. The sleeve and bypass (n=72 and 27) vs banding (n=15) resulted in higher ΔKOOS pain at 1 year: 32.9 ±21.3 and 30.7 ±22.6 vs 10.2 ±21.4, p=0.001. Sleeve and bypass patients also achieved a higher % of their potential ΔKOOS pain improvement than did banding (65.2% and 60.1% vs 16.8% of remaining KOOS points to 100), and a higher % of patients improved to any degree (93.1% and 88.9% vs 66.7%). Radiographic severity did not predict ΔKOOS at 1 year, nor did the presence of key comorbidities. Patients lost weight in a near-linear fashion through 1 year (Fig. 1), but their KOOS improvements plateaued at 1 month. This held true in sleeve and bypass subgroups (with altered anatomy), while banding showed less consistent ΔKOOS despite a similar trend in %EWL. Baseline leptin levels in obese KOA were higher than non-obese KOA and non-obese/non-OA controls from other cohorts (100.2 ±61.9 vs 26.2 ±16.7 and 15.4±13.8, p<0.001). Similarly, IL-1Ra, a potential marker of OA progression, was much higher than non-obese KOA or controls (1123±940 vs 324.0±145.6 and 272±130.0, p<0.001). Within obese KOA, higher leptin levels predicted worse xrays (KL0/1 vs KL2/3/4, p = 0.037). After 1 year, mean leptin and IL1-Ra from obese KOA patients had decreased (p<0.001).

Conclusion: Bariatric surgery improves knee OA symptoms proportionally to %EWL. Most relief occurs during the 1st month before much weight loss, suggesting a metabolic impact beyond mechanical load reduction on joints – at least with the sleeve and bypass that alter digestive anatomy. Leptin and IL-1Ra serum levels are elevated in obese KOA vs non-obese KOA and controls - and fall after bariatric surgery which could contribute to knee pain relief.

SESSION INFORMATION
Session Date: Tuesday, November 15, 2016
Session Title: ACR/ARHP Combined Abstract Session: Orthopedics and Rehabilitation
Session Type: ACR Concurrent Abstract Session
Session Time: 4:30PM-6:00PM

Background/Purpose: The first metatarsophalangeal joint (1MTPJ) is frequently affected in gout. This study aimed to identity ultrasound features of the 1MTPJ in people with gout and people with asymptomatic hyperuricaemia compared with normouricaemic controls.

Methods: Participants with gout (n=23), asymptomatic hyperuricaemia (n=29) and age- and sex-matched normouricaemic control participants (n=34) underwent a grey-scale and power Doppler ultrasound assessment of both 1MTPJs using a Phillips iU22 ultrasound machine with a 10 MHz, 55mm linear array transducer. No participants had clinical evidence of gout flare at the time of scanning. The images were assessed by two blinded independent radiologists for the presence of the double contour sign, tophus, erosion, effusion, synovial hypertrophy, and synovitis. Cartilage thickness and tophus diameter were also measured. Inter-reader reliability was assessed using Cohen's kappa (k) and intra-class correlation coefficients (ICC). Binary logistic and linear regression models were used to determine between-group differences in the ultrasound features. A stepwise linear regression was used to determine which ultrasound features were independently associated with gout compared with asymptomatic hyperuricaemia.

Results: Inter-reader reliability was moderate for the presence of the double contour sign, tophus, erosion, synovial hypertrophy and effusion (k=0.42 to 0.59), good for synovitis (k=0.66) and excellent for cartilage thickness and tophus diameter (ICC=0.81 and 0.86 respectively). Compared to normouricaemic control participants, participants with gout and with asymptomatic hyperuricaemia had more frequent double contour sign (Table, odds ratio (OR) 3.91, *P*=0.011 and OR 3.81, *P*=0.009, respectively). Participants

with gout also had more erosion (OR 10.13, P=0.001) and synovitis (OR 9.00, P<0.001) and had greater tophus diameter (0.00mm vs. 1.68mm, P=0.035). There was no significant difference in cartilage thickness between groups. More severe erosion and synovitis grades and a less severe effusion grade were independently associated with a diagnosis of gout compared with asymptomatic hyperuricaemia (R^2 for model = 0.65, $p < 0.001$).

Conclusion: Urate deposition, synovitis and bone erosion are common at the 1MTPJ in people with gout, even in the absence of flare. Furthermore, although individuals with asymptomatic hyperuricemia lack ultrasound features of inflammation or structural joint changes, they demonstrate a similar frequency of urate deposition. These data support the concept that gout is a disease of chronic inflammation in response to intra-articular urate crystal deposition.

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016
Session Title: ACR/ARHP Combined Abstract Session: Orthopedics and Rehabilitation
Session Type: ACR Concurrent Abstract Session
Session Time: 4:30PM-6:00PM

Background/Purpose: Rheumatic and musculoskeletal conditions are leading causes of work disability. A previous trial showed a preventive work disability intervention delivered by vocational rehabilitation counselors (VRCs) reduced job loss among people with arthritis; however, VRC services are not readily available to most people with arthritis. Occupational therapists (OTs) and physical therapists (PTs) could implement a similar intervention, yet this has not been evaluated. The aim of this study was to examine the efficacy of a structured work disability prevention program delivered by OTs and PTs on work limitations and unemployment over two years.

Methods: This single-blind, parallel-arm randomized trial enrolled participants age 21-65 who were employed 15 or more hours/week, and reported a doctor-diagnosed rheumatic or musculoskeletal condition and a concern about staying employed due to their health. The intervention consisted of a 1.5 hour meeting, a written action plan, written materials on disability-related employment issues and supports, and telephone calls at 3-weeks and 3-months by trained OTs or PTs. Control group participants received the written materials but had no contact with the interventionists. The primary outcome was work limitations, measured with the Output Job Demand subscale of the Work Limitations Questionnaire (WLQ). The secondary outcome was unemployment: i) permanent and ii) both temporary and permanent. Intent to treat analyses were performed. For the primary analysis, a two-sample t-test was used to assess the effect of the intervention on the 24-month change in the WLQ subscale. As the secondary analysis, we evaluated the intervention effect on time to permanent unemployment using the Kaplan-Meier procedure and the log-rank test. The same approach was also used to evaluate the time to the first job loss (temporary or permanent). ClinicalTrials.gov NCT01387100.

Results: Between October 2011 and January 2014, 652 individuals were assessed for eligibility and 287 participants were randomized: 143 intervention and 144 control participants. 264 participants (92%) completed two year data collection. There was no difference in the mean WLQ change scores from baseline to two year follow-up (-8.6 ± 1.92 intervention vs. -8.33 ± 2.22 control (p=.93)); however, there was an effect on unemployment: 11 (8%) participants experienced permanent job loss at 2-years in the intervention arm and 25 (18%) in the control arm (p=.03) (Figure 1a). 47 (35%) intervention participants and 65 (46%) control participants experienced any unemployment during the follow up period (HR: 0.70 (0.48, 1.01), p = 0.06) (Figure 1b).

Conclusion: The intervention did not have an effect on work limitations but did reduce work cessation.

SESSION INFORMATION
Session Date: Tuesday, November 15, 2016
Session Title: ACR/ARHP Combined Abstract Session: Orthopedics and Rehabilitation
Session Type: ACR Concurrent Abstract Session
Session Time: 4:30PM-6:00PM

Background/Purpose: Regular physical activity (PA) reduces risk of cardiovascular disease, cancer, diabetes, and premature death. Moreover, PA can counteract the reduction in fitness, muscular strength, and endurance associated with aging, prevent or mitigate decline in physical function, and reduce risk and injury from falls. However, whether the increased joint loading associated with certain types or intensity of PA increases the risk of developing knee osteoarthritis (OA), or accelerate the progression of disease is uncertain. Prior studies about PA and knee OA risk used self-reported PA, which is subject to recall and social desirability bias, and activities captured may be limited. We analyzed the association between objectively measured physical activity and risk of developing knee OA in a community-based cohort of middle-aged and older adults.

Methods: We used data from the Osteoarthritis Initiative (OAI), an ongoing prospective cohort study of adults with elevated risk of symptomatic knee OA. Physical activity was measured by a uniaxial accelerometer worn on a waist belt for seven continuous days in two data collection cycles; minutes-per-week of moderate-equivalent intensity physical activity were calculated from these data. Incident knee radiographic OA (ROA), symptomatic OA (sROA), and joint space narrowing (JSN) were analyzed as outcomes. Incident ROA was assessed by Kellgren-Lawrence grade ≥2 in a knee that was KLG 0 or 1 at baseline, and sROA was defined as ROA plus pain, aching, or stiffness in the same knee. We defined knee JSN as ≥1 grade increase in either the medial or lateral tibiofemoral compartments from the previous clinical visit in a knee that did not have Kellgren-Lawrence grade ≥2 with JSN≥1 at baseline. The study population was free of the outcome at baseline (ROA n = 902, sROA n = 1,331, JSN n = 985), and were followed up to four years. Because outcomes were assessed every two years, we used discrete survival analysis and estimated hazard ratios (HR) and 95% confidence intervals (CI). Multivariable analyses adjusted for age, sex, race, body mass index, education, history of knee injury, and hip OA and symptoms.

Results: Participants who met the US Department of Health and Human Services (HHS) recommended physical activity level (≥150 min/week of moderate-intensity equivalent aerobic activity) had neither significantly increased nor decreased hazard of incident radiographic knee OA (HR: 1.57; 95% CI: 0.71–3.45), symptomatic knee OA (HR: 1.37; 95% CI: 0.58–3.21), or joint space narrowing (HR: 0.78; 95% CI: 0.35–1.72), compared with those who did not meet recommendations.

Conclusion: Meeting physical activity guidelines was not associated with the risk of developing knee OA or joint space narrowing over up to four years of follow up among OAI participants. Given the proven benefits of physical activity on joint health and general health, our results support the HHS physical activity recommendations to adults.

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016
Session Title: ACR/ARHP Combined Abstract Session: Orthopedics and Rehabilitation
Session Type: ACR Concurrent Abstract Session
Session Time: 4:30PM-6:00PM

Background/Purpose: Varus thrust, bowing-out of the knee during gait, i.e., appearance (or worsening) of varus during stance improving in late stance or swing, was associated with medial tibiofemoral OA progression in a single-site study. To determine replicability in a multi-center study and if thrust is associated with incident OA, we undertook an OAI ancillary study. We hypothesized that: 1) in knees without OA [KL<2 at enrollment (0m) and 12m visits], thrust at 12m (our study *baseline*) is associated with subsequent a) incident OA (KL≥2) and b) medial joint space narrowing (JSN); and 2) in knees with OA (KL≥2 at 0m or 12m), thrust at 12m is associated with subsequent medial JSN. We further considered the hypothesized associations adjusted for *static* alignment, anticipating some but not complete attenuation.

Methods: Gait was observed for thrust at 4 sites by 2-3 trained examiners/site at 12m. In knees KL<2 at 0m and 12m, incident OA was analyzed as subsequent incident KL≥2, medial JSN by whole grade and by partial grade (all dichotomous), and annualized JSN in mm (continuous) after 12m. In knees KL≥2 at 0m or 12m, progression was analyzed as subsequent medial JSN by whole grade and by partial grade, and annualized JSN. Outcomes were assessed up to 96m. Alignment was measured in 3 other sub-studies: mechanical axis (hip-knee-ankle angle, HKA) using 2 full-limb x-ray measurement approaches (HKA-DC and HKA-JD), and anatomical axis (femorotibial angle) on knee x-ray (FTA). All analyses were knee-level; we used multivariable logistic and linear regression methods with GEE to account for between-limb correlation.

Results: The incident OA sample included 4187 knees from 2610 persons [age 60.5 (SD 9.2), BMI 27.8 (4.5), 1455 (56%) women]; the progression sample included 3421 knees/2284 persons [age 62.6 (9.0), BMI 29.6 (4.8), 1339 (59%) women]. Thrust was not associated with incident KL≥2 or medial JSN in knees without OA (Table 1, upper half), but was associated with all progression outcomes (Table 1, lower half). The thrust/progression association was attenuated (Table 2) but an independent association persisted in partial grade and annualized JSN models including HKA-JD and FTA. After adjusting for HKA-DC, thrust was no longer associated with progression.

Conclusion: Over up to 7 years of follow-up observation, varus thrust was associated with medial knee OA progression but not incident OA. Gait observation for thrust may offer a simpler (vs. radiographic methods for alignment) approach to predicting knee OA progression, which is translatable to larger scale studies with multiple examiners.

Session Title: Education

Session Type: ACR Concurrent Abstract Session

Session Time: 4:30PM-6:00PM

Background/Purpose: The Center of Excellence (COE) in Musculoskeletal (MSK) Care and Education was established at the Salt Lake City Veterans Affairs Medical Center (SLCVAMC) in 2012. A major element of the COE is the MSK Week, an interprofessional, multidisciplinary, multilevel program for students and postgraduate trainees affiliated with the University of Utah. Objectives included increasing osteoporosis awareness among learners and improving access to appropriate screening and treatment for Veterans. We evaluated the impact of the MSK Week on internal medicine (IM) residents' recognition and treatment of osteoporosis during their VA-based continuity clinic experience before and after training.

Methods: We conducted a retrospective cohort study of patients ages 50+ enrolled at SLCVAMC from July 1, 2013 to May 31, 2014. We used time-dependent multivariable Cox proportional hazard models evaluating the impact of the MSK Week on 5 osteoporosis-related outcomes: (1) completion of 25-hydroxyvitamin D measurement, (2) completion of dual energy x-ray absorptiometry (DXA), (3) diagnosis of osteopenia, (4) diagnosis of osteoporosis, and (5) initiation of osteoporosis medications. Multivariable models adjusted for confounders including age, sex, alcohol and tobacco use, diabetes, fractures, hyperparathyroidism, vitamin D deficiency, renal disease, and medications

Results: We identified 26 IM trainees (PGY1) who completed the MSK Week in 7 groups. In our cohort of 43,678 veterans, 1,154 encountered a trainee who had completed the MSK Week (thus "exposed" to the training) and 42,524 patients who did not.

[a]per 10,000 patient-days

Patients encountering a trained provider were more likely to have each outcome, with strongest effect in diagnosis of osteoporosis (RR = 7.1, 95% CI: 4.4, 11.2) and completion of DXA (RR = 4.4, 95% CI: 3.0, 6.1). In the univariate analyses, training was associated with increases in all outcomes, with HRs (95% CI) ranging from 7.0 (3.8-12.8) for osteoporosis diagnosis to 1.5 (1.3-1.8) for vitamin D measurement; $p < 0.0001$ for all. Adjusting for confounders, the effect of the MSK Education Week was significant for osteoporosis diagnosis (HR = 3.9, 95% CI: 2.1, 7.3), medication therapy (HR = 2.9, 95% CI: 2.0, 4.1), and evaluation with DXA (HR = 1.8, 95% CI: 1.1, 2.9).

Table 2 – Results from univariate and multivariate Cox proportional hazards regression

	Univariate Results				Multivariable Results			
		95% Confidence Interval				95% Confidence Interval		
Outcome	**HR**	**Lower**	**Upper**	**P-value**	**HR**	**Lower**	**Upper**	**P-value**
Vit D Lab	1.528	1.304	1.789	<.0001	1.017	0.867	1.192	0.839
DXA	3.300	2.063	5.279	<.0001	1.782	1.109	2.865	0.017
Osteopenia	2.414	1.515	3.846	<.0001	1.324	0.829	2.115	0.240
Osteoporosis	6.955	3.773	12.821	<.0001	3.904	2.090	7.293	<.0001
Bisphosphonate	3.403	2.400	4.825	<.0001	2.874	2.018	4.093	<.0001

Conclusion: Participation in the MSK Education Week was associated with improved access to appropriate care for Veterans, with increases in the rates of residents' use of screening DXA, diagnosis, and treatment of osteoporosis following training. Next steps will include evaluation of the impact of the MSK Education Week on long-term osteoporosis outcomes, including rates of fragility fracture.

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016

Session Title: Education

Session Type: ACR Concurrent Abstract Session

Session Time: 4:30PM-6:00PM

Background/Purpose: Understanding epidemiology and biostatistics is crucial for rheumatologists to accurately interpret the rheumatic disease literature and make appropriate clinical decisions. In 2014 rheumatology program directors (PD) endorsed the need for materials to support teaching and learning in this area, with a preference for web-based interactive modules. Acknowledging this need, we developed Critical Literature Assessment Skills Support – Rheumatology (CLASS-Rheum). We report on the development, implementation, feasibility and results of our 6-month pilot.

Methods:

CLASS-Rheum was organized as 10 modules on topics encountered in relevant journals (data/distributions, case series, cohorts, case control studies, randomized controlled trials, crossover studies, survival analysis, non-inferiority trials, systematic review/meta-analysis, instrument performance). Based on the science of test-enhanced learning, we developed 3-9 questions/module in rheumatologic contexts. The Learning Catalytics® platform allowed participants to access CLASS-Rheum on any web-enabled device, in synchronous, asynchronous, individual and team formats, with immediate feedback, answer rationales and supporting references.

With IRB exemption, six rheumatology programs of varied size across the US participated from January-June 2016. Each program had autonomy over implementation format and timing. Demographics were collected anonymously via RedCap. Data on use and feasibility were collected in person, via conference calls, email and RedCap. Learning Catalytics® captured responses to CLASS-Rheum questions.

Results:

Thirty fellows participated; 12 first year of fellowship, 14 second year, three third year, and one fourth year. 80% were women, 17% had pediatrics or internal medicine/pediatrics training, 10% had degrees in epidemiology/biostatistics. 62% were very interested and 34% somewhat interested in improving their understanding of epidemiology/biostatistics.

Variability in responses to CLASS-Rheum questions suggested an appropriate range of item difficulty. When team format was used with fellows responding individually and again after small group discussion, correctness of trainees' responses increased.

Trainees reported CLASS-Rheum helped identify knowledge gaps, address learning needs and reinforce learning. Trainees' comments indicated it was "engaging" "fun" and "helpful in challenging me to assess/clarify my own knowledge in an applied manner." Trainees highlighted answer rationales as useful resources and described increased confidence and skill in assessing the quality of the literature after completing CLASS-Rheum.

Instructors/PD found CLASS-Rheum gave them insight into fellows' learning needs and a feasible program to address them. They expressed desire for additional modules to support longitudinal assessment.

Conclusion:

CLASS-Rheum can be successfully implemented to support teaching in a range of rheumatology training programs. It was well received, the content was perceived as relevant, and the formats feasible and useful. CLASS-Rheum should be evaluated in a larger number of programs, with subsequent isomorphic modules to provide longitudinal assessment.

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016

Session Title: Education

Session Type: ACR Concurrent Abstract Session

Session Time: 4:30PM-6:00PM

Background/Purpose: The 2015 ACR/AHRP Workforce Study examined the adequacy of the future supply of and demand for rheumatology services in the U.S. Understanding the role that GME plays in training, recruitment, and bridging the gap in excess demand for pediatric rheumatology services was a critical component.

Methods: The 2015 ACR/ARHP Workforce Study was completed using several data sources including ACR member data, state licensure registries, ABP certificates, AAMC, ACGME, and National Matching Registry Program data and the ACR Workforce Survey. Significant factors affecting demand included healthcare utilization, practice trends, disease prevalence, population demographics, per capita income, and access to care trends. Clinical FTE was defined as 1.0 FTE for private practice and 0.5 FTE for academic practice. It was assumed 5% of the workforce was in private practice vs. 95% in academic practice. Regional practice patterns were also analyzed.

Results: According to ACGME, there are 34 pediatric rheumatology programs; currently up to 40 training slots are offered annually that are 3 years in length (Table 1). Of the 3,301 general pediatric residents graduating annually, 31% enter fellowships but only 0.7% choose rheumatology. More than half (68%) of all pediatric rheumatologists are female. Of the 30% international medical graduate (IMG) fellows, 76% plan to practice in the U.S. On average, approximately 30-45% of the first year fellowship positions

go unfilled with another 3.9% not graduating. By 2030, there is an anticipated 20% reduction in workforce (n=231) will result in an almost two-fold in excess demand (n=461).

Conclusion: The current U.S. pediatric rheumatology workforce is in jeopardy of accelerated decline due to inadequate productivity and increased attrition. GME future challenges include an increased unfilled positions rate, loss of 25% IMGs to practice outside the US, regional misdistribution, projected retirement rates, and increased percent women, many of whom indicate choosing part time work. Increasing training slots alone is unlikely to be effective. Innovation through GME efforts to bridge the excess demand gap is critical and may include loan repayment, recruitment incentives, further evaluation of GME requirements, IMG practice recruitment strategies, in addition to other mechanisms to improve access to care. Efforts targeting recruitment of pediatric trainees are essential to increase interest and commitment to GME in this underserved field. Table 1. Pediatric Rheumatology Fellows Trend Data

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016

Session Title: Education
Session Type: ACR Concurrent Abstract Session
Session Time: 4:30PM-6:00PM

Background/Purpose: Despite the prevalence of musculoskeletal conditions, the majority of internal medicine trainees at the University of Maryland complete residency with little exposure to rheumatology and score in 16th to 35th percentiles on the rheumatology portion of the annual in-training-exam. In order to improve trainee knowledge and clinical decision making in rheumatology, we created a web-based, self-directed core rheumatology curriculum; the first module addresses the topic of gout. Web-based learning is a standardized, convenient, and accessible method to deliver didactics. We assessed the efficacy of the gout module by using the script concordance testing (SCT) method.

Methods: This prospective observational study included internal medicine trainees at the University of Maryland Medical Center. Participants completed a baseline SCT and an electronic module on gout pathophysiology, clinical presentation, and therapeutic management. Immediate post-testing was performed with an identical SCT. A validated SCT was created for each module in the curriculum. Pre- and post-test scores were compared to the scores of the expert panel, which included 2 rheumatology fellows, 9 academic rheumatologists, and 1 community rheumatologist. A one-way ANOVA was used to compare trainee and expert groups as well as pre- and post-test scores. Cronbach's alpha was used to calculate test reliability. An effect size was calculated using Cohen's d. A one-way ANOVA was used to compare the effect of post-graduate year and academic year on SCT score.

Results: One hundred twelve trainees completed paired pre- and post-tests for analysis. The 20-case SCT achieved high reliability (Cronbach alpha > 0.75). At baseline, the trainees' average SCT score was 31 points (M=31.71, SD=3.15); whereas the experts' average SCT score was 40 points (M=40.65, SD=1.72). After the didactics, trainees' SCT scores increased on average 2.56 points $F(1, 232) = 43.12$; ($p<.0001$). Cohen's d showed a strong effect size (d=1.48). Expert SCT scores were on average 8.9 points higher than trainee pre-test scores; whereas at post-test experts' SCT scores were on average 6.3 points higher. Both of these differences were statistically significant ($p<.0001$). There were no significant score differences between second and third year residents on pre- or post-test ($p>.05$). In subgroup analysis by academic year, 2015 trainees scored on average 1.71 points lower on the pre-test compared to 2014 trainees ($p=.01$). There were no significant differences between 2014 and 2016 trainees on the pre-test ($p>.05$). There were no significant differences between academic years on the post-test SCT ($p>.05$).

Conclusion: Trainee test scores significantly increased after the educational intervention in this study. There were no significant differences in post-test SCT scores when analyzed by academic year or post-graduate year. Expert SCT scores were higher at baseline and remained higher after the didactics, which lends support to the construct validity of the tool as the experts had higher clinical competence. Re-testing after 12 months to evaluate durability of knowledge is currently ongoing.

Learning Rheumatology through Fellow-Generated Questions: The Rheumatology Image of the Week Project

Jonathan S. Hausmann, Rheumatology, Beth Israel Deaconess Medical Center, Boston, MA; Rheumatology, Boston Children's Hospital, Boston, MA
First publication: September 28, 2016

SESSION INFORMATION
Session Date: Tuesday, November 15, 2016
Session Title: Education
Session Type: ACR Concurrent Abstract Session
Session Time: 4:30PM-6:00PM

Background/Purpose:

There has been increasing interest in using online tools to train physicians. However, most online content does not encourage active

learning, and as a result, does not translate into lasting knowledge. I sought to develop an active learning, learner-generated, question-based curriculum, and to disseminate this educational content through social media.

Methods:

Rheumatology Fellows-In-Training (FITs) were invited to participate in the Rheumatology Image of the Week project (#RheumIOW). Each fellow was asked to create questions from one topic of the ACR Image Bank. After participation, FITs were surveyed on their experience.

Questions were reviewed by the ACR Audiovisual Aids Subcommittee. Every Tuesday, starting on 8/4/15, one question was shared via ACR accounts on Twitter, Facebook, and LinkedIn. Online engagement was analyzed and number of Image Bank page views was recorded. For the first month, #RheumIOW tweets were compared with other tweets from the ACR, and Image Bank page views were compared for the month prior to and after starting #RheumIOW.

Results:

28 FITs from 23 different training programs participated. 50% of participants had Twitter accounts and most (78.5%) had "beginner" or "intermediate" experience with social media. The most common reasons to participate were "to learn" (50%) and "to teach" (28.6%).

116 questions were created; the first four are shown in Figure 1. Results from the FIT survey are shown in Figure 2.

Since August, #RheumIOW questions received 4003 Twitter clicks, 7790 Facebook clicks, and 645 LinkedIn clicks. For the first month, as compared to other ACR tweets, those relating to #RheumIOW had 32 times more clicks. Image Bank images relating to #RheumIOW increased in hits from 2- to 100-fold.

Conclusion:

In this project, rheumatology trainees generated educational micro-content, which they found to be a valuable educational experience and useful to learn rheumatology. Learner-generated questions have previously been shown to be highly effective for learning. At the same time, questions were popular with online users, who actively sought the answer from the ACR Image Bank. These users benefited from "practice testing," the finding that material is better learned and retained when it is tested, rather than when it is simply read.

#RheumIOW shows a novel, inexpensive, and effective way to engage learners through the creation of educational content, which can be shared with the public for their benefit. This method of active learning can be used in the future to address the educational needs of the rheumatology community.

Figure 1. #RheumIOW questions distributed in August 2015.

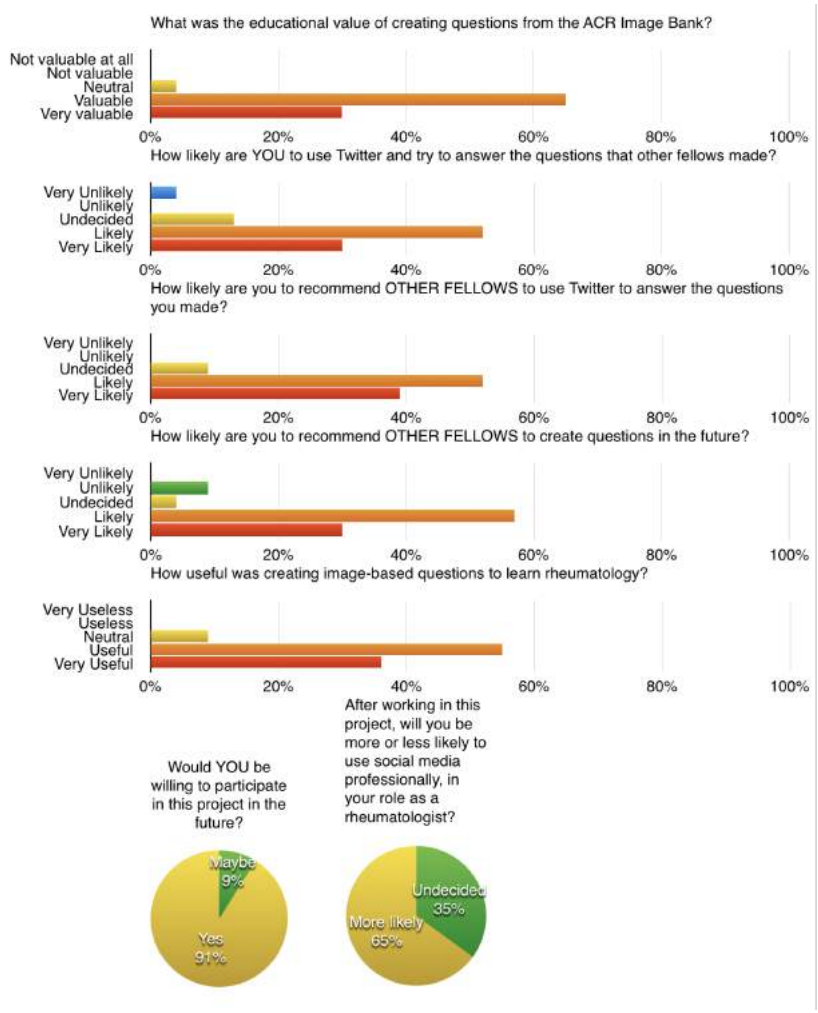

Figure 2. Results of FIT survey after participation in #RheumIOW.

From Art to Science: A Mobile App for Point-of-Care Relevance Determination for the Musculoskeletal Exam

Joy-Ann Tabanor, Joongheum Park, Heidi-Anne Hanson and Hnin Hnin Oo, Department of Medicine, Englewood Hospital and Medical Center, Englewood, NJ

First publication: September 28, 2016

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016

Session Title: Education

Session Type: ACR Concurrent Abstract Session

Session Time: 4:30PM-6:00PM

Background/Purpose: The physical exam is an essential part of the assessment of patients with musculoskeletal (MSK) complaints. Few doctors are aware of the sensitivity and specificity of special tests in the MSK exam, which leads to

misconceptions regarding the relevance of a particular maneuver. Relevance can be further elucidated by determining the pre- and post-test probability of a particular diagnosis. However, it is impractical to perform these types of calculations at the bedside. To address this issue, we developed the MSK Application (app) based on a clinical decision-making support system with the major feature being called the '**Relevance Determination Engine**'.

Methods: A team of residents was created to generate ideas and outline an approach to the app's development. A literature search was performed to review the evidence behind various examination techniques in terms of sensitivity and specificity. We chose the Apple operating system (iOS) platform and used Xcode 8 as the software development tool. Information on each special test in the MSK exam was converted into JavaScript object notation language, which is simple and facilitates continuous maintenance by team members who are not technologically savvy. The app design is consistent with iOS Human Interface Guidelines. It will be published to the App Store in July, 2016.

Results: The MSK App allows users to search for a special test in the MSK exam according to anatomical region, patient's symptoms or differential diagnosis. A summary of how to perform the exam, as well as the sensitivity, specificity and likelihood ratios are given. Users are also provided with a link to a YouTube video demonstrating the exam. The app serves as a teaching tool in evidence-based medicine (EBM) by highlighting the relevance of each special test. This is achieved by utilizing a feature called the 'Relevance Determination Engine', which automatically calculates the post-test probability for a test. The default pre-test probability of 50% can be adjusted with simple manipulation of a slider bar (Figure 1).

Conclusion: The MSK App is an exciting and innovative approach to education at the bedside developed by residents for residents and medical students. It bridges the gap between physical diagnosis and EBM by calculating point-of-care post-test probability. Further developments will expand content by adding pictures and videos. Data from user surveys will also be analyzed.

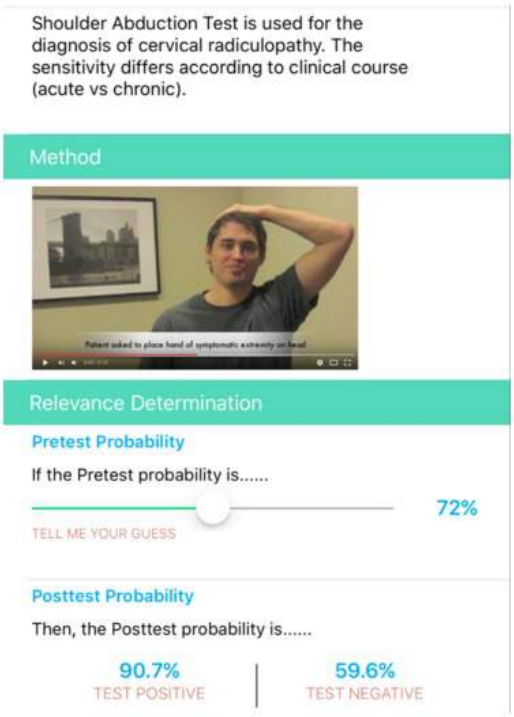

Figure 1. A screenshot from the MSK App prototype showing the Relevance Determination Engine.

Mortality in Patients With Rheumatoid Arthritis and Interstitial Lung Disease Treated With First Line TNFi or Rituximab Therapies Druce KL, Iqbal K, Watson K, Symmons DPM Hyrich KL, Kelly C on behalf of the BSRBR-RA

Background/Purpose: Pulmonary involvement, including interstitial lung disease (ILD), is common in patients with rheumatoid arthritis (RA) and is associated with increased mortality. Early reports suggested that TNFα inhibitors (TNFi) may be linked to the development, or exacerbation, of ILD, and in response, in 2005 the British Society for Rheumatology advised caution in their use for patients with RA-ILD. In contrast, no comparable recommendations have been provided for rituximab (RTX), which is often used where contra-indications for TNFi exist. This study aimed to examine 5-year mortality in patients with RA-ILD starting either RTX or TNFi as their first biologic therapy for RA.

Methods: Participants in the British Society for Rheumatology Biologics Register for RA with clinician reported RA-ILD at baseline starting either TNFi or RTX as their first biologic for RA were included in this analysis. Date and cause of death were captured on regular study follow-up forms and through linkage with the UK National Death Register. Death rates, per 1000 person years (pyrs) were calculated (95% CI); censoring occurred at death, 12/6/2015, or 5 years following first registration, whichever came first. The frequency with which ILD was mentioned on death certificates was examined. Kaplan-Meier survival curves were generated, with risk comparisons made between the RTX and TNFi cohorts using Cox regression using an ever exposed model, adjusted for potential confounders. Eligibility of confounders was determined by clinically relevant justification or statistical significance ($p<0.05$), after adjustment for treatment effects.

Results: Of 353 eligible RA participants with RA-ILD, 310 were treated with TNFi (all recruited before 2008) and 43 were treated with RTX patients (all recruited after 2008). During the first 5 years of follow-up, there were 76 deaths in 804.9 pyrs observed in the TNFi cohort and 8 deaths in 156.7 pyrs in the RTX cohort; death rates were 94.4 (74.4-118.1) and 51.0 (22.0-100.5) per 1000 pyrs, respectively. ILD was recorded on 36.5% of the 74 available death certificates from the TNFi cohort and all of the three certificates available in RTX cohort. The unadjusted mortality risk in the RTX treated patients was numerically half that in the TNFi treated patients, although this was not statistically significant (HR 0.51, 95%CI 0.25-1.06; Figure 1). Adjustment for baseline age, sex, disability, disease activity, and disease duration made little difference to the estimate (0.50, 0.23-1.08).

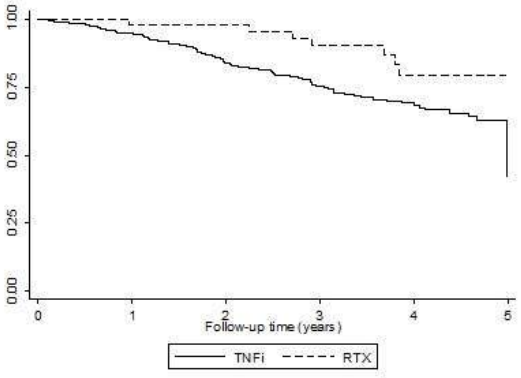

Figure 1 - Kaplan-Meier survival curves for death following exposure to TNFi or RTX over the first 5 years following therapy commencement, within an intention to treat analysis.

Conclusion: Patients who were selected to receive RTX as their first biologic for RA appeared to have better long-term survival compared to patients who had received TNFi, although this difference was not statistically significant. Absence of information on

severity or subtype of ILD prevents drawing conclusions regarding the relative safety of these 2 therapies for RA-ILD and more detailed analysis in a larger dataset should be undertaken.

Risk of Incident Cancer with Biologic and Tofacitinib Therapy in Rheumatoid Arthritis

Bryant R. England[1], Sofia Pedro[2], Ted R Mikuls[3] and Kaleb Michaud[2,4], [1]Division of Rheumatology, Department of Internal Medicine, University of Nebraska Medical Center, Omaha, NE, [2]National Data Bank for Rheumatic Diseases, Wichita, KS, [3]Veteran Affairs Nebraska-Western Iowa Health Care System and University of Nebraska Medical Center, Omaha, NE, [4]Rheumatology, University of Nebraska Medical Center, Omaha, NE

First publication: September 28, 2016

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016

Session Title: Epidemiology and Public Health II: Obesity, Cancer and Mortality

Session Type: ACR Concurrent Abstract Session

Session Time: 4:30PM-6:00PM

Background/Purpose: The immune system recognizes, controls, and eliminates tumors through a process of immunosurveillance. In RA, where there is an increased incidence of lymphoma and lung cancer, there has been much concern regarding the potential for biologic therapies to increase cancer incidence. While epidemiologic reports have been somewhat conflicting, several suggest an increased risk of skin cancer with anti-TNF therapy. Newer non-TNF biologic and small molecule therapies have been subject to limited investigation. We examined the associations of biologic and small-molecule therapies with incident cancer in RA.

Methods: We studied RA patients without prevalent cancer participating in the National Data Bank for Rheumatic Diseases (NDB), a longitudinal US-wide observational study that includes semiannual patient questionnaires from 1998 to 2015. Malignancy was determined per a standard protocol that included patient report, patient/family interview, review of medical records, and linkage with the National Death Index. We calculated cancer incidence rates using Poisson regression stratified by medications and the adjusted risk of incident cancer in multivariable Cox proportional hazards models. In Cox models, we analyzed medications individually (remains on drug indefinitely after initiation), grouped by mechanism of action (e.g. anti-TNF), and in a time-varying hierarchical model (MTX monotherapy, other DMARDs, anti-TNF, non-TNF biologics, and tofacitinib [TOF]).

Results: Among 11,582 patients, 6,262 biologic/TOF initiations (mean age 58 years, 80% female, and 48% current/former smoker; n=1,621 non-TNF and n=222 TOF) and 5,320 DMARD initiations (mean age 59 years, 79% female, and 49% current/former smoker) were identified with 1,456 incident cancers (812 excluding non-melanoma skin) occurring during 47,243 patient-years of follow-up. Cancer incidence rates/1,000 PY are shown in Table 1. Risk of incident cancer by medications in a hierarchical drug model and for individual therapies in separate models are shown in Table 2.

Table 1. Unadjusted cancer incidence rates (95% CIs) per 1,000/PY

	All Cancer	Solid Tumor	Lymphoproliferative
DMARD	18.68 (17.52-19.91)	7.50 (6.77-8.29)	11.78 (9.11-14.98)
Biologic/TOF	17.82 (16.29-18.44)	6.51 (5.60-7.52)	11.65 (7.97-16.44)
TNF	17.78 (16.24-19.42)	6.52 (5.60-7.55)	10.71 (7.17-15.38)
Non-TNF	14.91 (11.88-18.48)	3.40 (2.05-5.31)	22.73 (9.14-46.84)
Tofacitinib	22.76 (8.35-49.55)	11.38 (2.35-33.26)	0.0 (0-660.1)

Table 2. Associations of biologic and small molecule therapy with incident cancer (excluding non-melanoma skin cancer).

	HR	95% CI	P
*Hierarchical model**			
MTX monotherapy	*Referent*	-	-
DMARDs	0.67	0.50-0.90	0.01
TNF	1.18	0.86-1.63	0.31
Non-TNF	0.80	0.52-1.22	0.29
Tofacitinib	0.73	0.30-1.80	0.50
*Individual comparison vs mono MTX (separate models)**			
TNF	1.27	0.96-1.64	0.089
non-TNF	0.95	0.63-1.43	0.81
Etanercept	1.39	1.09-1.77	0.01
Adalimumab	0.99	0.73-1.36	0.97
Infliximab	1.60	1.25-2.04	<0.001
Golimumab	1.47	0.47-4.68	0.51
Certolizumab	1.09	0.48-2.48	0.85
Rituximab	1.87	1.07-3.27	0.03
Abatacept	0.80	0.44-1.46	0.47
Anakinra	0.28	0.09-0.88	0.03
Tocilizumab	1.90	0.77-4.73	0.16
Tofacitinib	4.36	1.36–13.96	0.01

*Covariates: age, sex, race, education, income, smoking history, comorbidity, HAQ, pain, global assessment, alcohol use, number prior DMARDs and biologics, RA duration

Conclusion: We observed increased rates of solid tumors with TOF and lymphoproliferative malignancies with non-TNF biologics, though both had imprecise estimates. After adjustment for several confounding variables, we did not find an increased risk of cancer with biologic or TOF relative to MTX monotherapy. Combination and non-MTX DMARD therapy had the lowest risk of incident cancer, and several therapies individually were associated with increased cancer risk modeled against MTX monotherapy. These findings highlight the complexity of determining cancer risk with therapies, and show how reasonable changes to methodological analysis can provide disparate results.

Treatment Decisions Following Diagnosis of Cancer During TNFi inhibitor Treatment in Patients with Rheumatoid Arthritis: results from the BSRBR-RA Druce KL, De Cock D, Watson K, Symmons D, Hyrich KL on behalf of the BSRBR-RA

Background/Purpose: Despite early concerns, evidence has suggested that use of TNFα inhibitors (TNFi) may not be associated with an increase in cancer risk in patients with rheumatoid arthritis (RA). Nevertheless, uncertainty remains about appropriate treatment decisions following a diagnosis of cancer in patients receiving TNFi. The aims of this analysis were to describe (i) treatment decisions and (ii) outcomes in the 5 years following a diagnosis of cancer in patients with RA receiving TNFi.

Methods: This descriptive analysis included participants from the British Society for Rheumatology Biologics Register for RA (BSRBR-RA) who develop a first cancer while receiving TNFi (+90 days) prior to 01/04/2011. Cancer and death data were captured through linkage with the UK National death and cancer registers held by the Health and Social Care Information Centre (HSCIC). Treatment data were captured via regular clinical follow-up forms. Initial treatment decisions in all patients following diagnosis and subsequent treatment decisions among patients who survived at least 6 months were examined. Decisions were examined in all cancers and separately for the five most common cancer sites. Overall and site-specific mortality are described using percent of deaths and Kaplan Meier survival function.

Results: During 118355 person years of follow-up in 12499 patients who had ever been exposed to TNFi, 404 first cancers occurred on TNFi (74 lung, 65 breast, 35 colorectal, 36 lymphoma, 18 prostate and 176 other). Within 6 months of diagnosis, 95 (24%) patients died (median time to death (TTD):52 days (IQR: 22-100)) with the highest death rate among patients with lung cancer. Of the 309 patients surviving the first 6 months, 67% stopped TNFi at cancer diagnosis. Over the subsequent 5 years, 47% remained off all biologics, 26% continued on TNFi and 25% started an alternative class of biologic after a median of 510 days. Only 2 patients restarted a TNFi therapy and 5 discontinued their TNFi after 6 months. Treatment decisions varied among the 5 most common cancer sites, with a majority of patients (64%) with prostate cancer continuing their initial TNFi treatment over 5 years. Of patients with breast cancer and lymphoma 32% and 40% of patients, respectively started an alternative treatment; the majority switched to rituximab.

Table. On TNFi (+90 days) cancer events, deaths and treatment decisions made by 6 months and 5 years						
	All cancers	Lung	Breast	Lymphoma	Colorectal	Prostate
N (all patients)	404	74	65	36	35	18
Died within first 6 months, n(%)	95 (23)	39 (53)	3 (5)	1 (3)	6 (17)	1 (6)
5 year survival, % (95% CI)	44 (39, 49)	5 (1, 13)	68 (55, 78)	69 (52, 82)	49 (31, 64)	72 (46, 87)
Initial treatment decision among patients surviving at least 6 months following cancer diagnosis (n=309)						
n	309	35	62	35	29	17
Stopped TNFi, n (%)	207 (67.0)	32 (91.4)	47 (75.8)	29 (82.8)	20 (69.0)	4 (23.5)
Remained on TNFi, n (%)	102 (33.0)	3 (8.6)	15 (24.2)	6 (17.2)	9 (31.0)	13 (76.5)
Subsequent biologic treatment decisions over 5 years among patients surviving at least 6 months following cancer diagnosis (n=309)						
Continued TNFi, n (%)	81 (26.2)	3 (8.6)	9 (14.5)	5 (14.3)	8 (27.6)	11 (64.7)
Initially continued but later stopped treatment, n (%)	5 (1.6)	0 (0)	2 (3.2)	0 (0)	1 (3.4)	1 (5.9)
Restarted TNFi, n (%)	2 (0.6)	2 (5.7)	0 (0)	0 (0)	0 (0)	0 (0)
Median days to treatment re-start (IQR)	171 (163-179)	171 (163-179)	-	-	-	-
Switched to analternative biologic, n (%)	76 (24.6)	3 (8.6)	20 (32.3)	14 (40.0)	5 (17.2)	2 (11.8)
Median days to treatment start (IQR)	503 (310.5-890)	499 (430-504)	696 (275-950)	547 (369-771)	661 (323-814)	410 (369-451)
Discontinued all biologics, n (%)	145 (46.9)	27 (77.1)	31 (50.0)	16 (45.7)	15 (51.7)	3 (17.6)
Still alive at 5 years, n (%)	174 (56%)	4 (11%)	44 (71%)	25 (71%)	17 (58%)	13 (76%)

Conclusion: Treatment decisions following cancer diagnosis in patients receiving TNFi were highly variable and differed by the site of cancer diagnosis. Although around two thirds of patients discontinued their TNFi, only one third of patients with prostate cancer discontinued. Patients with cancer at sites associated with longer survival were also more likely to continue or restart a biologic over the following five year period. If biologics were restarted, most patients started an alternative class of drug.

Session Title: Epidemiology and Public Health II: Obesity, Cancer and Mortality

Session Type: ACR Concurrent Abstract Session

Session Time: 4:30PM-6:00PM

Background/Purpose: Early, aggressive treatment to achieve remission is the primary goal when treating early RA, and is associated with improved long-term outcomes. We have previously shown that individuals who smoke and have excess weight (potentially modifiable factors) are less likely to achieve sustained remission in the first 3 years. Here we explore how smoking, excess weight, and sex affect rate of DAS28 improvement in the first 3 years of early RA.

Methods: Data were drawn from a multicenter prospective cohort study of ERA patients seen in usual care settings. Inclusion criteria were: meeting 1987 or 2010 ACR criteria, <12 months symptom duration at entry, DAS28≥2.6 at entry, and information on BMI and DAS28 at baseline and at least 1 follow up visit. Patients were followed every 3 months in year 1, 6 months in year 2, and annually thereafter. We examined how sex, excess weight (overweight: BMI 25-29.9; obese: BMI 30+) and smoking (current/former/never) impacted DAS28 at baseline and over time using linear growth models. Covariates included baseline age, race, education, comorbidities, symptom duration, and treatment.

Results: The sample included 1109 patients with a mean [SD] age of 54 [15], symptom duration of 6 [3] months; most were female (n=795; 72%) and white (n=893; 81%). Among males 44% (n=138) were overweight, 35% (n=109) were obese and 22% (n=70) smoked; among females, 31% (n=248) were overweight, 32% (n=257) were obese, and 15% (n=121) smoked. At enrollment, most (n=810; 73%) were on MTX. Results of the growth curve model without covariates showed that average DAS28 at baseline was moderate to high (random average DAS28: 4.6, 95% CI: 2.7, 6.2), and DAS28 dropped significantly at each time point (random mean rate of change per visit: b -0.33 (95% CI: -0.60, -0.07). Sex, excess weight, and smoking were not significantly associated with baseline DAS28 (p>0.05). However, each attenuated the rate of DAS28 change over time. The average rate of improvement in DAS28 was lower in women vs men (b: 0.09; 95% CI: 0.05-0.12); those who were overweight (b: 0.05; 95% CI: 0.01-0.09) and obese (b:0.09; 95% CI: 0.05-0.13) vs. healthy weight, and current smokers vs. non-smokers (b:0.07; 95% CI: 0.03-0.12), at each time point. Former smoking did not significantly impact DAS28 trajectory (b:0.03; 95% CI: -0.01-0.06).

Conclusion : Results from a large multi-center ERA cohort study showed that sex, excess weight and smoking significantly attenuated the rates of improvement in RA disease activity over the first 3 years. Improvement among former smokers was similar to those who had never smoked. These results contribute to growing evidence of how lifestyle also may impact treatment outcomes and the potential value of referring patients to proven community-based smoking cessation and weight management programs.

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016

Session Title: Epidemiology and Public Health II: Obesity, Cancer and Mortality

Session Type: ACR Concurrent Abstract Session

Session Time: 4:30PM-6:00PM

Background/Purpose : Weight loss may explain the obesity paradox for mortality, since those who unintentionally lose weight to reach normal BMI may have higher mortality than those with obesity and stable weight. A prior study among RA patients found an association between weight loss and increased mortality. However, weight was examined close to time of death in established RA without a non-RA comparison so the findings may not be specific to RA. Therefore, we investigated the association of weight change in the early RA period with subsequent mortality, and included a matched non-RA group to evaluate the influence of RA.

Methods : We identified incident RA by 1987 ACR criteria during follow-up of the Nurses' Health Study (1976-2012) to form a cohort followed before and after RA onset. We created a comparison cohort by matching RA cases to non-RA comparators by age and year at the index date of RA diagnosis. Anthropometric, behavioral, and clinical data were collected through biennial questionnaires. To capture the entire early RA period, weight change was defined as the difference between weight at 4 years before and 4 years after RA diagnosis ("peri-RA") or index date ("peri-index"). We used Cox regression to estimate HRs for mortality by weight change categories separately in each cohort. We combined both cohorts to evaluate the RA-specific effect and weight change on mortality.

Results : Among 121,700 women, we identified 875 subjects with incident RA, matched to 7,459 non-RA comparators. In the RA cohort, 16.2% lost >10 lbs peri-RA; 12.1% of comparators had weight loss >10 lbs peri-index. There were 243 (27.8%) deaths in the RA cohort and 1,369 (18.4%) deaths among comparators. After adjustment for BMI, smoking, diet, physical activity, comorbidities (cancer, CVD, and diabetes), erosions, serostatus, and nodules, weight loss >10 lbs peri-RA had HR for mortality of 1.61 (95%CI 1.12-2.32, **Table**), identical to the comparison cohort (HR 1.61, 95%CI 1.38-1.89). Weight gain was not significantly associated with mortality in either cohort. When combining both cohorts, RA had higher absolute mortality risk, but there was no interaction between RA or comparators with weight change for mortality (p_{int}=0.86, **Figure**).

Conclusion : In this large prospective study with up to 36 years of follow-up, weight loss around RA diagnosis increased subsequent mortality risk among women. We found similar results in non-RA comparators and evaluated weight change in the early RA period when disease-specific processes are most likely to contribute to weight loss or gain. Therefore, an obesity paradox for mortality may occur in the general population but is not specifically related to RA.

Table. Hazard ratios for mortality according to peri-RA* or peri-index* weight change, analyzed separately in RA and comparison cohorts.

			Age-adjusted[1]		Age and pre-RA/index BMI adjusted[2]		Multivariable adjusted[3]

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016

Session Title: Epidemiology and Public Health II: Obesity, Cancer and Mortality

Session Type: ACR Concurrent Abstract Session

Session Time: 4:30PM-6:00PM

Background/Purpose: Body composition changes resulting from ageing (decreased muscle mass and increased fat tissue) are frequently not accompanied by concomitant changes in body mass index (BMI). Thus, BMI has low accuracy for estimating death risk attributed to changes in body composition in the older adults. Currently, the best method for body composition analysis in routine clinical practice is dual energy X-ray absorptiometry (DXA). However, the few studies on body composition by DXA and mortality risk in elderly have some limitations, such as analysis not stratified by sex and not compartmentalized (subcutaneous and visceral tissues) assessment of body fat. Thus, we sought to investigate the association between body composition by DXA (including visceral fat measurement) and mortality in a longitudinal, prospective, population-based cohort of elderly subjects.

Methods: 839 community-dwelling subjects (516 women, 323 men), ≥65 years, were assessed by questionnaire on clinical data, laboratory exams and body composition by DXA using Hologic QDR 4500A equipment. DXA APEX software computes visceral adipose tissue (VAT) by subtracting the subcutaneous adipose tissue (SAT) from the total android fat, which was automatically set to 20% of the distance from the iliac crest to the base of the skull. All analyses were performed at baseline. Total body fat was expressed by fat mass index (FMI) [(total body fat (kg) / height^2 (m)]. Sarcopenia was defined as low appendicular muscle mass adjusted for fat. Mortality was recorded during 4 year-follow-up. Multivariate logistic regression was used to compute odds ratios for all-cause and cardiovascular mortality.

Results: Over a mean 4.06 ± 1.07 years of follow-up, there were 132(15.7%) deaths. In men, after adjustment for age, BMI, smoking, physical activity, alcohol, diabetes, dyslipidemia, cardiovascular event, recurrent falls, 25OHD and PTH, the presence of sarcopenia (OR 11.36, 95% CI: 2.21-58.37, p=0.004) and visceral fat mass(OR 1.99 95%CI: 1.38-2.87, p<0.001, for each 100g-increase) significantly increased all-cause mortality risk, while total body fat (FMI) was associated with decreased mortality risk (OR 0.48, 95% CI: 0.33-0.71, p<0.001). Similar results were observed for cardiovascular mortality in men: sarcopenia (OR 14.84, 95%CI: 5.15-47.72, p<0.001), visceral fat mass (OR 1.66, 95% CI: 1.31-2.10, p<0.001) and total body fat (OR 0.57,95% CI: 0.43-0.76, p <0.001). In women, only sarcopenia was predictor of all-cause (OR 62.88, 95% CI: 22.59-175.0, p<0.001) and cardiovascular death (OR 74.54, 95% CI: 9.72-571.46, p <0.001).

Conclusion: Sarcopenia and fat distribution are associated with all cause and cardiovascular mortality risk in elderly, and they are different according to sex. Visceral fat and subcutaneous fat have opposite roles on mortality risk in elderly men, and this is distinct from what is observed in young adults.These findings point to the risk of encouraging weight loss in the elderly aiming young adult goals. Furthermore, DXA seems to be a promising tool for evaluation risk of mortality in elderly, since it is easily applicable in clinical practice.

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016

Session Title: Metabolic and Crystal Arthropathies I: Mechanisms of Disease

Session Type: ACR Concurrent Abstract Session

Session Time: 4:30PM-6:00PM

Background/Purpose: Gout is an inflammatory arthritis caused by precipitation of monosodium urate (MSU) crystals in synovial joints. MSU crystals interact with resident macrophages that release pro-inflammatory cytokines, interleukin-1 beta (IL-1β) and chemokines, interleukin-8 (IL-8). MSU crystals are phagocytosed in a process mediated by toll-like receptor (TLR2). Proteoglycan-4 (PRG4) is a lubricating mucinous glycoprotein released by synovial fibroblasts and exhibits a multifaceted homeostatic role in the synovial joint. We have recently shown that recombinant human PRG4 (rhPRG4) can inhibit agonist-induced TLR2 activation. The objective is to evaluate the efficacy of rhPRG4 in modulating MSU activation of macrophages. We hypothesized that rhPRG4 inhibits MSU phagocytosis by human macrophages dose-dependently and inhibits MSU-induced IL-1β and IL-8 gene expression.

Methods: THP1 human monocytes were differentiated into macrophages using 5ng/ml phorbol 12-myristate13-acetate for 48 hours at 37^{o}C. A total of 500,000 macrophages were plated per well in sterile tissue culture plates and were treated with MSU crystals (100μg/mL) for 6 hours at 37^{o}C, and afterwards in the absence or presence of rhPRG4 (25, 50, 100, 200μg/mL) for 24 hours at 37^{o}C. Following incubation, the percent of macrophages that phagocytosed MSU was quantitatively determined using flow cytometry, based on an increase in cellular side-scatter. RNA was extracted and cDNA was synthesized followed by qRT-PCR using TaqMan Fast Advanced Master Mix and primers for human IL-1β and IL-8. IL-1β and IL-8 media supernatant concentrations were determined by commercially available ELISA.

Results: Flow cytometry scatter plots of MSU phagocytosis by macrophages in the absence or presence of rhPRG4 is shown in figure 1A. rhPRG4 treatment significantly inhibited MSU phagocytosis ($p<0.05$) (fig. 1B). MSU treatment resulted in a significant induction of IL-1β gene expression which was inhibited by rhPRG4 treatment (100 and 200μg/ml) ($p<0.05$; fig. 2A), and a significant reduction in IL-1β protein concentration at the 200μg/ml rhPRG4 concentration ($p<0.05$; fig. 2C). Likewise, MSU treatment resulted in a significant induction of IL-8 gene expression which was inhibited by rhPRG4 treatment (50, 100 and 200μg/ml) ($p<0.05$; fig. 2B), and a significant reduction in IL-1β protein concentration at the 100 and 200μg/ml rhPRG4 concentrations ($p<0.05$ and $p<0.001$; fig. 2D).

Conclusion: rhPRG4 inhibits MSU phagocytosis and the resultant inflammatory response by human macrophages and may be useful as a biological treatment for acute gout exacerbations.

Session Date: Tuesday, November 15, 2016
Session Title: Metabolic and Crystal Arthropathies I: Mechanisms of Disease
Session Type: ACR Concurrent Abstract Session
Session Time: 4:30PM-6:00PM

Background/Purpose: Patients with gout have an increased risk of cardiovascular events. The presence of tophi is associated with enhanced cardiovascular risk. Increased platelet reactivity is a risk marker for cardiovascular events. The glycoprotein VI (GPVI) receptor is found exclusively on platelets and megakaryocytes and is the predominant platelet receptor for collagen. It remains intact on platelets under resting conditions. The proteolytic cleavage of GPVI occurs upon specific activation of platelets and is detectable in plasma as soluble GPVI (sGPVI). Therefore elevated plasma sGPVI is a marker of platelet activation and a risk marker for adverse cardiovascular outcomes. The aim of this study was to assess platelet activation, as measured by plasma sGPVI

level in gout.

Methods: Following ethics approval and informed consent, blood samples were taken from patients with gout. Control samples were obtained from healthy volunteers. Demographic and clinical data were collected for all participants. Blood samples were processed as double spun platelet poor plasma. Plasma sGPVI levels were measured using ELISA. Mann-Whitney U test was used to compare groups. Spearmans Rank Correlation Coefficient was used to assess for associations between sGPVI and demographic and clinical markers. IBM SPSS Statistics Version 20 was used for data analysis.

Results: 121 patients were included, 27 during gout flare, 41 with intercritical gout, and 53 healthy controls. There were no significant differences in demographic details between the groups. Median (IQR) sGPVI levels were 6.51 ng/ml (4.52, 8.41) in gout flare, 3.58 ng/ml (2.11, 5.55) in intercritical gout, and 2.19 ng/ml (1.72, 3.31) in healthy controls.Plasma sGPVI levels in both gout groups were significantly increased compared to healthy controls ($p<0.005$ for each) (Figure 1). sGPVI levels were significantly increased in gout flare compared to intercritical gout ($p=0.001$). There was no significant difference in sGPVI levels in gout patients with and without tophi, median (IQR) 3.58 (2.26, 6.08) vs 2.94 (1.91, 6.01) ($p=0.441$), or in those prescribed colchicine, median (IQR) 3.60 (2.19, 6.06) vs 3.12 (2.12, 6.49) ($p=0.773$). There was moderate correlation between sGPVI levels and VASPain ($r=0.40$), and VASQOL ($r=0.33$). There was a weak correlation with CRP ($r=0.23$) and no correlation with ESR ($r=0.049$). sGPVI level did not correlate with presence of tophi ($r=0.115$) or colchicine use ($r=0.042$).

Conclusion: Patients with both tophaceous and non-tophaceous gout exhibit platelet hyperactivity as demonstrated by elevated plasma sGPVI levels. Platelet activation is exacerbated during acute gout flares. Colchicine therapy does not influence plasma sGPVI levels. Platelet activation probably contributes to the elevated cardiovascular risk in gout patients and antiplatelet therapy warrants consideration in this patient population. Figure 1

Session Date: Tuesday, November 15, 2016

Session Title: Metabolic and Crystal Arthropathies I: Mechanisms of Disease

Session Type: ACR Concurrent Abstract Session

Session Time: 4:30PM-6:00PM

Background/Purpose: Genome-wide association studies (GWAS) have identified loci associated with serum urate levels and the risk of gout. Some of these loci interact in a non-additive fashion with dietary exposures to influence the risk of gout. This study aimed to systematically investigate non-additive interaction between alcohol exposure and urate-associated loci for the risk of gout.

Methods: A total of 3,312 New Zealand European and Polynesian (Maori/Pacific) people with and without gout were genotyped for 28 urate-associated genetic variants and tested for non-additive interaction with alcohol exposure (none versus any intake) influencing the risk of gout. Publicly-available genotype and serum urate data from the Atherosclerosis Risk in Communities (ARIC) study and the Framingham Heart Study (FHS) (n=7,110 European subjects) were used to test for non-additive interaction between specific genetic variants and alcohol exposure for the risk of hyperuricaemia (HU). Multivariate-adjusted logistic regression was done including an interaction term. $P<8.6x10^{-4}$ was the significance level after application of a correction factor of 58.

Results: Non-additive interaction of alcohol exposure with *GCKR* (*rs780094*) and *A1CF* (*rs10821905*) was observed in Europeans to influence the risk of gout ($OR_{Interaction}=0.28$, $P=1.5x10^{-4}$ and $OR_{Interaction}=0.29$, $P=1.4x10^{-4}$, respectively). There was evidence for interaction of *A1CF* with alcohol exposure in determining HU in the ARIC/FHS sample set ($OR_{Interaction}=0.60$, P=0.018), but not for *GCKR* ($OR_{Interaction}=0.82$, P=0.18). Analysis of genotype groups stratified by alcohol exposure revealed that at *A1CF* alcohol exposure suppressed the gout risk conferred by the A-positive genotype ($OR_{No\ Alcohol}=2.21$; $OR_{Alcohol}=0.93$) (Table). At *GCKR* alcohol exposure eliminated the genetic effect on gout - the ORs for each genotype group were equivalent ($OR_{T-}=2.07$; $OR_{T+}=2.39$) (Table). In Polynesians there was no experiment-wide evidence for non-additive interaction with alcohol in the risk of gout for any locus ($P>8.6x10^{-4}$). However at *GCKR* there was nominal evidence for interaction in a direction consistent with that observed in Europeans ($OR_{Interaction}=0.62$, P=0.05). At the five urate transporter loci (*SLC2A9, ABCG2, SLC17A1, SLC22A11, SLC22A12*) there was little or no evidence of interaction with alcohol in determining the risk of gout, with nominal evidence only in Europeans at *SLC17A1* ($OR_{Interaction}=0.46$, $P_{Uncorrected}=0.027$).

Conclusion: We describe a novel non-additive interaction of alcohol exposure with *GCKR* (glycolytic gene) and *A1CF* (apolipoprotein B mRNA editing gene) to influence the risk of gout in Europeans. These data support the hypothesis that alcohol influences the risk of gout via glucose and apolipoprotein metabolism. Table. Alcohol intake and gout association in genotype-stratified groups in Europeans for *A1CF* and *GCKR*.

		No Alcohol Intake		**Any Alcohol Intake**

Session Date: Tuesday, November 15, 2016

Session Title: Metabolic and Crystal Arthropathies I: Mechanisms of Disease

Session Type: ACR Concurrent Abstract Session

Session Time: 4:30PM-6:00PM

Background/Purpose: Tophi contribute to musculoskeletal disability, joint damage and poor health-related quality of life in people with gout. The aim of this study was to examine the clinical and genetic features of tophaceous gout.

Methods: Participants (n=1778) fulfilling the 1977 ARA gout classification criteria, recruited from primary and secondary care, attended a study visit which included a detailed clinical assessment. The presence of palpable tophi was recorded. *SLC2A9 rs11942223* and *ABCG2 rs2231142* (SNPs associated with gout) and *ABCG2 rs10011796* (SNP associated with allopurinol response in a US study population) were genotyped (linkage disequilibrium between the two *ABCG2* SNPs $r^2<0.11$ for all ancestral groups). Clinical and genetic features of tophaceous gout were analysed using a case-control study design (tophi vs. no tophi). Polynesian ancestry was separated into Western Polynesian (Tonga, Samoa, Niue, Tokelau) and Eastern Polynesian (Māori, Cook Island).

Results: Compared to participants without tophi, those with tophi were older, had an earlier age of gout onset, longer disease duration and higher serum creatinine, and were more likely to be of Māori or Pacific (Polynesian) ancestry. Participants with tophi also reported more frequent gout flares and higher use of colchicine, prednisone, non-steroidal anti-inflammatory drugs and urate lowering therapy. There was no difference in frequency of the minor (protective) allele for *SLC2A9 rs11942223* between the two groups (p=0.14, Table). In contrast, the risk alleles for both *ABCG2* SNPs were present more frequently in those with tophi (odds ratio (OR) 1.24 for *rs2231142* and 1.33 for *rs10011796,* p<0.05 for both). Analysis of *ABCG2* risk allele frequencies according to ancestry demonstrated that the effect of *rs2231142* was present only in participants of Māori or Pacific ancestry (OR 1.50, p=0.004), with the strongest effect in those of Western Polynesian ancestry (OR 1.71, p=0.017). The *rs10011796* risk allele was strongly associated with tophi in the Western Polynesian group (OR 3.76, p=0.002), but not in the Eastern Polynesian group (OR 0.87, p=0.60). The *ABCG2* associations persisted in the Western Polynesian group after adjusting for age, sex, highest recorded serum urate, serum creatinine, age of gout onset, disease duration, and when including both *ABCG2* variants in regression models.

Conclusion: Tophaceous gout is associated with prolonged disease duration and severe manifestations of disease. These data suggest that variation in ABCG2 function plays a role in development of tophaceous disease in some populations with high prevalence of severe gout.

Table. Allelic odds ratios [OR] for tophaceous disease according to ancestry

		All (n=1778)		Māori or Pacific ethnicity (n=851)		Non-Māori, Non-Pacific ethnicity (n=927)		Eastern Polynesian ancestry (n=464)		Western Polynesian ancestry (n=387)

Session Date: Tuesday, November 15, 2016
Session Title: Metabolic and Crystal Arthropathies I: Mechanisms of Disease
Session Type: ACR Concurrent Abstract Session
Session Time: 4:30PM-6:00PM

Background/Purpose: Mitochondria play a central role in induction of an NLRP3 inflammatory response essential for gouty pathology. Mitochondria are in part self-encoding, possessing a 16.5 kb genome which encodes 36 genes. The objective of this study was to test whether mitochondrial genetic variation and copy number could contribute to susceptibility to gout in New Zealand Polynesians. The Māori and Pacific (Polynesian) populations of New Zealand exhibit a high prevalence of gout (6 and 8%, respectively).

Methods: To test for association of mitochondrial genetic variation with gout 439 whole mitochondrial genomes from Māori and Pacific men with Polynesian maternal grandmothers (327 cases, 112 controls) were generated using Illumina MiSeq technology. Association of mtDNA copy number variation with gout was investigated by a relative read depth approach using high throughput sequence data from two independent data sets (whole genome sequencing (n=73) and resequencing of urate loci (n=385)). Quantitative PCR was undertaken for mtDNA copy number replication in an independent sample set of 632 Polynesian male and female cases and 579 controls. Association analyses were done using R v3.3.0 adjusting by age and proportion of Polynesian ancestry.

Results: Within Polynesia, there is relatively little mitochondrial genetic diversity, with around 96% of those sequenced belonging to the B4a1a and derived sub-lineages. A lineage-specific heteroplasmy in hypervariable region I was found to associate with a higher risk of gout (e.g. heteroplasmy at position 16179: OR 3.28, P = 0.009; heteroplasmy at position 16181: 3.86, $P = 9x10^{-5}$; heteroplasmy at position 16182: 3.43, P = 0.005). Relative to autosomal DNA an additional 10 mtDNA copies protected from gout in the whole genome sequence (OR=0.87, P=0.004) and resequence (OR=0.91, $P=3.3x10^{-4}$) sample sets, including when using asymptomatic hyperuricemic (urate > 0.40 mmol/L) control individuals (OR=0.81, P=0.004 and OR=0.90, P=0.002, respectively) (Table). To replicate, quantitative PCR of mtDNA from the 1211 gout cases and controls showed that with each unit decrease in ΔCt (which reflects an increase in mtDNA content), there was also a decrease in gout risk using asymptomatic hyperuricemic controls (OR=0.76, P = 0.03). However there was no significant association of increased mtDNA copy number with gout risk using all controls (OR=0.92, P=0.32).

Conclusion: It is unclear whether the reduced mtDNA copy number in gout is a consequence of the gouty pathology or whether the reduced mtDNA copy number causally contributes to the risk of gout. The latter possibility is supported by the consistent protection towards gout of increased mtDNA copy number using hyperuricemic controls, consistent with a role for mitochondria in monosodium urate crystal formation and/or the immune response. Alongside research showing that mitochondria play a central role in induction of the NLRP3 inflammasome, these genetic observations support a role for mitochondria in the etiology of gout.

Session Title: Metabolic and Crystal Arthropathies I: Mechanisms of Disease

Session Type: ACR Concurrent Abstract Session

Session Time: 4:30PM-6:00PM

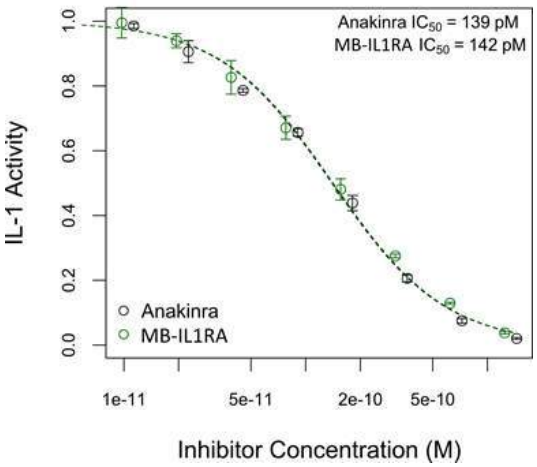
Background/Purpose: A primary challenge for intra-articular delivery of protein and peptide therapies has been their short residence time in the joint tissues. The IL-1 receptor antagonist (IL1RA) could be therapeutic for treating local joint inflammation in monoarticular gout flare, osteoarthritis flare, or post-ACL injury. However, it has been limited by its short half-life in the joint, and previous attempts to prolong its residence time have led to decreased potency. A novel strategy for tissue-targeted local delivery involves fusion of a matrix-binding domain that binds to charged proteoglycans within the extracellular matrix. We describe here the generation of a matrix-binding interleukin-1 receptor antagonist (MB-IL1RA) fusion without loss of activity.

Methods: The matrix binding peptide is 21 amino acid sequence derived from the heparin-binding domain of HB-EGF. The MB-IL1RA fusion protein was expressed in E. coli and purified to homogeneity. Activity was tested in a cell-based assay using IL-1 to stimulate an NF-kB-driven luciferase reporter. Retention in articular cartilage tissue was tested in newborn bovine cartilage tissue explants. After incubation of either anakinra or MB-IL1RA with the tissue, the cartilage was washed into medium with no drug and assayed via Western analysis for drug remaining in the tissue.

Results: The 50% inhibitory concentrations (IC50s) of MB-IL1RA and anakinra were determined in the NFkB reporter cells in the

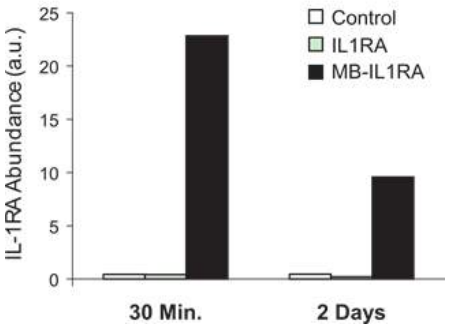
presence of 5 ng/ml interleukin-1β, yielding IC50s of 175 pM ± 23 pM for anakinra and 152 pM ± 26 pM for MB-IL1RA (mean of 9 experimental repeats; a representative run is shown in Figure 1).

FIGURE 1



After wash-out of bovine cartilage explant disks for 30 min., IL-1RA (anakinra) was undetectable in the tissue by Western analysis (densitometric analysis shown in Figure 2). In contrast, the MB-IL1RA fusion protein was robustly detectable within the tissue even after two days of wash-out in plain medium.

FIGURE 2



Conclusion: The novel therapeutic fusion protein MB-IL1RA allows delivery of an IL-1 inhibitor to the articular cartilage and extended residence time within the tissue, while retaining full potency of the inhibitor. MB-IL1RA is a candidate therapeutic for IA administration to treat local inflammation in the joint in acute flares of gout and OA.

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016
Session Title: Miscellaneous Rheumatic and Inflammatory Diseases II
Session Type: ACR Concurrent Abstract Session
Session Time: 4:30PM-6:00PM

Background/Purpose: There is an unmet need for effective therapies for patients (pts) with non-infectious intermediate, posterior, or panuveitis who are at risk for long-term side effects from chronic corticosteroid use. The therapeutic goal in uveitis is to achieve quiescence and adalimumab (ADA) has been shown to lower uveitic flare or vision loss in pts with active (VISUAL I) and inactive (VISUAL II) uveitis[1,2]. As 40-50% of uveitis pts have accompanying extra-ocular rheumatic associations such as Behcet's disease, sarcoidosis, understanding ocular quiescence will not only aid ophthalmologists but also rheumatologists in the overall management of the pt[3]. The objective of this study is to assess the control of inflammation over time in pts treated with ADA in the VISUAL I and II trials.

Methods: Adults with non-infectious intermediate, posterior, or panuveitis were enrolled in 2 global phase 3, double-masked trials: VISUAL I (pts with active uveitis despite ≥2 weeks [wk] of prednisone [PS] 10–60 mg/d) and VISUAL II (pts with inactive disease dependent on 10–35 mg/d of PS to maintain inactivity). Pts were randomized 1:1 to receive placebo (PBO) or ADA (80 mg wk0, followed by 40mg every other wk from wk1 up to 80wks). In VISUAL I, all pts received a PS burst followed by taper to 0mg by wk15. In VISUAL II, PS taper to 0mg was mandatory by wk19. Quiescence as a pre-specified endpoint was defined as no new active inflammatory lesions and anterior chamber cell grade and vitreous haze grade ≤0.5+. Steroid free quiescence at each visit was additionally reported from wks16-52 for VISUAL I and from wk20- 52 for VISUAL II. Non-responder imputation was used for missing data. Statistical comparison between PBO and ADA was based on Chi-square test. Adverse events (AEs) were monitored.

Results: A greater proportion of pts in the ADA group than the PBO group achieved quiescence at each visit in both VISUAL I and VISUAL II. Statistical significance between ADA and PBO groups were observed at each visit from wks8-52 for VISUAL I, excluding wks 12 and from wks8-52, excluding wks12 and 32 for VISUAL II **(Fig. A,B)**.Similar results were observed for pts in steroid-free quiescence. Statistically significant differences between ADA and PBO groups occurred at each visit from wks20-52 for VISUAL I and from wks20-52, except wk32 for VISUAL II **(Fig. C,D)**.Safety data from the VISUAL I and II trials have previously been reported[1, 2]. Rates of AEs were similar between ADA and PBO groups.

Conclusion: Pts with non-infectious, intermediate, posterior, or panuveitis achieved significantly higher rates of quiescence and steroid-free quiescence with ADA treatment than PBO in the VISUAL I and II trials. The safety profile of ADA was consistent with the known safety profile across the approved ADA indications. **References:**

SESSION INFORMATION
Session Date: Tuesday, November 15, 2016
Session Title: Miscellaneous Rheumatic and Inflammatory Diseases II
Session Type: ACR Concurrent Abstract Session
Session Time: 4:30PM-6:00PM

Background/Purpose: Diffuse Idiopathic Skeletal Hyperostosis (DISH) is a poorly understood condition characterized by new bone formation mainly affecting the spine. An association of DISH with Type 2 DM (T2D) has been reported for years, but whether the relationship is genetic is unknown. To investigate whether genetic loci for T2D and related quantitative traits play a role in DISH pathogenesis, we constructed genetic risk scores (GRSs) for T2D, fasting insulin, and fasting glucose to assess the association of these GRSs with DISH.

Methods: A convenience sample of 3,117 patients from the COPDGene Study was used to investigate the association between T2D

and DISH. COPDGene is a multicenter study that enrolled 10,129 smokers between 2008-2011 to define subtypes of smoking related lung disease and their genetic associations. HRCT of the chest, DNA, medical history, and diabetes status (self-report or taking antidiabetic medications) were obtained. Two readers visually scored spine imaging on HRCT for DISH, based on Resnick criteria. Genotyping was performed using the Illumina Omni-Express Chip. An 83 SNP T2D GRS, a 43 SNP fasting glucose GRS, and a 22 SNP fasting insulin GRS based on validated GWAS loci, alone and in combination, were calculated. In the combined GRS, each SNP was used once. Univariate analyses between age, sex, race, BMI and DISH were performed. A logistic regression model adjusted for age, sex, race, and BMI was used to estimate the association of each GRS with DISH.

Results: We analyzed 437 DISH cases and 2,680 controls among men and women in the COPDGene study who had available HRCTs of the chest. See Table 1 for odds ratios (OR) for the univariate and multivariate models. In the univariate analysis, DISH was associated with male sex, increasing age, and the T2D phenotype (Table 1). The T2D GRS was associated with diabetes (OR 1.05, 95% CI 1.03-1.07, P<0.0001). None of the four GRSs tested (T2D, fasting insulin, fasting glucose, combination) were associated with DISH (Table 1).

Table 1. Association between DISH, clinical features and GRSs

Variable	Odds Ratio	Adjusted* Odds Ratio	Confidence* Interval	P-value for adjusted model*
Age (years)	1.06	1.07	1.06-1.08	<0.0001
Sex (male)	2.96	3.51	2.73-4.50	<0.0001
Race (non-Hispanic White)	1.52	.94	0.72-1.24	<0.0001
BMI (kg/m^2)	1.09	1.12	1.10-1.14	<0.0001
Diabetes status	2.64	1.49	1.13-2.0	0.005
T2D GRS	0.99	0.99	0.97-1.01	P=0.44
Fasting glucose GRS	0.98	1.01	0.98-1.04	P=0.51
Fasting insulin GRS	1.01	1.00	0.96-1.04	P=0.85
Combined GRS	0.99	1.00	0.98-1.02	P=0.96

***Adjusted for age, gender, race, BMI**

Conclusion: This is the first study to use GRS to examine the link between DISH and diabetes related traits. T2D genes are not associated with DISH despite a correlation to T2D, arguing against a genetic relationship. The previously reported associations of DISH with T2D may be due to the effects of increased levels of circulating proteins produced in diabetics, such as insulin and osteocalcin, on the bone formation pathway. The role of smoking remains to be explored. Further studies are warranted to better elucidate the mechanisms that associate diabetes with DISH.

Session Title: Miscellaneous Rheumatic and Inflammatory Diseases II

Session Type: ACR Concurrent Abstract Session

Session Time: 4:30PM-6:00PM

Background/Purpose: Deficiency of adenosine deaminase 2 (DADA2) is an autosomal recessive autoinflammatory disease resulting from a loss-of-function mutation in Cat Eye Syndrome Chromosome Region Candidate 1 (*CERC1)* gene encoding for ADA2 protein. Patients present with systemic inflammation and vasculopathy. In this study, we presented the characteristics of the pediatric and adult DADA2 cases.

Methods: Clinical and laboratory features of thirteen DADA2 patients (8 Male, 5 Female), diagnosed at Hacettepe University Pediatric and Adult Rheumatology Department between 2014-2016, have been summarized. Mutations in *CECR1* were detected by Sanger sequencing.

Results: Ten patients were homozygous for G47R; one was compound heterozygous for G47R and G47V while two patients were heterozygous for G47R mutation. Nine patients had been followed up with the diagnosis of polyarteritis nodosa (PAN). There was consanguinity in 6 cases, and 2 were siblings. The median (min-max) age at onset of the symptoms and diagnosis was 6.5 (1.5-35) and 17 (3-45) years, respectively. All patients suffered from recurrent episodes of fever and abdominal pain with elevated acute phase reactants. Livedo reticularis (n= 12, (92.3%)), erythema nodosum (n=6, (46.2%)), raynaud's phenomenon (n=4, (30.8%)) and digital ulcers (n=1, (7.7%)) were common skin manifestations. Neurological and musculoskeletal involvement was; in the form of myalgia (n = 13, (100%)), arthralgia (n= 12, (92.3%)), arthritis (n= 9, (69.2%)), peripheral neuropathy (n=7, (53.8%)), ischemic stroke (n=7, (53.8%)), strabismus (n=5, (38.5%)), hemorrhagic stroke (n=2, (15.4%)), spinal cord atrophy (n = 1, (7.7%)), and optic neuritis (n = 1, (7.7%)) . One patient had been diagnosed with core myopathy through co-incidental muscle biopsy finding. Eight patients had aneurysms in medium-sized abdominal visceral arteries (hepatic artery, renal artery, and superior mesenteric artery). As renal involvement, one patient had focal segmental glomerulosclerosis (collapsing variant), one mesangial proliferative glomerulonephritis, and one had renal amyloidosis. There was testicular involvement in 3 (23.1%) patients and one had testicular torsion. One patient had intestinal perforation. Two adult patients died soon after diagnosis of DADA2. One patient was asymptomatic on only colchicine for almost 10 years. Rest of the patients responded well to etanercept therapy.

Conclusion: ADA2 deficiency is a recently defined disease and the data about its phenotype increases with the introduction of new cases with different symptoms. Stroke, peripheral neuropathy, livedo reticularis, myalgia, recurrent episodes of fever and recurrent abdominal pain are important findings to suspect DADA2. In our series, we have described for the first time spinal cord atrophy, core myopathy, and mesangial proliferative glomerulonephritis in DADA2 patients.

Rheumatologic Consequences of Immunotherapy to Treat Malignancies: The Tip of an Iceberg

Background/Purpose: Immune checkpoint inhibitors (ICIs) targeting cytotoxic T-lymphocyte-associated protein 4 (CTLA-4) and programmed cell death protein 1 (PD-1) pathways are increasingly used to treat multiple malignancies and prolong survival. By activating T-cells, ICIs also cause immune-related adverse events (IRAEs). Rheumatic IRAEs are not well described. We report our initial experiences with ICI-induced inflammatory arthritis, crystalline arthritis and sicca syndrome.

Methods: We report patients seen in Johns Hopkins Rheumatology clinics from 2012-2016 with new rheumatic symptoms during or following treatment with anti-CTLA-4 and/or anti-PD-1 therapy for solid tumors.

Results: We identified 17 patients receiving selected ICIs and developing rheumatic IRAEs (table 1). Mean age was 59.5 years. Cancer types included melanoma, non-small cell lung cancer, small cell lung cancer, colon cancer and renal cell carcinoma. ICI regimens included anti-PD-1 or anti-CTLA-4 monotherapy (n=8) or combination therapy (n=9). Eleven of 17 patients developed 3 subtypes of inflammatory arthritis (RA-like symmetrical polyarthritis, reactive arthritis, oligoarticular large joint arthritis); and 5/5 with arthrocentesis had inflammatory synovial fluid (WBC range 9854-28,400 cells/mm^3, >70% PMNs); 5 had confirmatory imaging (3 ultrasound, 1 MRI, 1 CT). RF and CCP were negative in these arthritis patients. Two patients developed new pseudogout or gout confirmed by joint aspiration or dual energy CT. Four patients developed severe sicca with marked salivary hypofunction. Non-rheumatic IRAEs experienced included: pneumonitis, colitis, interstitial nephritis, hypophysitis and thyroiditis. ANAs were positive in 6/17. Corticosteroids were given to 9/11 patients with inflammatory arthritis, several requiring prednisone >1 mg/kg. Three patients required methotrexate and anti-TNF therapy for inflammatory arthritis.

Conclusion: This is the largest series to our knowledge of inflammatory arthritis and the first report of sicca syndrome and crystalline arthritis due to ICIs. These rheumatic IRAEs cause severe symptoms, and arthritis may require significantly higher doses of steroids for management than for usual inflammatory arthritis. As ICIs are increasingly used for a range of malignancies, new cases of rheumatic IRAEs will likely emerge, and rheumatology referrals will increase. Further research is needed to understand mechanisms, determine risks, and develop management algorithms. Table 1: Demographic features, cancer types, and immunotherapy of included patients.

Patient	Age	Sex	Race	Type of malignancy	Cancer therapy	Rheumatic IRAE	Best overall response (RECIST 1.1)
1	58	Male	Caucasian	Renal cell carcinoma	Anti-PD-1 Anti-CTLA-4	Inflammatory arthritis	Stable disease

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016
Session Title: Miscellaneous Rheumatic and Inflammatory Diseases II
Session Type: ACR Concurrent Abstract Session
Session Time: 4:30PM-6:00PM

Background/Purpose: To analyze the potential use of the main features at diagnosis (epidemiological, clinical, laboratory) as prognostic factors and to estimate the risk of death in adult patients with hemophagocytic syndrome (HS).

Methods: In June 2013, the Spanish Autoimmune Diseases Study Group (GEAS-SEMI) created a national registry (REGHEM) of adult patients with HS. Patients were diagnosed according to fulfillment of the criteria of the Histiocytosis Society proposed in 1991 and updated in 2004. The HScore, a prognostic score, which includes 9 clinical, laboratory and histopathological features and ranges from 0 to a maximum of 337 points, was calculated at diagnosis. Time-to-event analyses for death are presented as Kaplan-Meier curves.

Results: By January 2016, the REGHEM registry included 116 adult patients with HS, 68 (59%) men and 48 (41%) women, with a mean age at diagnosis of 49 years (range 14-84 years); 19 (16%) were not born in Spain. The main underlying diseases were chronic infections in 20 (17%) cases, autoimmune/rheumatologic disease in 33 (28%), neoplasia in 23 (22%) and transplantation in 4 (3%); the remaining 36 (31%) patients had no identifiable underlying disease. Sixty-one (53%) patients died. Patients who died were more frequently male (69% vs. 47% in survivors, p=0.03), had a higher mean value of serum ferritin (6662 vs. 3570 ng/mL, p=0.028), a lower mean hemoglobin value (7.6 vs. 8.3 g/dL, p=0.021), a lower mean white blood cell count (1570 vs. 2450 $x10^6$/L, p=0.022), a lower mean platelet count (24000 vs. 66000 $x10^6$/L, p<0.001), and a higher mean HScore compared with survivors (230 vs. 205, p=0.05). Survival Kaplan-Meier curves (**Figure 1**) showed that the highest survival rate was in patients with underlying chronic infections while the poorest survival was found in patients with underlying neoplasia (HR 2.41, 95% CI 1.09-5.3).

Conclusion: Hemophagocytic syndrome is a multisystemic disease that remains fatal in > 50% of adults. Survival was significantly reduced in males, and in patients with underlying neoplasia, high ferritin values, severe cytopenias and high HScores. These prognostic factors could help identify patients at greater risk of death, who could benefit from more aggressive specific treatment of

potential triggers and intensive supportive care.

SESSION INFORMATION
Session Date: Tuesday, November 15, 2016
Session Title: Miscellaneous Rheumatic and Inflammatory Diseases II
Session Type: ACR Concurrent Abstract Session
Session Time: 4:30PM-6:00PM

Background/Purpose: Macrophage activation syndrome (MAS) constitutes over 5% of multi-organ dysfunction syndrome in adults, leading to 60-70% mortality without early treatment. H-Score, the only validated diagnostic tool in adults, is often too complex for bedside use. Our objective was to determine clinical predictors of MAS and build a simple yet accurate risk calculator for use by clinicians to facilitate early recognition.

Methods: Electronic Health Records were used to identify patients hospitalized at a single academic center between 2009-12 with

serum ferritin levels (SFL) of ≥ 2,000 ng/dL. Patients with chronic hemolytic disorders and those receiving chronic transfusions were excluded. Diagnosis of MAS was determined using a) ≥ 5/8 of HLH-2004 or ≥4/5 of adapted HLH-2004 criteria, or b) H score of ≥169, or c) treatment modified specifically for MAS. Control patients met none of these criteria. Organ Dysfunction and INfection (ODIN) definitions determined presence of organ dysfunction. Coagulopathy was determined based on score of ≥4 on "International Society of Thrombosis and Hemostasis Diagnostic Algorithm". Hepatobiliary dysfunction was defined as ≥2 of: ALP, ALT, AST elevation more than 3 times normal limits, or bilirubin ≥ 5.8 mg/dL (sepsis definitions). The optimum SFL cut point was identified based on prediction accuracy for MAS at various thresholds. Following standard univariate analysis, logistic regression determined independent predictors of MAS. Parameter estimates were used for a weighted risk score for MAS.

Results: Of the 527 hyperferritinemic patients identified, 67 MAS cases [70% women, 60% non-white, median age 41 (18-83)] were identified; 69 controls with similar demographics were selected from remaining patients [67% women, 60% non-white, median age 42 (19-84)]. Univariate analysis of clinical and outcome parameters associated with presence of MAS is presented in Table-1. A SFL cut-off of 5,000ng/dL had maximal accuracy predicting MAS. Independent predictors of MAS were coagulopathy, hematologic dysfunction, SFL≥ 5,000 ng/dL, and fever≥ 101.3° F. Using a simple count of signs positive, MAS incidence was 0% (0/19) in patients with 0 signs positive versus 93% (27/29) in patients with 4 signs positive ($p<.0001$).

Conclusion: MAS increases the need for critical care admission and intervention. Presence of 3 of: coagulopathy, SFL≥ 5,000, cytopenia, or fever≥ 101.3° F should alert the clinicians to the possibility of MAS in hospitalized patients.

Table 1. MAS is significantly associated with higher likelihood of fever, elevated ferritin level, organomegaly, and organ dysfunction, as well as higher probability of death, prolonged hospitalization, and higher need for critical interventions.

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016

Session Title: Rheumatoid Arthritis – Clinical Aspects V: Challenges in the Assessment and Management of Established RA

Session Type: ACR Concurrent Abstract Session

Session Time: 4:30PM-6:00PM

Background/Purpose: Discordance between patient and physician assessment of rheumatoid arthritis (RA) disease activity strongly associates with pain scores. Patient-reported outcomes measurement information system (PROMIS) 29 is recommended as the preferred battery of measures to collect in musculoskeletal pain studies. We evaluated the discordance between Routine Assessment of Patient Index 3 (RAPID3) and Clinical Disease Activity Index (CDAI) and investigated the associations between RA activity measures, discordance and patient-reported outcome measures using PROMIS29.

Methods: For RA subjects enrolled in the University of Pittsburgh Rheumatoid Arthritis Comparative Effectiveness Registry (RACER), a cross-sectional analysis was performed for all RACER patients who completed PROMIS29 short form and had RAPID3 and CDAI recorded. Association between CDAI and RAPID3 was evaluated by the percentage of agreement, Pearson¡¯s correlation coefficient, and kappa statistics. For subjects in remission/low disease activity by CDAI who had RAPID3 scores (0-10) consistent with near remission or low disease activity (¡Â 2) versus moderate or high disease activity (>2), predictors were

determined using logistic regression.

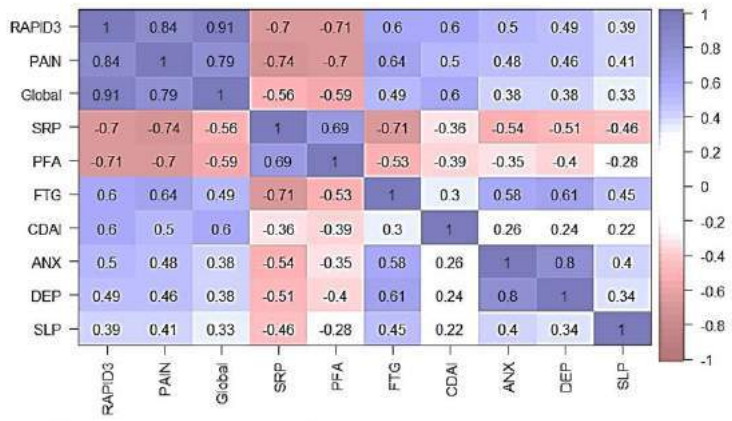
Results: For the 363 subjects analyzed, age was 64.2 +/- 13.8 (mean +/- SD) years with disease duration of 13.9 +/- 13.1 years. CDAI was moderately correlated with RAPID3 (r=0.60, p<0.0001). PROMIS domains were correlated with RAPID3 and CDAI with various degrees (Figure). RAPID3 had strongest correlation with pain intensity (r = 0.89, p<0.001) and pain interference (r=0.84, p<0.001). Overall agreement between disease severity categories of CDAI and RAPID3 were fair (percent agreement = 40.1, kappa=0.21) (Table). In subjects with remission to low disease activity by CDAI, pain intensity (standardized regression coefficient beta = 1.33, p<0.001) and physical function (beta = -0.21, p<0.001) among PROMIS29 domains predicted discrepancies between CDAI and RAPID (Akaike information criterion (AIC) =110.2). When pain intensity and physical function were removed from the model, pain interference (beta = 0.18, p<0.001 and impaired social roles (beta = -0.11, p=0.001) predicted discrepancies (AIC = 168.9).

Conclusion: Discordance between CDAI and RAPID3 was frequent, especially among subjects with remission/low disease activity by CDAI. These subjects were predicted by PROMIS29 measures associated with pain intensity. Our data suggest that PROMIS29 helps to understand the discordance between patient and physician assessment of disease activity.

Table. Disease activity categories by Routine Assessment of Patient Index 3 (RAPID3) and Clinical Disease Activity Index (CDAI)

	CDAI			
RAPID3	Remission	Low	Moderate	High
Near remission	**35**	16	3	0
Low	13	**27**	7	0
Moderate	12	59	**43**	4
High	0	43	63	**33**

Figure. Correlation among PROMIS29 domains, RAPID3, and CDAI



RAPID3: Routine Assessment of Patient Index, CDAI: Clinical Disease Activity Index, PAIN: pain interference, Global: pain intensity, SRP: abilities to participate in social roles and activities, PFA: physical function, FTG: fatigue, ANX: anxiety, DEP: depression, SLP: sleep disturbance

SESSION INFORMATION
Session Date: Tuesday, November 15, 2016
Session Title: Rheumatoid Arthritis – Clinical Aspects V: Challenges in the Assessment and Management of Established RA
Session Type: ACR Concurrent Abstract Session
Session Time: 4:30PM-6:00PM

Background/Purpose: Rheumatoid arthritis, is the leading cause of disability and chronic pain. Psychiatric disorders such as depression and anxiety adversely impact reported pain and may also be influenced by systemic inflammation. We conducted a comprehensive, longitudinal investigation to assess the association of depressive and anxiety disorders, including severity of symptoms, with subjective and physician-assessed indicators of arthritis severity among outpatients with recent onset inflammatory arthritis.

Methods: Data included 148 subjects (mean age = 57.7, 72% female) from a prospective longitudinal Early Arthritis Cohort (<12 months symptoms at baseline) from 2012 to 2015. Presence of anxiety or depressive disorder was indicated via self-report annually, and severity of psychiatric symptoms was assessed using the Patient Reported Outcomes Measurement Information System (PROMIS) scales each visit. Arthritis activity indicators included patient reported visual analogue scales for pain fatigue, and functional status (modified health assessment questionnaire; mHAQ), physician global disease activity, swollen 28 joint count, tender 28 joint count, Lansbury weighted joint count, erythrocyte sedimentation rate (ESR), c-reactive protein (CRP), and composite indices (DAS28ESR-3variable, Clinical Disease Activity Index (CDAI)). Patients were re-assessed at each visit (visit range = 1 thru 7 visits, median (IQR) months followed 18(11,22)). Linear regressions and bivariate and partial correlations (controlling for number of visits and presence of a current mood or anxiety disorder for symptom-based analyses) first examined the cross-sectional relationship between mental health variables and indicators of arthritis severity. Linear regressions controlling for number of visits examined the longitudinal relationship between change in mental health symptoms on indicators of arthritis severity. Only results significant at the 0.01 level are reported to adjust for multiple comparisons.

Results: The presence of a current mood or anxiety disorder was reported by 10.7% and 6.3%, respectively, of the cohort at any time. Fatigue was associated with both a mood disorder (*Beta* = 0.27, t (202) = 4.025, $p < 0.001$) and anxiety disorder (*Beta* = 0.197, t (197) = 2.814, $p < 0.01$). Increasing severity of anxiety and depressive symptoms were significantly associated with pain, fatigue, CDAI, tender joint count, mHAQ and the Lansbury index (r range = 0.156-0.514). Severity of depressive symptoms were associated with ESR, DAS28 and CRP. When controlling for the presence of a mood or anxiety disorder and number of visits, most associations remained statistically significant. Worsening of anxiety (*Beta* = 0.212, t (314) = 3.85, $p < 0.001$) and depressive symptoms (*Beta* = 0.207, t (314) = 3.75, $p< 0.001$) over time were significantly associated with CRP values.

Conclusion: Indicators of disease severity were impacted by mental health factors, particularly severity of chronic pain and fatigue. Severity of mental health symptoms were a better indicator of disease severity than the presence of a psychiatric disorder alone. These findings have important implications for screening, prevention, and treatment.

Session Title: Rheumatoid Arthritis – Clinical Aspects V: Challenges in the Assessment and Management of Established RA

Session Type: ACR Concurrent Abstract Session

Session Time: 4:30PM-6:00PM

Background/Purpose: Depression and anxiety are reported to predict poorer treatment outcomes in rheumatoid arthritis (RA).[1] Whether this can be confirmed in larger, prospective studies as well as in psoriatic arthritis (PsA) remains to be explored. In this study we aimed to assess if baseline depression/ anxiety is associated with remission rates in RA and PsA.

Methods: From the prospective, multicenter NOR-DMARD study we included RA and PsA patients starting first-time tumor necrosis factor inhibitors (TNFi) and DMARD naïve patients starting methotrexate between 2006 and 2012. Depression/anxiety was assessed using the EuroQoL (EQ5D) question 5. The predictive value of baseline moderate/extreme depression/anxiety (present/absent) on remission after 3 and 6 months treatment was explored in prespecified logistic regression models adjusted for age, sex, disease duration and smoking.

Results: A total of 1450 RA/ 805 PsA patients were included (mean (SD) age 54.4 (13.5)/ 48.0 (12.4) years, median (25^{th}-75^{th} percentile) disease duration 0.4 (0.0-5.0)/ 1.0 (0.1-6.8) years, 68.7/ 50.7% females and 28.6/ 28.6% current smokers). Similar percentages of RA and PsA patients reported to be moderately (40.7 vs. 40.7%)/ extremely (2.8 vs. 3.0%) depressed/ anxious at baseline (p=0.98). Baseline depression/ anxiety negatively predicted DAS28<2.6, SDAI≤3.3 and ACR/EULAR Boolean remission after 3 and 6 months treatment in RA (table 1). Corresponding findings in PsA were less consistent (table 2). In subgroup analyses of TNFi and methotrexate treated patients depression/ anxiety was found to be negatively predictive of remission at 6 months in RA, but not in PsA (table 1-2). **Table 1**

		Odds ratio (95%CI) for remission when depressed/ anxious at baseline (logistic regression analyses)		
		All RA patients	**RA patients treated with TNFi with or without methotrexate**	**DMARD naïve RA patients treated with methotrexate**

Table 2

		Odds ratio (95%CI) for remission when depressed/ anxious at baseline (logistic regression analyses)		
		All PsA patients	PsA patients treated with TNFi with or without methotrexate	DMARD naïve PsA patients treated with methotrexate
After 3 months	DAS28ESR < 2.6	0.73 (0.49-1.1) p=0.13	0.79 (0.42-1.48) p=0.46	0.67 (0.38-1.18) p=0.16
	SDAI ≤ 3.3	0.62 (0.39-0.97) p=0.04	0.61, (0.34-1.11) p=0.11	0.58 (0.27-1.22) p=0.15
	ACR/EULAR Boolean	0.52 (0.31-0.86) p=0.01	0.43 (0.22-0.85) p=0.02	0.64 (0.28-1.44) p=0.28
	DAPSA < 4	0.45 (0.28-0.72) p=0.001	0.44 (0.23-0.81) p=0.009	0.45 (0.21-0.95) p=0.04
After 6 months	DAS28ESR < 2.6	0.92 (0.60-1.41) p=0.69	0.93 (0.47-1.85) p=0.85	0.93 (0.52-1.65) p=0.80
	SDAI ≤ 3.3	0.69 (0.44-1.08) p=0.11	0.65 (0.33-1.27) p=0.21	0.81 (0.43-1.50) p=0.50
	ACR/EULAR Boolean	0.63 (0.39-1.03) p=0.07	0.81 (0.40-1.64) p=0.56	0.53 (0.26-1.05) p=0.07
	DAPSA < 4	0.66 (0.42-1.03) p=0.07	0.69 (0.36-1.34) p=0.28	0.67 (0.36-1.26) p=0.21

Conclusion: Baseline depression/ anxiety may reduce likelihood of remission in RA. Whether this also is the case in PsA needs to be explored in larger patient samples and using validated remission criteria. Depression and anxiety are factors with potential impact for disease outcome and should be considered in routine care and in treat-to-target strategies. 1 Matcham F, Norton S, Scott DL, et al. Symptoms of depression and anxiety predict treatment response and long-term physical health outcomes in rheumatoid arthritis: secondary analysis of a randomized controlled trial. *Rheumatology (Oxford)* 2016;55:268-78.

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016

Session Title: Rheumatoid Arthritis – Clinical Aspects V: Challenges in the Assessment and Management of Established RA

Session Type: ACR Concurrent Abstract Session

Session Time: 4:30PM-6:00PM

Background/Purpose: Opiate use has come under increasing scrutiny related both to over-use and under-use. The patterns of opiate use over time in a population-based cohort of patients with inflammatory diseases such as rheumatoid arthritis (RA) have not been well characterized. We used health plan data to characterize both trends over time as well as variability in individual physician prescribing of short and long term opiates.

Methods: We used national Medicare data from 2006-2014 and identified a closed cohort of RA patients by requiring two diagnosis codes (ICD9 714.0, 714.2, 714.81) from rheumatologists separated by 7 days. To be included in the analysis, patients must have at least 6 consecutive observable months (enrolled in Medicare Part A, Part B and Part D coverage, not enrolled in Part C) prior to 1/1/2007. Follow up started at 1/1/2007 and end at the earliest of: dis-enrollment, 90 days before death, or end of study (12/31/2014). Any oral opiates use (one or more filled prescriptions) was assessed every six months for patients who remained under follow-up over the entirety of each 6 month interval. Generalized estimating equations with repeated measure was used to calculate odds ratios for the receipt of opiates in each 6 month interval. A separate cohort was created using 2014 Medicare data to assess the variability in prescribing opiates among rheumatologists for their RA patients (assigned based on at least one physician encounter in 2014 with an RA diagnosis code). We restricted this analysis to rheumatologists with at least 10 RA patients enrolled in Medicare for the entire year. The proportion of RA patients using opiates was calculated by dividing RA patients with at least two opiate prescriptions in 2014 by the total number of RA patients treated by each U.S. rheumatologist.

Results: For the longitudinal analysis, we identified 73,834 RA patients meeting eligibility criteria. Patient characteristics were (mean age 67.6 (12.2), 80.0% Female, 80.1% White, 12.3% Black). In 2006, the most commonly used opiates were medications that combined acetaminophen with hydrocodone or with propoxyphene (withdrawn from U.S. in 2010). Over 2006-2014, trends (Figure) showed overall opiate use increased slowly but significantly and reach a peak in 2010, and decreased thereafter. Following the withdrawal of propoxyphene in 2010, use of hydrocodone and tramadol increased commensurately such that overall opiate use declined only slightly. Factors associated with opiate use included younger age, female, white race, disability, lower income and baseline NSAID use. In 2014, practice-level variability between U.S. rheumatologists (n=4,900) in the use of opiates for their RA patients was high. In rheumatology practices at the 50th percentile, 46% of RA patients used opiates. The proportion of patients using opiates at the 25th and 75th percentiles was 37% and 55%, respectively. At the extremes (1st and 99th percentile), 0-92% of RA patients within each rheumatologist's practice were treated with opiates. However, among all patients in the analysis, only 43% of RA patients had any of their opiate prescriptions written by a rheumatologist.

Conclusion: In the US, opiate use peaked in RA patients in 2010 and is now undergoing slight declines. There was substantial variability between rheumatologists in the proportion of their RA patients using opiates, although fewer than half of patients had their opiate prescriptions written by rheumatologists. Withdrawal of the 2nd most commonly used opiate (propoxyphene) from the U.S. market in 2010 had minimal effect on overall use, as it was replaced with greater use of other opiates.

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016

Session Title: Rheumatoid Arthritis – Clinical Aspects V: Challenges in the Assessment and Management of Established RA

Session Type: ACR Concurrent Abstract Session

Session Time: 4:30PM-6:00PM

Background/Purpose : Obesity has been associated with worsened RA outcomes and increased disease activity. However, few longitudinal studies have investigated whether weight loss might improve RA disease activity. We hypothesized that weight loss improves RA disease activity in routine clinical care.

Methods : We conducted a retrospective cohort study among RA patients that met 1987/2010 ACR criteria at a single academic medical center from 2012 to 2015. We included patients with at least two Clinical Disease Activity Index (CDAI) measures and corresponding body mass index (BMI) measures at routine clinic visits. We collected data on sociodemographic, lifestyle, medications, laboratory values, and RA characteristics at each clinic visit. We identified the maximum and minimum weight for each individual to calculate Δweight, as well as corresponding CDAI measures at these visits to calculate ΔCDAI. We defined significant weight loss as losing ≥5 kg, and a significant improvement in disease activity as ≥5 point improvement in CDAI (validated as the minimally clinically important difference, MCID). We used logistic regression to estimate the odds ratio (OR) for improved disease activity according to significant weight loss and baseline BMI category. We used linear regression to evaluate the association between Δweight and ΔCDAI among those who were overweight/obese and lost at least 1 kg.

Results : We identified 178 RA patients to include in the study. There were a total of 854 clinic visits, with a median of 5 visits per patient (range 2-11) in 1.8 years (IQR 1.3-2.4) of follow-up. Mean age at baseline was 60.2 years (SD 13.5) and median time for Δweight was 1.1 years (IQR 0.6-1.5). At baseline, 66% were overweight/obese, mean RA duration was 11.9 years (SD 9.5), 78% were seropositive, and mean CDAI was 11.6 (SD 9.2) with 42% in high/moderate disease activity by CDAI. Patients who were overweight or obese and lost >5 kg had three-fold increased odds of disease activity improvement by MCID compared to those who did not lose 5 kg (OR 3.03, 95%CI 1.18-7.83, **Table**). Among those who were obese/overweight at baseline, for each kg of weight lost, CDAI decreased by 1.15 (95% CI -1.88, -0.42; p=0.0026, **Figure**), adjusted for age, sex, RA duration, smoking, steroid use, serostatus, and time for weight loss.

Conclusion : These results suggest that weight loss may be associated with improved disease activity in patients with RA in a routine clinical setting. Weight loss has the potential to be a non-pharmacologic intervention to improve RA disease activity. Further studies of weight loss interventions and RA disease activity are necessary to confirm these results in other populations.

Table. Odds ratio for significant RA disease activity improvement (≥5 point improvement in CDAI) according to significant weight loss (≥5 kg) and BMI category at baseline (n=178).

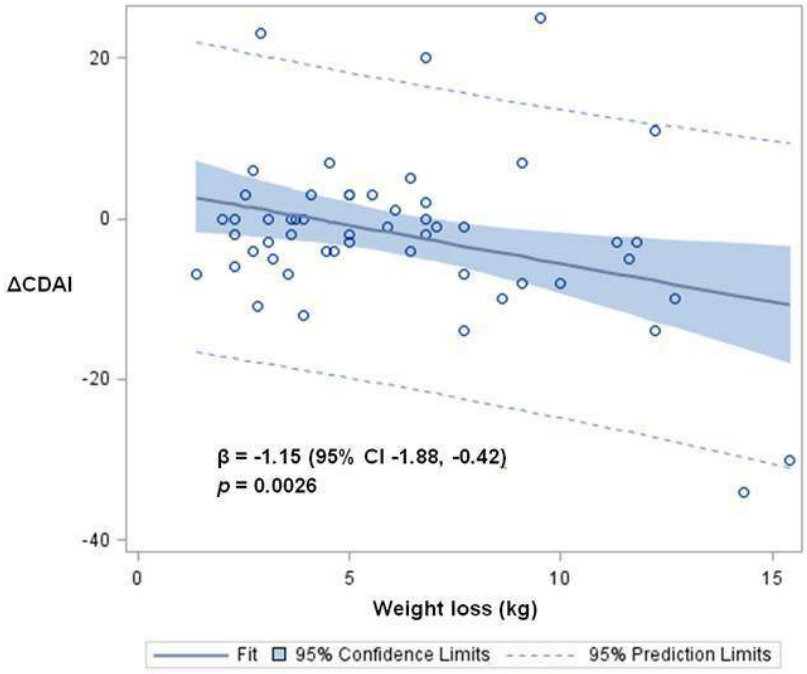
Weight loss and baseline BMI category	Outcomes / Total in category (n)	OR (95% CI)*
Did not lose 5 kg and overweight/obese at baseline	18 / 93	1.0 (Ref)
Lost 5 kg and overweight/obese at baseline	10 / 24	**3.03 (1.18-7.83)**
Did not lose 5 kg and normal BMI at baseline	19 / 57	1.90 (0.88-4.11)
Lost 5 kg and normal BMI at baseline	0 / 4	**

*Adjusted for sex

**No one in this category had disease activity improvement so we were unable to estimate the odds ratio. Weight loss was defined as the difference between the maximum and minimum weights (kg) at routine clinical visits. ΔCDAI was calculated using measures at these corresponding clinic visits.

BMI, body mass index; CDAI, Clinical Disease Activity Index; CI, confidence interval; OR, odds ratio; RA, rheumatoid arthritis

Figure. Scatterplot of weight loss vs. ΔCDAI among patients with rheumatoid arthritis who were overweight or obese at baseline and lost any weight* during follow-up (n=53).



*Weight loss was defined as the difference between the maximum and minimum weight (in kg) measures at routine clinic visits. ΔCDAI was calculated using measures at the corresponding clinic visits. The linear regression model was adjusted for age, sex, RA duration, smoking (ever/never at baseline), serostatus (seropositive/seronegative), steroid use (ever/never at baseline), and time for weight loss.

Session Title: Rheumatoid Arthritis – Clinical Aspects V: Challenges in the Assessment and Management of Established RA

Session Type: ACR Concurrent Abstract Session

Session Time: 4:30PM-6:00PM

Background/Purpose: Despite the availability of safe and effective treatments and the establishment of treatment guidelines, real-world effectiveness remains suboptimal largely due to low patient adherence with prescribed treatment. The purpose of this study was to systematically evaluate sociodemographic, health insurance, and disease-related factors associated with non-adherence with anti-rheumatic medications (ARM) in a large observational cohort of RA patients followed in Canadian routine clinical care.

Methods: RA patients enrolled in the Ontario Best Practices Research Initiative (OBRI) clinical registry and had at least two years of follow-up were included in the analysis. Non-adherence with treatment was defined as ARM discontinuation due to the patient non-adherence. Independent predictors of non-adherence with ARM were evaluated with multivariate cox-regression using both time-fixed and time-dependent variables. Factors considered included patient sociodemographics (age, gender, race, education status, annual income, smoking history), health insurance information (private vs. non-private, % coverage), disease parameters (RA duration, presence of erosion, RF positivity, DAS28, physician global, HAQ-DI, number of comorbidities), types of medications used, and physician characteristics (gender, academic position, urban vs. rural, distance from patient's residence).

Results: A total of 1,762 patients were included in the analysis with a mean (SD) age of 57.4 years and disease duration of 8.5 (9.3) at the time of enrolment to the registry (baseline). At baseline, the majority of patients were female (77.7%), Caucasian (85.1%), had post-secondary education (55.3%), and had private insurance (67.2%). In terms of disease severity, 54.5% had a prior erosion, 69.5% were RF positive, and mean (SD) DAS28 was 4.5 (1.5). Table 1 shows the association between all factors considered in the analysis and non-adherence with ARM. In multivariate analysis, married status, RF positivity and higher number of comorbidities were identified as significant predictors of increased adherence while higher physician global score, NSAID use, and polypharmacy were associated with non-adherence. **Table 1: Independent Predictors of Patient Non-Adherence with ARM**

Conclusion: In this systematic approach to identify factors associated with patient non-adherence with ARM, a variety of factors encompassing sociodemographic, disease, and medication characteristics, were identified as significant independent predictors of non-adherence. These results should be taken into consideration when developing patient adherence support programs and in the choice of treatment regimens.

Predicting the Response to TNF Inhibition or B Cell Depletion Therapy from Peripheral Whole Blood Gene Expression Profiles in Patients with Rheumatoid Arthritis

Session Title: Rheumatoid Arthritis – Small Molecules, Biologics and Gene Therapy IV: Biomarkers

Session Type: ACR Concurrent Abstract Session

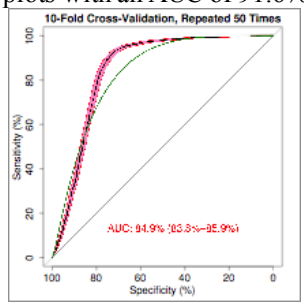
Session Time: 4:30PM-6:00PM

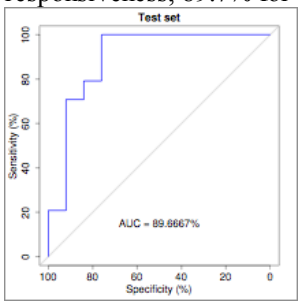
Background/Purpose: The ORBIT study demonstrated that rituximab is non-inferior to a TNFi-first strategy in biologic naive, sero-positive patients with active RA over 12 months (Lancet doi.org/10.1016/S0140-6736(16)00380-9). However, a significant

proportion of patients failed to respond to their first biologic drug and switched to an alternative. The ability to identify and stratify these patients prior to treatment would improve patient care and optimise the use of scarce financial resources. The aim of this study was to identify peripheral blood transcriptional biomarkers in the ORBIT cohort that can predict subsequent response/non-response to biologic therapy.

Methods: RNA was sequenced (Illumina NextSeq 500) from the peripheral blood of 241 patients recruited to the ORBIT study, after depletion of ribosomal and globin RNA. 70% (n=169) of samples were used to develop response prediction models, and 30% (n=72) were reserved for validation. Clinical response was defined as a fall in DAS28-ESR of >1.2 units between baseline and three months. Multiple machine learning techniques were used to train models that predicted 1) general responsiveness to both TNFi and rituximab therapy 2) differential response to TNFi or rituximab therapy. Tenfold cross validation was used to train the models, which were then tested on the validation set.

Results: Three gene sets were identified using support vector machine (SVM) recursive feature elimination. These predicted: general responsiveness to both TNFi and rituximab therapy (8 genes), response to TNFi therapy (23 genes) or rituximab (23 genes) respectively. When tested on the validation set, these models resulted in ROC plots with an AUC of 91.6% for general responsiveness, 89.7% for TNFi response, and 85.7% for rituximab response.





ROC plot showing the performance of the 25-feature SVM RBF classifier predicting specific response of TNFi therapy. When the drug specific models were combined, the sensitivity, specificity, PPV and NPV for response prediction at 3 months were 96%, 91%, 96% and 92%, respectively. Patients who were predicted to respond at three months were also more likely to have a DAS28 good response (43% v 23%) or DAS28 remission (23% v 10%) at 12 months.

Conclusion: At baseline, whole blood transcriptomic profiles of biologic naive patients with sero-positive RA predict future responsiveness to TNFi and rituximab therapy. These signatures needs to be validated but if they prove to be robust they will herald a new stratified approach to treatment selection resulting in improved patient outcomes.

Session Title: Rheumatoid Arthritis – Small Molecules, Biologics and Gene Therapy IV: Biomarkers
Session Type: ACR Concurrent Abstract Session
Session Time: 4:30PM-6:00PM

Background/Purpose: Tofacitinib is an oral Janus kinase inhibitor for the treatment of RA. A novel automated quantification method for RA MRI-detected pathology using statistical shape modelling technology (RAMRIQ) provides a tool that may be even more responsive than the sensitive RAMRIS semi-quantitative standard.[1] We aimed to determine if early changes in RAMRIQ were predictive of subsequent MRI and radiographic damage progression in a study of tofacitinib for the treatment of early RA in methotrexate-naïve patients with minimal radiographic progression.

Methods: We used data from an exploratory, Phase 2 randomized controlled trial comparing tofacitinib, methotrexate, and the combination (n=109) in early active RA.[1] All patients met ACR classification criteria for active RA. MRI was performed at baseline, 1, 3, 6, and 12 months. A single centralized reader read all MRI data; data for each patient were randomized by time point, and read in the same sitting. We examined changes in synovitis, osteitis and erosions for RAMRIQ and RAMRIS at 1 and 3 months and performed univariate analyses on their relationship to RAMRIS, RAMRIQ, and radiographic progression (modified total Sharp score [mTSS]) at 12 months.

Results: Reduction in RAMRIQ synovitis and osteitis at 1 and 3 months were significantly associated with reduction in RAMRIS erosion progression at 12 months (Table). Improvement in RAMRIQ synovitis and osteitis at 1 and 3 months were also associated with reduction in radiographic progression at 12 months, while RAMRIQ erosions at 1 and 3 months were not significantly associated with radiographic progression (Table). Early changes in RAMRIS erosion at 1 and 3 months were associated with radiographic progression at 12 months (Table). Treatment with tofacitinib alone or in combination with methotrexate was also associated with reduced progression in RAMRIS erosions ($p=0.017$ and $p=0.007$, respectively).

Conclusion: In this study, sensitive automated detection demonstrated that change in synovitis and osteitis predict subsequent RAMRIS erosion and radiographic progression. Treatment with tofacitinib as monotherapy or in combination with methotrexate was also highly predictive of no progression of erosive damage. Because of its enhanced sensitivity, novel quantitative imaging analysis has the potential to change RA clinical trial design where assessing structural damage is an objective. **Reference: 1.** Conaghan et al. Ann Rheum Dis. 2016; 75:1024-33.

Table: Univariate analyses of the relationship between RAMRIQ and RAMRIS measurements at Month 1 and 3 and RAMRIS erosion and radiographic progression at Month 12.

Session Date: Tuesday, November 15, 2016

Session Title: Rheumatoid Arthritis – Small Molecules, Biologics and Gene Therapy IV: Biomarkers

Session Type: ACR Concurrent Abstract Session

Session Time: 4:30PM-6:00PM

Background/Purpose: Patients with RA develop bone and joint damage due to chronic inflammation that is mediated by a destructive synovial pannus.[1] The pannus is composed of inflammatory cell types that act in concert with resident activated

fibroblast-like synoviocytes to trigger bone and joint damage. Here we describe that blockade of IL-6 signaling by sarilumab, a human mAb blocking the IL-6Rα, decreased circulating markers associated with synovial inflammation and tissue damage in patients with active, moderate-to-severe RA with inadequate response to MTX from MOBILITY (NCT01061736).

Methods: Sera were analyzed using ELISAs at baseline and posttreatment through week 52 from a subset of patients (N=384) receiving placebo or subcutaneous sarilumab (150 or 200 mg every 2 weeks [q2w]) plus weekly MTX. Percent change from baseline in biomarkers was analyzed using nonparametric methods (ANOVA-type) to evaluate differences between treatment groups at each time point. For exploratory purposes, percent changes from baseline in biomarkers were also compared between ACR50 responders at week 24 using similar methods, separately by treatment group. *P* values <0.05 were considered significant.

Results: Both doses of sarilumab significantly decreased markers of tissue destruction and synovial inflammation relative to placebo as early as week 2, with greater reductions observed at week 24 (Table). For most biomarkers, numerically greater differences from baseline were observed in the sarilumab 200 mg q2w group vs the sarilumab 150 mg q2w group. When changes from baseline in biomarkers were examined according to ACR50 response at week 24, significantly greater reductions in chemokine (C-X-C motif) ligand 13, a marker of lymphoid RA synovial phenotype, and MMP-3, a marker of synovial inflammation, were observed in ACR50 responders relative to nonresponders in the sarilumab 150 mg q2w group. Additionally, ACR50 responders demonstrated greater posttreatment reductions in collagen type I MMP-cleaved fragment (sarilumab 200 mg q2w group) and CRP (sarilumab 150 mg q2w group) compared with ACR50 nonresponders. Other biomarkers suppressed by sarilumab treatment (eg, RANK ligand) did not significantly differ by ACR50 response (not shown).

Conclusion: Sarilumab significantly reduced biomarkers of bone resorption and joint damage in patients with RA and an inadequate response to MTX. Differences in some biomarker levels observed between ACR50 responders and nonresponders suggest that the suppression of these biomarkers may contribute to a decrease in disease activity. **Reference: 1.** Srirangan et al. *Ther Adv Musculoskelet Dis*. 2010;2:247-256.

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016

Session Title: Rheumatoid Arthritis – Small Molecules, Biologics and Gene Therapy IV: Biomarkers

Session Type: ACR Concurrent Abstract Session

Session Time: 4:30PM-6:00PM

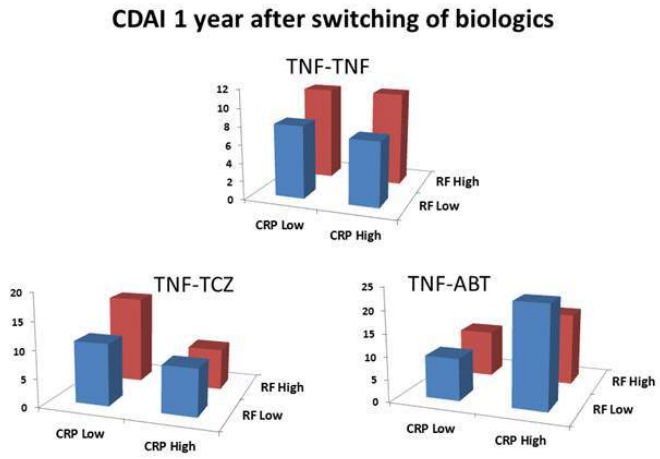
Background/Purpose: Eight biologics have been approved for rheumatoid arthritis (RA) in Japan. However, little is known regarding what to do when patients have an inadequate response to first biologics in daily clinical practice. This study aimed to evaluate the effectiveness of biologics as 2nd-line use in RA patients in daily clinical practice from our university cohort (FIRST registry).

Methods: We retrospectively examined more than 2500 patients who were treated with biologics in our institute between July 2003 and December 2015. We compared the effectiveness of TNF-inhibitors (TNFi), TCZ, ABA as 2nd-line use and efficacy of switching from 1st TNFi to 2nd TNFi, TCZ or ABA based on CDAI and biomarkers such as CRP, ESR and MMP3, IL-6 (LOCF). Propensity score (PS) were generated using multinomial logistic regression and the study groups were matched regarding baseline variables including age, disease duration, disease activity, concomitant use of MTX and PSL. In addition, in order to find out the characteristic of 2nd biologics, we conducted comparison between the upper (1yCDAI-H; low response) and lower (1yCDAI-L; good response) quartiles in CDAI at 1 y after switching.

Results: In terms of switching of biologics, CDAI at 1year was comparable among TCZ(n=141), 2ndTNFi（n=186）and ABT(n=91) after the adjustment by PS. Interestingly, comparison between the upper (1yCDAI-H) and lower (1yCDAI-L) quartiles in CDAI at 1 y after switching revealed that disease activity might improve despite of a high disease activity at switching in the case of TCZ. In addition, higher CRP, MMP-3 at switching were predictive factors for better outcome despite of higher RF factor in the case of switching to TCZ. Titer of Serum IL-6 but not TNF was markedly elevated in patients showed better outcome. In contrast, ABT showed a lower efficacy especially in the patients with RF low, CRP high. (Figure).

Conclusion: After adjustment using PS-score, RA patients with prior anti-TNF exposures had similar outcomes after switching. Our results imply us that CRP, MMP3 and RF titer at switching gives us important information for switching. Of note, higher CRP or MMP-3, suggesting inadequate suppression of IL-6 by first biologics, might predict better outcome of TCZ.

Figure: CDAI 1 year after switching biologics categorized by titer of CRP and RF at switching (cut off titer was defined using ROC



curve)

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016
Session Title: Rheumatoid Arthritis – Small Molecules, Biologics and Gene Therapy IV: Biomarkers
Session Type: ACR Concurrent Abstract Session
Session Time: 4:30PM-6:00PM

Background/Purpose: Considering the increased cardiovascular risk in RA patients and the influence of biologics, especially tocilizumab (TCZ) on the lipid profile, we aimed to investigate the differential effect of biologics on cardiovascular risk-associated biomarkers.

Methods: This ancillary study used serum samples at inclusion (M0) and 6 months (M6) of active RA patients inadequate responders to a 1st iTNF participating to the randomized ROC (Rotation or Change of Biotherapy, NCT01000441) trial, which compared EULAR response at M6 between a 2nd iTNF and another biologic (IV TCZ, abatacept or rituximab). At baseline and M6,

we assessed lipoprotein-related apoproteins ($ApoA_1$ and $ApoB_{100}$ reflecting mainly high density lipoprotein (HDL) and low density lipoprotein (LDL), respectively) and cardio-metabolic markers: lipoprotein(a) (Lp(a)) and adipokines (leptin and adiponectin) for the calculation of leptin/adiponectin ratio (LAR), that estimates insulin resistance. We compared the M0-M6 change of each marker between the 2nd iTNF group and the other biologic group and between the 2nd iTNF group and TCZ. We also compared this M0-M6 change according to the EULAR response in each group of treatment.

Results: From the 300 patients included in the ROC trial, 203 were tested due to the availability of the serum samples: 96 in the 2nd iTNF group and 107 in the other biologic group (47 TCZ, 26 abatacept and 34 rituximab). None of the measured markers deteriorated between M0-M6 in the two groups. Conversely, $ApoA_1$ level significantly increased in the 2nd iTNF group (+0.008 ±0.22g/L mean ±standard deviation, p<0.001) as well as in the other biologic group (+0.06 ±0.29 g/L, p<0.001). Lp(a) level only decreased in the other biologic group (-0.02 ±0.09 g/L, p=0,02), mainly due to TCZ (-0,06 ±0.08 g/L, p<0,001). TCZ also improved ApoA1 (+0.11 ±0.32 g/L, p <0.001) and adiponectin (+ 0,48 ±1.38 mg/L, p=0.02) levels. Compared to the 2nd iTNF group, Lp(a) and LAR decreased more in the other biologic group and Lp(a) and ApoA1 levels were improved in the TCZ group (Table 1). The improvement in the biomarkers level was mainly due to the EULAR responders in each group of treatment. Thus, Apo1 level increased with 2nd iTNF (+ 0.14 g/L difference between responders and non-responders, p=0,001), with other biologic (difference +0.1 g/L, p = 0.04) and with TCZ (difference +0.3 g/L, p=0.03).

Conclusion: In active RA patients in inadequate response to a 1st iTNF, cardiovascular risk-associated biomarkers did not deteriorate whatever the 2nd line of treatment and even improved in responders. Lp(a) and ApoA1 levels, both involved in atherogenesis, improved with a 2nd iTNF as well as with other biologics, but more with TCZ. This improvement seems driven by EULAR responders arguing for the control of RA as a major factor for cardiovascular risk improvement.

SESSION INFORMATION
Session Date: Tuesday, November 15, 2016
Session Title: Rheumatoid Arthritis – Small Molecules, Biologics and Gene Therapy IV: Biomarkers
Session Type: ACR Concurrent Abstract Session
Session Time: 4:30PM-6:00PM

Background/Purpose: Treatment with disease-modifying antirheumatic drugs (DMARDs) is considered the standard of care for rheumatoid arthritis (RA). Over the past two decades, major advances have occurred in the treatment of RA with development of biologic DMARDS including tumor necrosis factor (TNF) inhibitors. It is not well-studied in what sequence these biologic DMARDs are being offered in RA patients in recent years. We aimed to describe patterns of biologic DMARD treatment for RA and identify factors associated with initial and subsequent choice of biologic DMARDs.

Methods: We conducted a prospective cohort study using claims data from a US commercial health plan (2004-2013) and Medicaid (2000-2010). We identified patients who aged ≥18 years with two diagnoses of RA (ICD-9 diagnosis code 714.xx) that are 7-365 days apart, first of which was defined as the index diagnosis. We then identified three separate groups of patients based on their DMARD use in the 365 day period pre-index: 1) incident RA patients who were naïve to any DMARDs, 2) prevalent RA patients with or without non-biologic DMARDs but naïve to biologic DMARDs and 3) prevalent RA patients with prior use of a biologic DMARD. Multivariable logistic regression models examined the effect of patient demographics, clinical characteristics and health care utilization factors on the initial and subsequent choice of biologic DMARDs for RA.

Results: We identified a total of 195,433 RA patients including 78,667 DMARD-naïve incident RA patients and 93,534 biologic-naïve prevalent RA patients and 23,232 biologic-experienced patients (**Table 1**). Patients in the commercial health plan were 87% more likely to initiate a biologic DMARD than those in Medicaid. African Americans were 30-40% less likely to initiate or switch biologics in all three RA groups when compared to White, non-Hispanic population. Prior use of steroid and non-biologic DMARD had positive association with biologic initiation as well as subsequent switching to another biologic drug. Etanercept (51%), adalimumab (22%), and infliximab (22%) were most commonly used first- and second-line biologics; anakinra and golimumab were most likely to be switched by other biologics (**Table 2**).

Conclusion: Younger age, private insurance type, and White race were significantly associated with higher odds of getting initial and subsequent treatment with biologics. There may be a need for future research examining the impact of selective prescribing of biologics on RA-related clinical outcomes.

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016

Session Title: Spondylarthropathies and Psoriatic Arthritis – Clinical Aspects and Treatment IV: Psoriatic Arthritis – Clinical

Session Type: ACR Concurrent Abstract Session

Session Time: 4:30PM-6:00PM

Background/Purpose: In 2013, Treat to Target (T2T) in SpA Recommendations by expert consensus stated that the target of treatment should be remission or inactive disease. The only data in PsA is the Tight Control of PsA (TICOPA) trial which confirmed that T2T using a target of minimal disease activity (MDA) was superior to standard care. However MDA is not remission. Potential definitions that would fit with the T2T Recommendations would be MDA meeting all 7 cut points, proposed as a definition of very low disease activity (VLDA), or the Disease Activity in PsA (DAPSA) remission cut point. Our aim was to investigate which patients achieve definitions of remission and VLDA and how much residual active disease is still present.

Methods: This analysis uses data from the TICOPA study where 206 patients with newly diagnosed PsA were randomised 1:1 to receive either tight control (4 weekly review and treatment escalated until in MDA) or standard care (12 weekly review, no protocol for treatment). Three potential definitions of remission/inactive disease were used

- VLDA where all 7 of the MDA cut points are met: tender joint count (TJC)≤1; swollen joint count (SJC)≤1; enthesitis count≤1;

PASI≤1; patient global visual analogue scale (VAS)≤20mm; patient pain VAS≤15; and health assessment questionnaire≤0.5.
- DAPSA remission where DAPSA≤4 (TJC + SJC + patient global VAS (cm) + physician global VAS (cm) + CRP (mg/l)
- Clinical DAPSA remission where DAPSA≤4 (TJC + SJC + patient global VAS (cm) + physician global VAS)

Results: At the end of the TICOPA study (48 weeks), 50 patients were in DAPSA remission, 58 in cDAPSA remission and 27 met VLDA. Unsurprisingly, the highest correlation in remission definitions was found between DAPSA and cDAPSA (Pearsons 0.927) with lower correlation between both DAPSA/cDAPSA and VLDA (0.609/0.593). The percentage exact agreement (PEA) for VLDA and the DAPSA/cDAPSA remission was 85.2/83.0% respectively. There were 25 people considered to be in DAPSA remission and 30 in cDAPSA remission who did not meet the VLDA cut off. In contrast only 2 people were not in DAPSA remission but did meet the VLDA cut off. Levels of residual active disease in patients meeting the remission/very low disease activity criteria are shown in the table. All definitions had similar proportions of people with residual disease but lower disease activity was seen in VLDA definition, particularly for swollen joint count and enthesitis as each domain had to score ≤1. All definitions had similar proportions of patients with raised CRP levels despite the CRP not being included in two of the definitions.

Conclusion: The VLDA criteria are more stringent than both DAPSA and cDAPSA remission, with a lower number of people meeting this definition and less residual disease activity. The inclusion of a laboratory marker seems unnecessary in the definition as high CRP levels are similar in all definitions, making target assessment easier in clinical practice.

		DAPSA remission n (%) (n=50)	cDAPSA remission n (%) (n=56)	VLDA n (%) (n=27)

Session Title: Spondylarthropathies and Psoriatic Arthritis – Clinical Aspects and Treatment IV: Psoriatic Arthritis – Clinical

Session Type: ACR Concurrent Abstract Session

Session Time: 4:30PM-6:00PM

Background/Purpose: Psoriatic arthritis (PsA) is an inflammatory arthritis affecting approximately 520,000 patients in the US and up to one third of patients with psoriasis. Studies in the past have found an increased risk of psoriasis and worsening disease with smoking. However, the association between smoking and psoriatic arthritis in psoriatic patients and the general population remains much debated with some studies showing an increased risk while other showing an inverse relationship. We aimed to study the risk of psoriatic arthritis with smoking among the general population and patients with psoriasis using a large inpatient US database.

Methods: Using the Nationwide Inpatient Sample (NIS) data from 2009-2011, we identified current smokers based on International Classification of Diseases, Ninth Revision (ICD-9) code 305.1 and identified previous smokers who had ICD-9 code V15.82 but without 305.1. NIS is the largest publicly available all-payer inpatient care database in the United States and is sponsored by the Agency for Healthcare Research and Quality as a part of Healthcare Cost and Utilization Project. Patients with Psoriasis were selected based on ICD-9 codes 696.1 and 696.8 while PsA were identified based on 696.0. Univariate and multivariate logistic regressions were used to derive odds ratio for measures of association. Statistical analysis was done using STATA version 13.0 (College Station, TX).

Results: NIS database from 2009-2011 contained 23,634,793 (weighted counts in the whole US population: N=117,033,987) records of discharges. Out of those, 13,850 (weighted N=68,392) had psoriatic arthropathy. Among the whole population, 81.66 % were non-smokers, 11.28 were active smokers while 7.06 % were previous smokers. Multivariate regression analysis after controlling for confounders (table 1) showed significantly higher incidence of PsA in active smokers as compared to non-smokers (OR 1.19, CI 01.12- 1.27, $p \leq 0.0001$) in the general population. The risk was further higher in active smokers with psoriasis (OR 3.02, CI 2.04- 4.47, $p \leq 0.0001$). Similarly, previous smokers were also at increased risk for PsA in the general population (OR 1.40, CI 1.31- 1.50, $p \leq 0.0001$) but the risk in patients with psoriasis was not statistically significant (OR 1.59, CI 0.93- 2.70, $p=0.091$). Hypertension, hyperlipidemia, obesity, diabetes mellitus and rheumatoid arthritis were all found to be independent risk factors in our multivariate regression model.

Conclusion: Active tobacco use was associated with a higher risk of PsA in the general population and a much higher risk was seen in patients with psoriasis. This is in sharp contrast to previous studies showing an inverse relationship. Moreover, the risk was significantly lower in previous smokers as compared to active smokers, suggesting that quitting smoking may lower the risk of PsA in patients with psoriasis. This lower risk was however not seen among the general population. As PsA usually develops 8-10 years later in patients with psoriasis, it may be considered a more severe phenotype that may develop in genetic susceptible patients (eg. HLA-C*06) with certain environmental exposures such as tobacco use. Hence, quitting smoking in psoriatic patients may prevent development of PsA. More studies are needed to get a better understanding of the mechanisms that explain this finding and identify gene-environment interactions.

Psoriatic Arthritis	Odds Ratio	Two tailed p-value	95% Confidence Interval	
No smoking Yes Psoriasis	2.87	<0.0001	2.26	3.66

Session Title: Spondylarthropathies and Psoriatic Arthritis – Clinical Aspects and Treatment IV: Psoriatic Arthritis – Clinical

Session Type: ACR Concurrent Abstract Session

Session Time: 4:30PM-6:00PM

Background/Purpose:

Psoriasis (Ps) precedes joint inflammation by an average of 10 years psoriatic arthritis (PsA) patients. Reports have demonstrated abnormal musculoskeletal imaging findings in psoriasis patients but arthritis biomarkers have not been identified. PsA patients demonstrate increased OCP frequency in the peripheral blood. We examined the association of imaging abnormalities and OCP frequency in a longitudinal psoriasis cohort without baseline musculoskeletal symptoms.

Methods:

Ps patients with > 5 years of psoriasis or >10% body surface area (any disease duration) were enrolled if they scored less than 36 on the PASE questionnaire and showed no active arthritis or enthesitis on rheumatologic exam. All patients were imaged with a 3-phase bone scan and Power Doppler Ultrasound (PDUS) of joints and entheses. If the bone scan revealed evidence of inflammation, a gadolinium enhanced 3T MRI was performed on the joint with the highest scintigraphy signal. Patients were contacted annually by phone or by a visit and those with new musculoskeletal symptoms were examined and PsA diagnosed by CASPAR criteria. Blood samples were drawn for OCP quantification from purified monocytes after 8-day cell culture.

Results:

42 Ps patients (50% female) were enrolled with a mean age 45±6 years, psoriasis duration 16±3 years, BMI 32±8 kg/m^2 and PASI score 8±5 and mean follow-up was 48.1±1 months. Eleven subjects had normal imaging studies (scintigraphy/MRI), 13 had active subclinical joint inflammation on imaging but 9 additional subjects, all with baseline imaging abnormalities, subsequently developed PsA. In the PsA group, 6/9 (66%) had synovitis/tenosynovitis (i.e. synovial thickening) and/or a knee effusion detected on ultrasound, compared to 5/33 (15%) in the patients without PsA. Characteristics of patients who developed PsA: 5 of 9 female, mean age 49, PASI 11.3, 5 of 9 with nail and 7 of 9 with scalp disease and mean psoriasis disease duration of 25.5 years. Active or prior enthesitis (calcification at insertions) by PDUS was noted in 9 patients without abnormal MRI or scintigraphy. Patients were categorized into 4 subsets based on the imaging analysis and/or clinical features: (1) no imaging abnormality, (Normal) n=11; (2) enthesitis or entheseal calcification, (Enthesitis), n=9; (3) sub-clinical joint inflammation, (Imaging); n=13; (4) development of PsA, (PsA) n=9. The OCP frequency was significantly different in the 4 patient subsets (P<.005) (Table 1). OCP frequency was similar in the patients who developed PsA and those with abnormal imaging findings and 3 to 4-fold higher than patients without imaging findings or enthesitis on US.

Conclusion:

Elevated OCP frequency was associated with abnormal imaging findings on scintigraphy and MRI. The combination of synovitis/tenosynovitis and/or a knee effusion on grey scale US and elevated OCP frequency identified psoriasis patients at risk for PsA.

Table 1. OCP frequency in 4 cohorts of Ps patients categorized by imaging results (mean+SEM).

	(1) Normal	(2) Enthesitis	(3) Imaging findings	(4) PsA

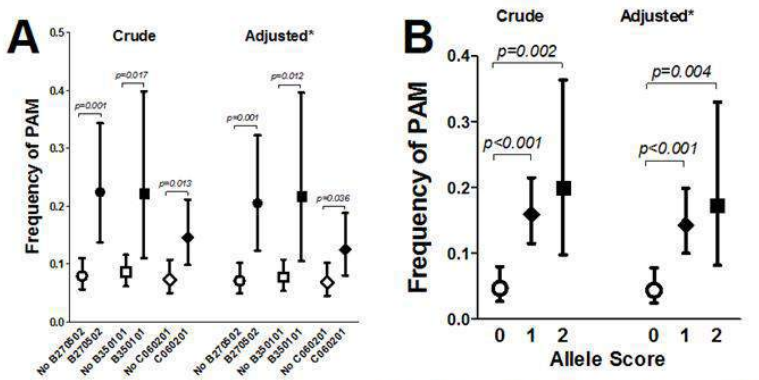
Session Date: Tuesday, November 15, 2016

Session Title: Spondylarthropathies and Psoriatic Arthritis – Clinical Aspects and Treatment IV: Psoriatic Arthritis – Clinical
Session Type: ACR Concurrent Abstract Session
Session Time: 4:30PM-6:00PM

Background/Purpose: Several human leukocyte antigen (HLA) Class I loci encoding the major histocompatibility complex (MHC) have been implicated both in psoriatic arthritis (PsA) susceptibility and in overall severity of disease. However, associations of these HLA alleles with specific manifestations of PsA have received little study. In particular, the contribution of HLA Class I alleles to peripheral arthritis mutilans (PAM), a potentially devastating manifestation of PsA, is unclear.

Methods: Patients from two prospective PsA cohorts were genotyped for HLA-B and C alleles. PAM was defined radiographically as osteolysis affecting≥50% of the articular surface on both sides of a joint. Associations of alleles with PAM were explored in multivariable logistic regression models adjusting for potentially confounding characteristics. An allele scores was constructed as the sum of an individual's positively associated alleles minus the sum of their inversely associated alleles.

Results: A total of 501 PsA patients were studied [mean age=56 years, 53% female, median PsA duration=18 years]. PAM was observed in 52 (10%). B*27:05:02, B*35:01:01, and C*06:02:01 were significantly associated with PAM in multivariable analyses (Fig 1A). There were no significant inversely associated alleles. One PAM-associated allele was present in 208 (42%) and 35 (7%) had two alleles. Compared with those with no PAM-associated alleles, the odds of PAM was nearly 3.5-fold higher for those with one allele (OR=3.59; p<0.001), and more than 4.5-fold higher for those with two alleles (OR=4.51; p=0.004) after adjusting for PsA duration, which was the only meaningful confounder of the PAM/allele association detected (Fig 1B). The strongest associations were observed for B*27:05:02 in the context of its B*27:05:02-C*02:02:02 haplotype (OR=4.70 compared with those with no B*27:05:02; p=0.001), B*35:01:01 in the context of its B*35:01:01-C*04:01:01 haplotype (OR=3.46 compared with those with no B*35:01:01; p=0.014), and C*06:02:01 in the context of its two common haplotypes (B*13:02:01-C*06:02:01 and B*57:01:01-C*06:02:01: OR=1.93 compared with those with no C*06:02:01; p=0.041). The area under the receiver operator curve (AUC) for detecting PAM knowing only the PAM-associated HLA-B and C alleles in their haplotype contexts was 0.682 (95% CI 0.610, 0.766). Adding PsA duration to the model increased the AUC to 0.738 (95% CI 0.672, 0.805).



Panel A depicts the crude and adjusted associations of HLA B*27:05:02, B*35:02:01, and C*06:02:01 with the frequency of peripheral arthritis mutilans (PAM). Panel B depicts the association with the same outcome for an allele score based on the sum of the three PAM associated alleles. For both, Means and 95% confidence intervals are depicted. Crude analyses are adjusted only for the other PAM associated alleles. Adjusted analyses also include adjustment for psoriatic arthritis duration.

Conclusion: The associations of specific HLA-B and C alleles observed with PAM supports the concept that the particular PsA sub-phenotype observed in an individual is genetically determined. Additional study is warranted to define how penetrance is determined among those with susceptibility alleles

SESSION INFORMATION
Session Date: Tuesday, November 15, 2016
Session Title: Spondylarthropathies and Psoriatic Arthritis – Clinical Aspects and Treatment IV: Psoriatic Arthritis – Clinical
Session Type: ACR Concurrent Abstract Session
Session Time: 4:30PM-6:00PM

Background/Purpose: Patients with psoriatic arthritis (PsA) have increased risk in cardiovascular diseases (CVD) including subclinical atherosclerosis. However, previous knowledge was limited to carotid atherosclerosis. The aim of this study was to determine whether PsA patients had a higher prevalence and severity of coronary atherosclerosis compared to control subjects. We also aimed to test the association between the disease characteristics and coronary atherosclerosis in PsA patients.

Methods: 82 PsA patients [male: 51 (62%); 51±11 years] were recruited. Coronary atherosclerosis was evaluated by computed tomography angiography (CTA). 231 control subjects [male: 155 (67%); 49±10 years] without known CVD and rheumatic diseases, who were referred to receive CTA scan due to chest pain and/or multiple CVD risk factors, were also recruited.

Results: PsA patients and controls were well matched in age, gender, smoking status, history of hypertension and dyslipidemia, lipid profile and fasting glucose (p ranged from 0.158 to 0.978). PsA patients had a higher prevalence of diabetes mellitus than controls [13 (16%) vs 15 (7%), p=0.012]. The prevalence of overall coronary plaque [52 (63%) vs 74 (32%), p<0.001], calcified plaque (CP) [27 (33%) vs 30 (13%), p<0.001], mixed plaque (MP) [19 (23%) vs 13 (6%), p<0.001], non-calcified plaque (NCP) [38 (46%) vs. 51 (22%), p<0.001], and combined MP/NCP [45 (55%) vs. 57 (25%), p<0.001] were all significantly higher in PsA patients. PsA patients also had higher coronary calcium score (CAC) compared with control subjects (46±151 vs 5±19, p=0.018). In patients with coronary plaque, 3-vessle diseases were seen in 11 (21%) PsA patients and 4 (5%) controls (p=0.007); while severe stenosis was seen in 7 (13%) PsA patients and 1 (1%) controls (p=0.008). After adjusting for traditional CVD risk factors, PsA remained the strongest predictor for all types of coronary plaques (Table 1). In all subjects with plaque (52 PsA patients and 74 controls), PsA was the only independent predictor for 3-vessel disease after adjusting for CVD risk factors [odd ratio: 5.724 (1.506-21.759), p=0.010]. In PsA patients, the PsA disease duration was the only disease specific characteristic which was correlated with the more vulnerable plaque types (MP/NCP) in univariate [1.057 (1.003-1.113), p=0.037] and multivariate analysis [1.067 (1.010-1.127), p=0.020; adjusted for age, gender, hypertension, diabetes, hyperlipidemia, family history of CVD and smoking]. The other independent predictor was male gender [3.519 (1.306-9.480), p=0.013].

Conclusion: PsA patients had higher prevalence and severity of coronary atherosclerosis compared with control subjects. Longer disease duration, but not older age, was independently correlated with the more vulnerable MP/NCP in PsA patients. Table 1. Independent predictors in multivariate analysis for coronary plaque in PsA patients and control subjects.

Session Title: Spondylarthropathies and Psoriatic Arthritis – Clinical Aspects and Treatment IV: Psoriatic Arthritis – Clinical

Session Type: ACR Concurrent Abstract Session

Session Time: 4:30PM-6:00PM

Background/Purpose: Patients with PsA were reported to have a higher incidence of cardiovascular disease (CVD) and subclinical carotid atherosclerosis due to underlying inflammation. Minimal disease activity (MDA) is a validated treatment target for managing PsA. While achieving MDA was associated with benefits in articular disease, it's effect on co-morbidities including CVD risk remained uncertain. This study aimed to investigate the effect of achieving sustained MDA on subclinical atherosclerosis evaluated by carotid intima-media thickness (IMT).

Methods: 100 PsA patients without overt CVD were recruited. Patients were followed for 2 years with clinical assessment every 4 months. Treatment was guided by a standardized protocol aiming at MDA. Sustained MDA(sMDA) was defined as achieving MDA

at each visit from month 4 to 12. Carotid IMT were evaluated at baseline, month 12 and 24 using a high-resolution B-mode ultrasound machine. IMT was calculated based on the measurements at bilateral distal, bulb and proximal internal carotid artery.

Results: This is an interim analysis of the ongoing study. 51 PsA patients [male: 27 (52.9%); 50 ±12 years] who completed 12 months follow-up were analyzed. After 1 year of intensive treatment, significant improvement in disease activity [DAPSA: 15 (10,21) at baseline to 5 (2, 10) at 12 months (p<0.001)] was observed, and a significantly higher proportion of patient achieved MDA [8 (15.7%) at baseline vs 28 (54.9%) at 12 months p<0.001]. Mean carotid IMT increased significantly from 0.620 mm ±0.112 to 0.654 mm ±0.120 (p=0.04). 11/51 (21.6%) patients achieved sustained MDA. Baseline disease activity measures (PASI and DAPSA) and HAQ scores were lower in sMDA group. At 12 months, the mean carotid IMT were significantly lower in the sMDA group than the non-sMDA group [0.612±0.049mm vs 0.668±0.130mm (p=0.030)] while no significant changes were observed in the maximum IMT. Baseline mean carotid IMT was associated with month 12 mean carotid IMT (p<0.001). Using ANCOVA, the adjusted mean carotid IMT remained significantly lower in the sMDA group (0.612±0.023 mm vs 0.666±0.012 mm respectively, p=0.041) after adjusting for baseline mean carotid IMT (Table 1). There was also a significant difference in the change in mean IMT (-0.01± 0.08mm in sMDA group, vs 0.05± 0.08mm in non-sMDA group, p=0.046). The results remained significant when the changes were expressed as percentage changes of the baseline mean IMT (-0.1± 10.6% vs 7.9± 11.7%, p=0.046). The differences were statistically insignificant after adjusting for baseline differences probably due to small number. No significant changes were observed in the change in maximum IMT.

Conclusion: Effective suppression of inflammation by achieving sustained MDA may prevent progression of subclinical atherosclerosis in PsA patients Table 1 Changes in Carotid IMT over a 12 month period in patients who can or cannot achieve sustained MDA

Session Title: Systemic Lupus Erythematosus – Clinical Aspects and Treatment IV: Biomarkers

Session Type: ACR Concurrent Abstract Session

Session Time: 4:30PM-6:00PM

Background/Purpose: The risk of atherosclerotic cardiovascular disease (CVD) is significantly increased in systemic SLE compared to age and gender matched controls. The implementation of nuclear magnetic resonance (NMR) analysis has allowed for the analysis of novel biomarkers of CVD, including assessment of lipoprotein particle counts/size as well as serum glycoprotein acetylation (GlycA) levels. GlycA is a proinflammatory biomarker that predicts 5 year all cause mortality and incident CVD in the general population. GlycA levels reflect the abundance of mobile N-acetyl sugar groups found in glycoproteins in circulating blood. We assessed the association of lipoprotein profiles and serum GlycA levels with vascular function, arterial inflammation, coronary plaque and lupus disease activity.

Methods: Clinical and demographic characteristics, SLE disease activity (by SLEDAI), damage accrual (by SLICC), Framingham risk score (FRS), and metabolic parameters were recorded at each visit. SLE (n=54) and matched healthy controls(n=32) underwent vascular function assessments by measuring peripheral arterial tonometry of the microvasculature (EndoPAT), arterial stiffness using a cardio-ankle vascular index (CAVI) and SphygmoCor, aortic inflammation by 18-fluorodeoxyglucose positron emission tomography/computerized tomography (FDG-PET/CT), and quantification of plaque by coronary CT angiogram (CTA). Lipoprotein profiles and GlycA levels were obtained by NMR analysis.

Results: Lupus and control individuals did not differ in gender, tobacco use, standard lipid profile or FRS but had higher prevalence of insulin resistance and BMI. Mean SLEDAI score was 3.5 ± 2.9. HDL, medium HDL and IDL particle counts were lower in SLE compared to controls ($p<0.001$), whereas medium VLDL particle counts and GlycA levels were significantly increased in SLE ($p =0.034$ and <0.001 respectively) when compared to controls. Among SLE patients, HDL particles negatively correlated with SLEDAI ($r= -0.33$, $p=0.015$) and non-calcified plaque by CTA ($r= -0.29$, $p=0.003$), VLDL particles positively correlated with non-calcified plaque ($r=0.24$, $p=0.015$) and arterial inflammation ($r=0.36$, $p=0.014$). Within SLE patients, GlycA levels significantly correlated with SLICC ($r=0.29$, $p=0.047$), insulin resistance ($r=0.36$, $p=0.007$), aortic inflammation, assessed by FDG-PET/CT ($r= 0.35$, $p=0.019$) and arterial stiffness using sphygmocor ($r=0.57$, $p<0.001$). In an unadjusted linear regression model, higher GlycA levels associated with increased arterial stiffness in SLE but not in controls ($r=0.62$, $p<0.001$) and this association remained significant after adjusting for FRS, BMI and insulin resistance. GlycA levels added incremental value in predicting non calcified plaque in lupus patients beyond FRS and Hs-CRP when added to nested models ($r=5.41$, $p=0.020$).

Conclusion: SLE individuals demonstrate significant increases in serum GlycA levels and a proatherogenic lipoprotein profile, even when lupus disease activity is low, in association with CVD risk markers. Future longitudinal analysis will assess the clinical implications of these findings and role of these tests as biomarkers of CVD in SLE.

Session Title: Systemic Lupus Erythematosus – Clinical Aspects and Treatment IV: Biomarkers
Session Type: ACR Concurrent Abstract Session
Session Time: 4:30PM-6:00PM

Background/Purpose: Patients with systemic lupus erythematosus (SLE) show a striking increase in risk of atherosclerotic cardiovascular disease (CVD) not explained by Framingham risk, when compared to age and gender matched controls. Immune dysregulation and innate immune responses associated to aberrant neutrophils (low density granulocytes, LDGs) may play a key role in conferring enhanced CV risk, driving vascular damage, oxidizing HDL and altering its function. Whether proinflammatory neutrophils are associated to and predict vascular inflammation, endothelial dysfunction, and eventually, clinical vascular events remains to be determined.

Methods: In this cross-sectional study, SLE patients fulfilling ACR classification criteria were compared to age and gender-matched controls. Clinical and demographic characteristics, Framingham Risk score, metabolic parameters, and lupus medications were recorded at each visit. Individuals underwent assessment of a) vascular function of various arterial territories: peripheral arterial tonometry of the microvasculature (Endopat), arterial stiffness by cardio-ankle vascular index (CAVI) and by Sphygmocor; b) aortic inflammation by FDG-PET/CT; and c) anatomical assessment of plaque by coronary CT angiogram. Circulating LDGs were quantified by flow cytometry. Cholesterol efflux capacity was quantified in radioactively-labeled cell lines upon exposure to control or lupus HDL.

Results: Lupus (n=54) and healthy controls (n=32) did not differ in gender, race, ethnicity or Framingham risk score. Mean disease duration was 16 ± 12 years and SLEDAI was 3.5 + 2.9. Arterial stiffness assessed by CAVI was increased in SLE (CAVI: 7.3[6.5-8.0]) vs. controls (6.3[5.9-7.4]; p = 0.004), and by Endopat augmentation index (AI75: 14.4 ± 18.7) vs. controls (5.5 ± 20.7, p = 0.022). Additionally, SLE patients displayed enhanced aortic inflammation by FDG-PET/CT (TBR: 1.63 [1.5-1.8]) vs. controls (1.56 [1.5-1.7], p=0.010). Differences between control and SLE persisted in multivariate regression analysis adjusting for Framingham Risk**.** HDL efflux was negatively associated with noncalcified plaque burden in SLE (b=-0.30, p=0.002), while LDGs were positively associated with noncalcified plaque burden (b=0.37, p<0.001), both persisting in multivariate regression analysis adjusting for Framingham Risk + body mass index or insulin resistance. In addition, number of lupus LDGs positively associated with damage (SLICC score (b=0.31, p=0.031)), CRP (b=0.46, p=0.001), and arterial stiffness (b=0.44, p=0.012).

Conclusion: Individuals with SLE demonstrate increased arterial stiffness and prominent arterial inflammation suggestive of widespread damage across both micro- and macro-vascular territories. These results support the hypothesis that aberrant neutrophil subsets significantly contribute to vascular damage and unstable plaque development in SLE. Results also support previous observations that neutrophils, through enhanced neutrophil extracellular trap formation, may disrupt HDL function and further promote atherogenesis.

Apolipoprotein L1 Risk Variants Associate with Prevalent Cardiovascular Disease

in African American Systemic Lupus Erythematous Patients

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016

Session Title: Systemic Lupus Erythematosus – Clinical Aspects and Treatment IV: Biomarkers

Session Type: ACR Concurrent Abstract Session

Session Time: 4:30PM-6:00PM

Background/Purpose: Two Apolipoprotein L1 (APOL1) risk variants (RV), G1 and G2, located on chromosome 22q12.3, have been associated with excess renal risk in African Americans (AA). The strongest correlations are in those with comorbid infectious or inflammatory diseases such as HIV or SLE collapsing glomerulonephropathy potentially owing to increased gene expression in the setting of chronic inflammation. APOL1 related cardiovascular disease (CVD) risk has been more controversial. Of four large, population-based studies, two reported 2-8 fold increased CVD in RV homozygotes while two others reported no increased risk. APOL1 associated CVD has never been assessed in a cohort with comorbid inflammatory disease. Accordingly, this retrospective cohort study evaluates prevalent CVD across APOL1 genotypes in SLE patients to test the hypothesis that the APOL1 cardiovascular phenotype is more penetrant in an SLE population.

Methods: PCR/sequencing was completed in 92 AA SLE patients. Subjects were stratified by genotype: ancestral (G0/G0), RV heterozygotes (RV/G0), and RV homozygotes (RV/RV). Clinical CVD endpoints including both *cardiac*: congestive heart failure, arrhythmia, and left ventricular hypertrophy; and *atherosclerotic*: coronary artery disease, myocardial infarction, peripheral vascular disease, vascular calcifications, and carotid artery disease were assessed by chart review. Logistic regression was used to test associations between the genotypes and a composite CVD end point defined by meeting one or more of the above parameters. Secondary analysis of atherosclerotic vs cardiac end points was also completed.

Results: The G0/G0, RV/G0, and RV/RV groups comprised 33%, 54%, and 13% of the cohort. Subjects were predominantly female (90%). There were no differences in history of SLE nephritis, diabetes, smoking, or age across the genotypes. Among patients with current or past nephritis, a larger percentage of the RV/RV group had progressed to ESRD at the time of study enrollment (G0/G0 or G0/RV: 8.3% vs RV/RV: 33%; OR: 3.8 p: 0.051). The RV associated with CVD; 21.2%, 41.7%, and 63.6% of the G0/G0, RV/G0, and RV/RV groups met the composite endpoint respectively (χ^2: 7.3; p: 0.026). When adjusting for CVD risk factors including smoking, ESRD, obesity, and hypertension, carrying one or more RV conferred a 3.1 fold increased risk of CVD (p: 0.03). The RV associated most strongly with atherosclerotic endpoints (OR: 7.5 p: 0.01) compared to cardiac disease end points (OR: 2.5, p: 0.22). These trends were present despite a shorter duration of SLE in the RV groups (groups (G0/G0: 15.1yrs ±8.6, G0/RV: 9.2±7.9, RV/RV: 12.9±10.5, p: 0.04).

Conclusion: The undulating inflammation of SLE plays an important role in each step of atherogeneisis from endothelial dysfunction to plaque rupture. In RV carriers, it may also increase the toxic protein burden leading to an amplified propensity towards CVD. Taken together, the RV is associated with prevalent CVD in this AA SLE cohort suggesting that SLE may be an important "second hit" in the relationship between APOL1 RV and CVD.

Early Proteinuria Response in Real Life Situation Predicts Long-Term Lupus Renal Outcome in Ethnically Diverse Group with Biopsy-Proven Nephritis

Michelle Lopes[1], Luciana Seguro[1], Maite Castro[2], Danielle Daffre[3], Eduardo Ferreira Borba[2] and Eloisa Bonfa[4], [1]Rheumatology Division, Hospital das Clínicas da Faculdade de Medicina da Universidade de São Paulo, São Paulo, Brazil, [2]Rheumatology, Hospital das Clinicas, Faculdade de Medicina, University of São Paulo, São Paulo, Brazil, [3]São Paulo University, São Paulo, Brazil, [4]Rheumatology Divison, Hospital das Clinicas, Faculdade de Medicina, University of São Paulo, São Paulo, Brazil

Session Date: Tuesday, November 15, 2016
Session Title: Systemic Lupus Erythematosus – Clinical Aspects and Treatment IV: Biomarkers
Session Type: ACR Concurrent Abstract Session
Session Time: 4:30PM-6:00PM

Background/Purpose: Treat to target strategies are becoming the best approach for several rheumatic disorders. Recently retrospective analyses of two important lupus trials have reported that proteinuria is the single best predictor of renal outcome in lupus patients. Samples from these trials were however mainly Caucasians and mostly from patients in the first nephritis episode with non-severe renal involvement at entry. In addition, on average, adherence to intervention protocols is higher in clinical trials than in non-research settings. The purpose of this study was therefore to determine in real-life situation if proteinuria was also a good predictor of renal outcome in a geographical region with more racial diversity.

Methods: 94 biopsy-proven lupus nephritis patients with at least 7 years longitudinal follow-up at the Rheumatology Division of a tertiary university hospital were consecutively selected. Data were obtained using a standardized electronic database protocol including demographic data, clinical and laboratorial findings and treatment. Proteinuria, serum creatinine (SCr), urine red blood casts (RBC) and anti-dsDNA antibody were evaluated at baseline and after 3, 6, 12 months and then 7 years of follow-up. We assessed the ability of these biomarkers at these different time points to predict good long term renal outcome (defined as SCr<1.5mg/dl) at 7 years. Receiver operating characteristic (ROC) curves were generated to assess parameter cutoff and performance at these time points and to select the best parameter considering sensitivity, specificity, positive and negative predictive values. Kaplan Meier curves were used to assess renal survival of each group.

Results: 80 (85.1%) were women, 38 (40.4%) were non-white patients and 38 (40%) were not in the first episode of nephritis. At baseline, patients had mean SCr of 1.73±1.34 mg/dl, proteinuria 5.46±4.51g/24h, albumin 2.45±0.78g/dl and SLEDAI 9.46±4.23. Proteinuria <0.83g/24h at 12 months of follow-up was the best single predictor of good long-term renal outcome (Sensitivity=90.3%, Specificity=78.3%, PPV=62.0% e NPV=90.3% AUC=0.86, p<0.001). The addition of other variables to proteinuria analysis such as SCr and RBC at month 12 did not improve the predictive performance of this parameter. Further evaluation of the proposed proteinuria cut-off (<0.83g/24h at 12 months) revealed that this parameter is a good predictor of 7 years renal survival (defined as years free of dialysis) for pure membranous (p=0.005), proliferative nephritis (p=0.043), blacks (p=0.002), whites (p=0.001), anti-dsDNA positive (p=0.001), males (p=0.028) and females (p=0.003) patients.

Conclusion: We demonstrated in a real-life situation that proteinuria at 12 months of follow-up was the single best predictor of good renal outcome at 7 years for an ethnically diverse group. We further validated this parameter as long-term predictor of renal outcome for distinct histological classes, races, gender and anti-dsDNA profile.

SESSION INFORMATION

Session Date: Tuesday, November 15, 2016
Session Title: Systemic Lupus Erythematosus – Clinical Aspects and Treatment IV: Biomarkers
Session Type: ACR Concurrent Abstract Session
Session Time: 4:30PM-6:00PM

Background/Purpose: Rituximab (RTX) has been used off-label in refractory SLE with variable clinical outcomes in different cohorts, with no predictive response markers available. However, the kinetics suggest that interruption of B cell maturation and differentiation, rather than removal of B cells per se, may underlie clinical success. The soluble form of CD23 (sCD23) is cleaved and released during B cell differentiation to memory phenotype (CD27+). Concerted binding of B cell activation factor (BAFF) to at least 3 receptors is a survival factor for naïve B cells, promotes class-switch and plasmablast differentiation. We aimed to investigate whether different sCD23 and BAFF profiles could be of value for predicting clinical response to RTX in patients with SLE.

Methods: We included 98 serum samples from 26 SLE patients (ACR 1982 revised criteria) taken 3 to 13 months prior to first RTX treatment. BAFF and sCD23 were determined using ELISA [upper limits of normal (ULN) given by manufacturers: sCD23 >5000pg/ml; BAFF >2ng/ml]. Data was analyzed in relation to B cell depletion (CD19+B cells<5/µl), clinical characteristics, anti-dsDNA and BILAG response at 6 months.

Results: Table 1 shows clinical data and results. Serum sCD23 and BAFF were weakly correlated in all samples (r^2=0.11; p=0.001). Levels of both analytes from individual patients were found to follow broadly consistent patterns. Patients could therefore be grouped according to levels greater or lower than ULN: Group I – High sCD23, Low BAFF; Group II – High sCD23, High BAFF; Group III – Low sCD23, Low BAFF; Group IV – Low sCD23, High BAFF. Patients in Groups I and IV had higher BILAG responses at 6 months. No patients in Group III had renal involvement.

Table 1.					
	Group I **High sCD23, Low BAFF** n=5	**Group II** **High sCD23, High BAFF** n=8	**Group III** **Low sCD23, Low BAFF** n=6	**Group IV** **Low sCD23, High BAFF** n=7	**Total** n=26
Ethnicity					
Caucasian	5 (100%)	3 (37.5%)	3 (50%)	3 (42.9%)	14 (53.8%)
Afro-Caribbean	0 (0%)	5 (62.5%)	2 (33.3%)	4 (57.1%)	11 (42.3%)

No	1 (20%)	6 (75%)	4 (66.7%)	2 (28.6%)	12 (46.2%)
M – Months; Depletion defined as less than 5 CD19+ B cells/µl					

Discussion: Group I: High sCD23: increased differentiation of naïve to memory B cells, together with a good response to RTX, suggest T cell stimulation is driving the process in a BAFF independent fashion. Group II: Poor depletion and high sCD23 suggests stimulation/maturation of post-germinal center B cells, with possible BAFF-driven differentiation to memory B cells and antibody producing B cells. B cell resistant to RTX-depletion in protected sites may explain poor clinical responses. Group III: Low sCD23 and BAFF suggests that B cells may not be central in the pathogenesis, with a more T cell dependent process. This could explain the poorer clinical response to RTX despite good depletion. Group IV: High BAFF stimulates autoreactive naïve B cell differentiation directly to plasmablasts and autoantibody production, bypassing memory B cells (Low sCD23). Resulting immune-complexes processed through antigen presenting cells (and IFN signature) continuously stimulate BAFF production.

Conclusion: Based on the patterns of sCD23 and BAFF and B cell biology observed in SLE we hypothesize that the combination of these biomarkers may identify distinct autoimmune pathways and likely predict clinical response.

SESSION INFORMATION
Session Date: Tuesday, November 15, 2016
Session Title: Systemic Lupus Erythematosus – Clinical Aspects and Treatment IV: Biomarkers
Session Type: ACR Concurrent Abstract Session
Session Time: 4:30PM-6:00PM

Background/Purpose: SLE patients can experience chronically active disease, remissions and flares, or long periods of quiescence. Accurately assessing disease activity is crucial for prescribing appropriate drug regimens, evaluating treatment outcomes, and detecting early onset of flares; however, there is currently no "gold-standard" biomarker for this determination. Though not in routine clinical use, the SLEDAI scoring system is often applied in clinical trials to evaluate the efficacy of new drugs. Scores <3 are typically considered as inactive disease, 4-15 as mild to moderate, and >15 as severe. The Immuno*Signature* (IMS) Technology further described below was investigated as a potential single serological surrogate for lupus disease activity that is amenable to routine use.

Methods: Sera from 500 SLE patients meeting the ACR classification criteria at diagnosis were evaluated by IMS at different times post-diagnosis. SLEDAI scores ranged from 0 (n=150) to 27. Patients with scores 2-27 (n=350) were selected to sample the range as uniformly as possible (median = 8; IQR 4-10). IMS assays were used to measure serum antibodies bound to a microarray of ~126,000 unique peptides designed to broadly sample chemical space, thereby providing a library of diverse epitope mimetics for antibodies to selectively bind. Peptide features with binding intensities that were significantly different between active and inactive SLE were identified by t-test. Support vector machine classifiers and linear regression models were trained and tested by 100 iterations of 5-fold cross validation.

Results: A total of 34,147 peptides were identified that significantly ($p<0.05$ after Bonferroni correction) differentiated active from inactive SLE (Fig 1). Receiver-operator characteristic (ROC) curves demonstrated significantly superior classification of the samples as inactive or active by an IMS classifier model, compared to standard biomarkers of disease activity such as C4 (not shown), C3, anti-dsDNA, and proteinuria (Fig. 2). Good discrimination was achieved by training on SLEDAI >8 vs. 0, with performance further enhanced when applied to extreme contrasts. For example, a classifier of SLEDAI >15 vs. 0 had an AUC of 0.90 (95% CI 0.88 - 0.92). Correlations of a linear IMS (r=0.48), C3 (r= -0.41) and anti-dsDNA (r=0.36) to SLEDAI were also determined.

Conclusion: A single serologic test, using specific binding patterns of serum antibodies on a highly complex and diverse mimetic peptide array, can molecularly determine SLE disease activity and improve upon current methods of evaluating and monitoring patients.

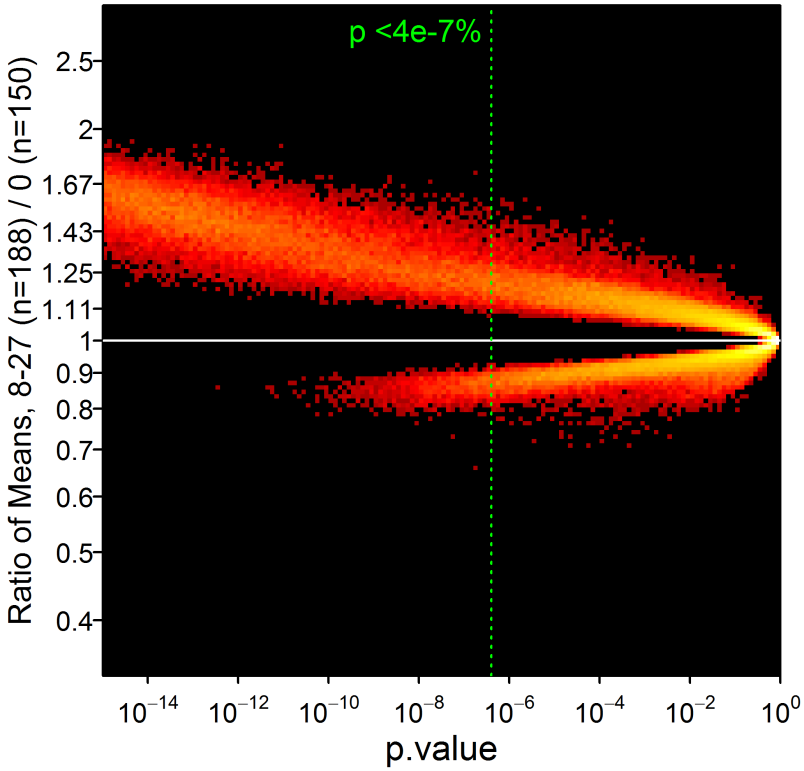

Figure 1. Differentiation of patients' lupus disease activity levels by peptide binding intensities. The ratio of mean intensity among samples from patients with SLEDAI >8 to mean intensity in patients with inactive disease (SLEDAI=0) is plotted vs. the p-value for the difference in means from a t-test.

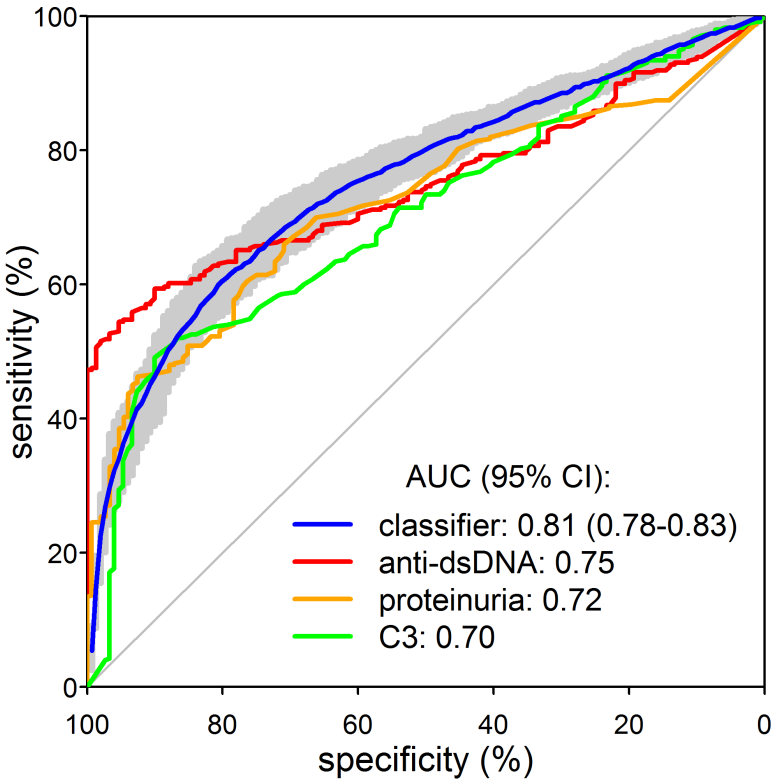

Figure 2. ROC curves for an ImmunoSignature classifier of disease activity compared to biomarkers, for identifying patients with active disease (SLEDAI >0). The gray region indicates the 95% confidence interval of the classifier.

Session Title: T Cell Biology and Targets in Autoimmune Disease - Oral Session

Session Type: ACR Concurrent Abstract Session

Session Time: 4:30PM-6:00PM

Background/Purpose: Inflammatory activity in RA relies on numerous anabolic processes; including cellular proliferation, cell trafficking, secretion of proinflammatory cytokines and release of antibodies. Lasting reversal of inflammation would require to correct such anabolic processes; ideally in the pinnacle pathogenic drivers of RA, HLA-class II-restricted CD4 T cells. CD4 T cells in RA patients are metabolically reprogrammed due to a lack of the catabolic enzyme phosphofructokinase 2 (PFK2) and an excess in the anabolic enzyme glucose-6-phosphate dehydrogenase (G6PD). It is insufficiently understood how metabolic reprogramming affects disease-relevant T cell effector functions and whether this metabolic defect is amendable to therapeutic intervention.

Methods: Patients with seropositive and clinically active RA as well as age-matched healthy controls were enrolled. For molecular and functional studies, the population of naïve $CD4^+CD45RA^+$ T cells was activated through TCR crosslinking. Metabolites and reactive oxygen species (ROS) were measured after 72 hr, cytokine production after 7 days. Arthritogenic activity was quantified by adoptive transfer into NSG mice carrying human synovium. To reset the cells' metabolic homeostasis, the following small molecule reagents were applied in vitro and/or in vivo: the G6PD inhibitor 6-amino-nicotinamide (6-AN), the gamma-glutamylcysteine synthetase (γ-GCS) inhibitor Buthionine-sulph-oximine (BSO), and the 1,4-naphthoquinone analog Menadione.

Results: Compared to healthy control T cells, RA T cells produced more NADPH ($p<0.05$), had lower ROS ($p<0.001$) and higher intracellular glutathione levels ($p<0.05$), indicative of excess glucose shunting into the pentose-phosphate pathway. Functional consequences included: higher cellular proliferation ($p<0.01$), faster cell-cycle passage ($p<0.001$), earlier naïve-to-memory conversion ($p<0.05$) and preferential Th1 and Th17 lineage commitment ($p<0.05$). G6PD inhibition restored intracellular ROS level, corrected the cell-cycle behavior and suppressed IFN-γ production. In human synovium-NSG chimeric mice, RA T cells promptly invaded into the synovial tissue ($p<0.001$), where they produced IFN-γ and IL-17 and stimulated production of TNF-α, IL-1β and IL-6. Treatment with BSO or Menadione corrected the metabolic abnormalities and suppressed inflammatory activity in the synovial tissue.

Conclusion: T cells in RA patients are biased towards anabolic metabolism, resulting in excessive biomass generation, hyperproliferation and secretion of proinflammatory effector molecules. The underlying molecular mechanisms involve the gain in NADPH and the shift of the redox balance towards reductive elements. Pharmacologic interventions that restore oxidant signaling are highly effective in normalizing the cell-cycle behavior of affected T cells and in suppressing synovial inflammation.

Citrullinated Aggrecan Peptides Are Targets of Auto-Reactive CD4+ T-Cells in Rheumatoid Arthritis

Hannes Uchtenhagen[1], Cliff Rims[1], Eddie James[2] and Jane H. Buckner[2], [1]Translational Research, Benaroya Research Institute at Virginia Mason, Seattle, WA, [2]Benaroya Research Institute at Virginia Mason, Seattle, WA

Session Date: Tuesday, November 15, 2016

Session Title: T Cell Biology and Targets in Autoimmune Disease - Oral Session

Session Type: ACR Concurrent Abstract Session

Session Time: 4:30PM-6:00PM

Background/Purpose: T-cell frequencies against citrullinated epitopes derived from major auto-antibody targets (vimentin, fibrinogen, α-enolase) are increased in rheumatoid arthritis (RA). Emerging serologic data suggests antibody reactivity against additional citrullinated proteins, including histones and aggrecan, in RA. Among these potential targets, previous studies found T-cell reactivity against aggrecan peptides in models of RA and to some extent in clinical samples (Boots AM *et al.,* 1997; Law SC *et*

al., 2012; Aggarwal A *et al.,* 2013). Here, we undertook a systematic approach to verify the relevance of aggrecan specific CD4+ T-cell responses in RA.

Methods: Citrullinated aggrecan epitopes were predicted for their binding to DRB1*04:01 and candidates confirmed using binding assays with recombinant protein. The immunogenicity of confirmed binders was then assessed using 14-day *in vitro* peptide stimulation cultures followed by tetramer staining and single-cell cloning from selected subjects. Epitopes eliciting a significant response were then used for *ex vivo* tetramer staining of PBMC from healthy controls and from CCP+ RA patients across a range of disease activities (based on RAPID3 scores).

Results: Starting with 28 cit-aggrecan peptides predicted to bind DR04:01, we identified 6 epitopes that activated and expanded CD4+ T cells with unusual strength for (modified) self-antigens. Using the corresponding tetramers we isolated cit-aggrecan specific T-cell clones specific for these peptides from RA patients. These clones selectively recognized citrullinated peptide and exhibited a Th1-like functional phenotype. *Ex vivo* tetramer analysis of PBMC revealed that a subset of RA patients had significantly increased frequencies of cit-aggrecan specific T-cells in comparison to healthy controls. Ongoing studies will determine whether cit-aggrecan specific T-cells arise early or late in disease, whether they have a distinct functional profile compared with healthy controls, and whether they exhibit expanded TCR clonotypes in established disease. Additionally, we are investigating the degree to which the serum from the blood or synovium contains antigens that specifically activate cit-aggrecan specific T-cell clones.

Conclusion: Citrullinated aggrecan, a protein associated with autoantibodies in a subset of RA patients, have the potential to elicit very strong CD4+ T cell responses. In a subset of patients these are apparent as strong *ex vivo* response and show a disease associated Th1-like phenotype and some signs of clonal expansion. So far the clinical correlations of these high frequencies remain unclear but are an intriguing target of our ongoing studies.

Session Date: Tuesday, November 15, 2016

Session Title: T Cell Biology and Targets in Autoimmune Disease - Oral Session

Session Type: ACR Concurrent Abstract Session

Session Time: 4:30PM-6:00PM

Background/Purpose: Regulatory T cells (Tregs) represent the fundamental T-cell capable of promoting self-tolerance and balancing excessive inflammation. Quantitative and qualitative Treg deficiencies have been characterized in several systemic rheumatic diseases. Previously we found that the catalytic activity of protein phosphatase 2A (PP2A) in murine Tregs is increased at levels significantly higher than in conventional T cells. Furthermore, mice in which Tregs lack PP2A develop multi-organ inflammation and severe autoimmunity. PP2A-deficient Tregs displayed reduced suppressive function *in vitro*. This study investigates the underlying molecular mechanism whereby Tregs lose lineage stability, suppressive function and convert to an effector phenotype.

Methods: We constructed a *Foxp3*$^{YFP-cre}$*Ppp2r1a*$^{flox/flox}$ mouse that lacked PP2A only in Tregs and could be tracked by virtue of co-expressing yellow fluorescent protein (YFP). Age and sex-matched *Foxp3*$^{YFP-cre}$ were used as controls. Foxp3 expressing

Tregs were isolated from *Foxp3*$^{YFP-cre}$*Ppp2r1a*$^{flox/flox}$ mice by flow cytometry cell sorting ($CD4^+YFP^+$). The adoptive T-cell transfer colitis model was used to determine the suppressive function of Tregs with and without PP2A deficiency *in vivo*. One million Tregs were adoptively transferred into *Rag1* knockout recipients either alone or at a 1:1 ratio with conventional $CD4^+$ T-cells. Five weeks later colon, small bowel, spleen and lymph nodes were collected for both histologic and flow cytometry analysis. Standard ELISA was applied to detect cytokines.

Results: Tregs ($CD4^+YFP^+$) isolated from twenty week old *Foxp3*$^{YFP-cre}$*Ppp2r1a*$^{flox/flox}$ mice demonstrated decreased levels of intracellular Foxp3 and IL-10 by flow cytometry. Furthermore, PP2A-deficient Tregs acquired an inflammatory phenotype by producing IL-17. When PP2A-deficient Tregs were co-transferred with effector T cells into *Rag1*-deficient mice, they lost weight and developed inflammatory colitis. This demonstrated that the transferred Tregs lost their suppressive function *in vivo*. In fact, co-transfer of PP2A-deficient Tregs with effector T cells accelerated weight loss and worsened colitis compared to transfer of effector T cells alone. Elevated levels of IL-17 in the sera were detected by ELISA compared to sera obtained from the group of mice in which wild type Tregs and effector T cells had been co-transferred.

Conclusion: PP2A is essential for Treg function and maintenance of stable Foxp3 expression. Tregs deficient in PP2A produce less IL-10 and more IL-17. The dependence of Tregs on the presence of PP2A points to approaches to restore and empower Teg function in autoimmune disease.

Rab4A Is Required for Development of Tregs, Restricts Antiphospholipid Antibody Production and Pro-Inflammatory Expansion of Macrophages and Neutrophils, and Blocks Pristane-Induced Intra-Alveolar Hemorrhage in a Mouse Model of SLE

Zachary Oaks[1], Thomas Winans[1], Nick Huang[1], Sarah Blair[1], Miguel Beckford[1], Katalin Banki[2] and **Andras Perl**[3], [1]SUNY, Syracuse, NY, [2]Clinical Pathology, SUNY Upstate Medical University, Syracuse, NY, [3]Department of Medicine, Upstate Medical University, Syracuse, NY

Session Title: T Cell Biology and Targets in Autoimmune Disease - Oral Session

Session Type: ACR Concurrent Abstract Session

Session Time: 4:30PM-6:00PM

Background/Purpose: Polymorphic haplotypes of the HRES-1 endogenous retrovirus at the 1q42 chromosomal locus have been associated with lupus susceptibility, in particular, with predisposition to antiphospholipid syndrome (APS) and protection from lung disease in patients with SLE (Arthritis Rheum. 58:532-540). Expression of the HRES-1/Rab4 protein of this genomic locus, which has been recently designated as Rab4A, is increased in T cells of SLE patients (J Immunol 182: 2063–2073) and lupus-prone mice (Ann Rheum Dis 73:1888–1897). Intra-alveolar hemorrhage is a rare but fatal complication of pulmonary involvement SLE. To determine the impact of this gene on disease development, mice with constitutively active Rab4A^{Q72L} alleles or lacking expression of Rab4A in T cells (*Rab4*A-KO^{CD4Cre}) have been generated in the C57Bl/6 strain.

Methods: Female mice were injected intraperitoneally with 0.5 ml of pristane and evaluated for pulmonary capillaritis (Rheumatology 46:1405-10). Mice were treated with 3 mg/kg rapamycin or solvent control for 7 days prior and 14 days post pristane injection. 14 days after pristane injection, spleen and lung tissues were examined for lineage specification within the adaptive and innate arms of the immune system by flow cytometry. Expression of Rab4A and activation of the mechanistic target of rapamycin complexes 1 (mTORC1) and 2 (mTORC2) were also examined by western blot. Production of antinuclear antibodies

(ANA) and antiphospholipid antibodies (aPL), such as anti-cardiolipin (ACLA) and anti-β_2 glycoprotein I autoantibodies (anti-β_2GPI) were measured by ELISA. Statistical analyses were performed using 2-tailed t-test and stated changes were significant at $p < 0.05$.

Results: Relative to wild-type (WT) mice (2.4±0.4), vasculitis scores were reduced in Rab4A^{Q72L} (1.1±0.1; p=0.021) and increased in Rab4A-KO^{CD4Cre} mice (3.6±0.2; p=0.042). ANA production was increased in Rab4A-KO^{CD4Cre} mice relative to age-matched WT (p=0.038) and Rab4A^{Q72L} controls (p=0.048). ACLA and anti-β_2GPI production was significantly reduced in Rab4A^{Q72L} mice relative to WT and Rab4A-KO^{CD4Cre} mice. mTORC1$^+$/mTORC2$^-$ IL-17-producing Th17 cells were increased 1.9-fold in the CD4$^+$ T cell compartment of Rab4A-KO^{CD4Cre} mice, and these cells were reduced by 48% in Rab4A^{Q72L} mice. In turn, mTORC1$^+$/mTORC2$^+$ CD4$^+$CD25$^+$ regulatory T cells (Tregs) were expanded 2.4-fold in Rab4A^{Q72L} mice, and these Tregs were reduced by 42% in Rab4A-KO^{CD4Cre} mice. Thymus-derived FoxP3$^+$Helios$^+$ Tregs were also expanded Rab4A^{Q72L} mice and depleted in Rab4A-KO^{CD4Cre} mice. IL-17-producing CD11b$^+$ pro-inflammatory macrophages were expanded 2.1-fold in the spleen and Gr1$^+$ neutrophils were expanded 8.4-fold in the lung of Rab4A-KO^{CD4Cre} mice. Rapamycin treatment did not block lung injury in pristane-treated WT or Rab4A-KO^{CD4Cre}mice.

Conclusion: Rab4A is required for mTORC1- and mTORC2-dependent development of Tregs, which restrict aPL production and pro-inflammatory expansion of macrophages and neutrophils and block pristane-induced intra-alveolar hemorrhage in a mouse model of SLE. Thus, constitutive activation of Rab4A blocks organ-specific disease development and offers a novel target for diagnosis and treatment of SLE.

Session Date: Tuesday, November 15, 2016

Session Title: T Cell Biology and Targets in Autoimmune Disease - Oral Session

Session Type: ACR Concurrent Abstract Session

Session Time: 4:30PM-6:00PM

Background/Purpose: Pathogenic immune responses can be profoundly shaped by the interplay between the periphery and the microenvironment. In this work we aimed at defining the immune mechanisms at the interface between the skin microenvironment and the periphery that are relevant for the disease pathogenesis in Systemic sclerosis (SSc), an autoimmune disorder of the connective tissue.

Methods:

Utilising an Immunomics platform that integrated in the same experimental flow: mass cytometry (CyTOF) for the identification of

disease-specific immune signatures (35 T cell specific markers), next generation RNAseq to characterize molecular patterns of antigen-specific T cells both in the periphery and in the skin microenvironment, NanoString platform to decipher the molecular characteristics of the skin microenvironment and various functional assays to validate the findings. Using this approach we interrogated peripheral blood (n=59) and compared them with healthy controls (n=33). We also compared paired lesional skin and peripheral blood derived T cells (n=7). Datasets were analysed by in-house developed computational tools.

Results:

Pathogenic Th17/Treg, Th17/Tfh cells and prototype Th17 cells were enriched in SSc subjects both in the periphery and in the skin microenvironment. Whole transcriptome analysis revealed skin derived T cells had elevated expression of IL-11 receptor (IL-11RA). Pathway analysis showed SSc skin derived T cells induced a distinct set of IL-17 regulated genes in dermal fibroblasts including IL-11. Skin derived IL-11 induced secretion of Th17 polarizing cytokines such as IL-1b and IL-6 from monocytes and polarized naive T cells to a Th17 phenotype. IL-11/IL-11RA signaling was regulated along a MAP3K8, STAT3 and PIM-1 signaling axis.

Conclusion:

By combining complementary *ex vivo* and *in vitro* approaches with non-biased data-driven analysis we could show that there exists a self reverberating pathogenic loop at the interface between the systemic and the skin microenvironment. This loop centred on the IL-17, IL-11 and IL11-RA triad expands and maintains disease-specific and pathogenic Th17 T cell subsets. Our findings have a dual translational valency both for targeted therapies and for understanding immune pathogenesis of SSc.

DOCK8 Associates with STAT5 and Promotes Regulatory T Cell Function

Erin Janssen[1], Mira Tohme[1], Sumana Ullas[2] and Raif Geha[2], [1]Immunology, Boston Children's Hospital, Boston, MA, [2]Boston Children's Hospital, Boston, MA

Session Date: Tuesday, November 15, 2016

Session Title: T Cell Biology and Targets in Autoimmune Disease - Oral Session

Session Type: ACR Concurrent Abstract Session

Session Time: 4:30PM-6:00PM

Background/Purpose: DOCK8 deficiency leads to autosomal recessive Hyper-IgE syndrome (AR-HIES). DOCK8 deficient patients develop recurrent sinopulmonary infections, chronic mucocutaneous viral infections, hyper-IgE, eosinophilia, food allergies, and severe dermatitis [1, 2]. We previously reported that the number and *in vitro* suppressive function of circulating regulatory T (Treg) cells are significantly reduced in DOCK8 deficient patients [3]. Paradoxically, they seldom develop autoimmunity, we propose that this is due to their impaired T effector (Teff) cell function.

Methods: We generated and analyzed *Dock8*$^{-/-}$ mice and mice with a selective DOCK8 deficiency in their Treg cells. Treg cell markers and *in vitro* suppressive function were investigated using flow cytometry. STAT5 phosphorylation was measured by flow cytometry and confocal microscopy. Using co-immunoprecipitation experiments, we examined the association between DOCK8 and STAT5.

Results: We determined that *Dock8*$^{-/-}$ mice have decreased Treg numbers and impaired *in vitro* function of Treg cells, but do not develop autoimmunity. In contrast, mice with selective DOCK8 deficiency in their Treg cells spontaneously develop lymphoproliferation, autoantibodies, and severe gastrointestinal inflammation, despite normal percentages of Treg cells. We found that DOCK8 associates with STAT5 and plays crucial role in IL-2 driven STAT5 phosphorylation and nuclear translocation in Treg

cells. These findings indicate that DOCK8 expression in Treg cells plays a critical role in self-tolerance by enhancing IL-2 driven STAT5 signaling, which is essential for Treg cell function, and suggest that deficient Teff cell function might protect DOCK8 deficient patients from autoimmunity.

Conclusion: These findings suggest that DOCK8 expression in Treg cells plays a critical role in self-tolerance by enhancing IL-2 driven STAT5 signaling. Furthermore, our data support the hypothesis that deficient Teff cell function may protect DOCK8 deficient patients from autoimmunity. References:

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016

Session Title: ACR/ARHP Combined Abstract Session: Pediatric Rheumatology

Session Type: ACR Concurrent Abstract Session

Session Time: 9:00AM-10:30AM

Background/Purpose: It is clear that young people (YP) with an autoimmune disease need a transitional process before they are transferred to the adult clinic. Therefore, a clinical transition pathway was implemented in 2009. Purpose of this transition pathway was to improve transition with provision of care developmentally appropriate, focus on achievement of self-management skills and supporting parents. The aims of this study were I) to evaluate the effectiveness of this clinical transition pathway, II) to evaluate the experiences and satisfaction in YA with autoimmune diseases in the transitional process.

Methods: All YP with an autoimmune disease who have been transferred from the pediatric to the adult rheumatology between 2009-2015 via the clinical transition pathway, were enrolled in this study. Most important points are an early start (14 years) with focus on self-management skills and independency using an individual transition plan (ITP) for each patient, joint consultations with professionals from pediatric and adult rheumatology and supporting parents in letting go. The ITP, a tool for developing self-management skills is essential in this pathway. Outcome measures for effective transition were drop out of care and completed ITP. To evaluate effectiveness electronic patients records(EPR) (n=158) were reviewed on completed ITP's and drop out of care. Additionally YA were asked to complete questionnaires after transition for the experience and satisfaction. Satisfaction with transition was measured with a transfer experiences scale, the OYOF-TES[1] (range 18-90) and a VAS scale (range 0-10); higher scores indicating higher satisfaction. Self-efficacy as an important variable for measuring self-management behavior was evaluated with the OYOF-SES[2] (range17-68, higher score, more SE).

Results: 158 YP were asked to participate, 77 YP returned questionnaires, a response rate of 50%. No difference was found between responders and non-responders on demographics and disease activity. Of 158 YA who ran through the clinical pathway, the overall rate of drop out was only 3.2% after one year. Of all YA 75% were transferred with an ITP. Satisfaction with transition measured with the OYOF-TES was high, 73.45 (SD 13.07). The VAS satisfaction was high with a mean of 7.6 (SD 1.62). Topics important for adolescents were discussed in almost all YA (96%). The OYOF-SES 58.65 (SD4.52).

Conclusion: The implementation of a clinical transition pathway was successful, a low dropout rate was seen and YP were satisfied with the transition process. High levels on the self-efficacy scale were reported, suggesting confidence of YP to achieve enough self-management skills. Cardiorespiratory Fitness in Children with Juvenile Idiopathic Arthritis Treated in the Biological Era is Comparable with Controls- a Cross-Sectional Study

Background/Purpose: Reduced cardiorespiratory fitness (CRF) has previously been found in children with juvenile idiopathic arthritis (JIA) compared to healthy children. However, little is known about CRF in JIA patients treated in the biologic era. The aims were to compare CRF in JIA patients who have had access to biological treatment from disease onset with controls, and to study associations between CRF and measures of disease activity in patients.

Methods: Patients with persistent oligoarthrtitis or polyarticular disease were recruited consecutively at Oslo University Hospital. Age- and sex-matched controls were selected randomly from the Norwegian Population Registry. In all participants, CRF was directly measured as peak oxygen uptake (VO_{2peak}) during a continuous graded exercise test on a treadmill until exhaustion. Present pain and pain and fatigue the last week were assessed by a Numeric Rating Scale (NRS). Puberty was self-rated using the Tanner

Scale. In patients, the Juvenile Arthritis Disease Activity Score 71 (JADAS 71) and the Childhood Health Assessment Questionnaire (CHAQ) were used to measure disease activity and functional disability, respectively. Differences between groups were tested with paired t-tests, or Wilcoxon rank test and correlations with Pearson or Spearman's rho correlation coefficients.

Results: Fifty-nine patients (50 girls, 9 boys) with JIA, 30 with persistent oligo arthritis and 29 with polyarticular disease (extended oligoarthitis and polyarticular RF +/-) aged 10-16 years and 59 controls were included. All patients had been encouraged to stay physically active with no general restrictions regarding physical activity. Twenty-five (42.4 %) patients used biological drugs. No differences were found in VO_{2peak} (mL/kg/min) in patients vs controls; 45.1 ± 8.5 vs 46.5 ± 8.5, (p=0.38). Furthermore, there were no differences in VO_{2peak} (mL/kg/min) in patients with persistent oligoarthritis vs polyarthritis; 45.0 ± 7.6 vs 45.3 ± 9.4, (p= 0.87) or in patients with active disease (n=39) vs patients in remission (n=20) (46.4 ± 9.7 vs 44.5 ± 7.9, p=0.43). In patients, there were no correlations between VO_{2peak} and JADAS 71, number of active joints in the lower extremities, use of medication, use of biological medication, disease duration, CHAQ, present pain and fatigue (all r<-0.3, p=NS). However, VO_{2peak} correlated weakly with pain last week (r= -0.28, p=0.03).

Conclusion: CRF in JIA patients treated in the biological era is comparable to controls, and also comparable between patients with persistent oligo arthritis and polyarticular disease. Even if less than half the patients used biological drugs, the positive results may be explained by advances in multidisciplinary treatment including less limitations regarding physical activity.

Table 1. Characteristics of patients and controls

	JIA (n=59)	Controls (n=59)	p-value
Age (yrs)	13.6 ± 2.2	13.5 ± 2.6	0.85
Height (cm)	157.6 ± 12.5	160.8 ± 12.3	0.17
Weight (kg)	48.3 ± 11.8	53.1 ± 15.2	0.06
BMI (kg/m^2)	19.2 ± 3.0	20.1 ± 3.5	0.12
NRS present pain (0-10)	0 (0-6)	0 (0-4)	0.04
NRS pain last week (0-10)	1 (0-7)	1 (0-6)	0.67
NRS fatigue last week (0-10)	3 (0-10)	3 (0-8)	0.90
Pubertal status (pre-, mid-, and postpubertal %)	23.7/61.0/15.3	16.9/67.7/15.3	0.65
Disease duration (yrs)	7.5 ± 3.8		
CHAQ score (0-3)	0.0 (0-1.4)		
JADAS (0-101)	3.2 (0-12.8)		
No medication	12 (20.3)		
NSAIDs	15 (25.4)		
DMARDs	39 (66.1)		
Biologics	25 (42.4)

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016
Session Title: ACR/ARHP Combined Abstract Session: Pediatric Rheumatology
Session Type: ACR Concurrent Abstract Session
Session Time: 9:00AM-10:30AM

Background/Purpose: The current JIA Core Set (ACR Pediatric 30) contains items that should be assessed in clinical trials for children with JIA. It was developed in 1997 without subsequent update. A shortcoming of the existing Core Set is the lack of patient/caregiver input in its development. The OMERACT JIA Core Set Group formed in 2015 as an international initiative to revise the existing Core Set with relevant patient/caregiver input. The aim of the current study, as part of the larger initiative, was to conduct focus groups to: 1) develop a comprehensive list of potential patient/caregiver outcome domains, 2) define the concept(s) represented by each domain, and 3) begin to prioritize these domains.

Methods: Patient and caregivers from North America participated in virtual focus groups (VFGs) about their experiences related to JIA. The VFGs utilized online discussion boards instead of in-person focus groups in order to accommodate more participants from diverse geographic regions, facilitate unrestricted sharing, and be efficient and cost-effective. Two sets of VFGs were performed: 1) caregivers and 2) adolescents and young adults with JIA. Eligibility was based on self-reported diagnosis of JIA and prior or current experience of JIA disease inactivity (>3 months). A qualitative researcher conducted the VFGs, which consisted of a 3-day online discussion board per group. Discussion guides sought to elucidate the impact of JIA on physical, mental and social health, and the perceived differences between active and inactive JIA. Participants answered questions individually and then could comment on others' responses. Transcripts were coded into domains with respect to OMERACT Core Areas and analyzed using NVivo 10.

Results: The caregiver VFG was split based on the age of their children: <15 years (n=10), and >15 years (n=10). The patient VFG was split into ages 15-17 (n=11), and 18-24 (n=13). Each group was diverse with respect to geography and categories of JIA, and included patients with active and inactive disease at the time of study. Participants discussed their experiences with JIA, life impact, resource use, pathophysiological manifestations, and adverse effects of JIA and its treatment. Data analysis revealed unique domains not represented in the current Core Set. Patients identified various psychosocial impacts of JIA and how it impacted participation in activities with their peers, school and/or job. Caregivers of younger children expressed fear for the future and unknown manifestations of JIA. Caregivers of older children identified the impact JIA had on the family and their child's participation in activities. Patients and caregivers characterized disease inactivity as the absence of pain, stiffness and swelling, increased activity participation, and improved mood and sleep quality.

Conclusion: The VFG format helped elicit concepts important to distinct and diverse groups of stakeholders affected by JIA. The current JIA Core Set lacks the patient/caregiver-centered domains identified in this study. Future efforts will perform VFGs in other geographic areas (Europe, Australia) and develop a model of the patient/caregiver experience of JIA that will inform the ongoing effort to expand the JIA Core Set.

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016
Session Title: ACR/ARHP Combined Abstract Session: Pediatric Rheumatology
Session Type: ACR Concurrent Abstract Session
Session Time: 9:00AM-10:30AM

Background/Purpose: Pharmachild is an international registry involving over 100 the Paediatric Rheumatology INternational Trials Organisation (PRINTO)/ the *Paediatric Rheumatology European Society (*PRES) centres in 38 countries. The registry was set up to evaluate long term safety and efficacy of treatments in children with JIA. The purpose of the study was to evaluate the occurrence of infections in JIA children and their relationship with biologics ± methotrexate (MTX) and other immunosuppressants.

Methods: Retrospective and prospective evaluation of moderate to very severe and serious infections. We investigated, by means of bivariate and multivariate modeling, the relationship between infections and the drugs used in the 6 month-history prior to the infection and, for patients without infections, in the 6 months prior to the last follow-up visit. The patients receiving only NSAIDs or intra-articular steroid injections were used as a reference.

Results: We analyzed 6969 patients, for a total of 689 (10%) patients with infections. Patients were systemic 639 (9%), polyarticular course 4587 (66%) and persistent oligoarthritis 1473 (25%). Patients with infections were treated in the previous 6 months primarily with MTX (82%), corticosteroids (32%), anti-TNF (52%), anti IL-1/IL-6 (8%), rituximab (2%) or other biologics (2%).Earlier age at diagnosis (≤7.7 years), ANA positivity, and systemic JIA category significantly increased the risk for infection (OR 2.3, 1.7 and 2.2, respectively). The analysis of the impact of the single immunosuppressive drugs showed that the risk for infection is increased by corticosteroids (OR 3.7), MTX (OR 2.8), cyclosporine (OR 5.3) and thalidomide (OR 13.7, 3/5 patients with infections). The same results were observed for biologics, in particular rituximab (OR 16.3, 14/22 patients with infections), IL-1 inhibitors as anakinra (OR 3.3) and, among TNF-α inhibitors, infliximab (OR 1.6). Conversely, abatacept resulted protective (OR 0.4). The multivariate analysis (table) revealed that the addition of steroids to both MTX and biologics (groups MTX + steroids and MTX + steroids + biologics) increased the risk of infections more significantly (OR 11.9 and 10.5, respectively) than only MTX (5.1) or MTX+Biologics (OR 3.7). A great increase in the risk for infection was associated with rituximab ± steroids ± DMARDs (OR 112, 95% CI 11-1000). The multivariate results were confirmed by removing rituximab patients from the model. **Table. Risk factors for infections in JIA patients by multivariate analysis. (REF: reference item)**

	Patients with infections N=689	Multivariate analysis OR (95%CI)
Drug Therapy		
Only NSAIDs and Intraarticular Steroids (REF)		
Rituximab ± Steroids ± DMARDS	12/16 (75%)	111.8 (10.7-999.9)
MTX+Biologics+Steroids	95/422 (23%)	10.5 (6.5-17.0)
MTX+Steroids	47/207 (23%)	11.9 (7.0-20.2)
Other combinations	102/689 (15%)	7.6 (4.8-12.0)
Only MTX	157/1418 (11%)	5.1 (3.3-7.9)
MTX+Biologics	181/2055 (9%)	3.7 (2.4-5.8)
Only Biologics	71/1077 (7%)	2.7 (1.7-4.3)
Diagnosis (Oligo Persistent arthritis as REF)		
Other JIA categories with polyarticular course	451/4587 (10%)	1.3 (1.1-1.6)
Systemic arthritis	100/639 (16%)	1.7 (1.3-2.3)
Age at JIA diagnosis (cut-off ≤7.7)	523/4136 (13%)	2.3 (1.9-2.7)
ANA (2 positive >1:160)	219/1595 (14%)	1.6 (1.3-1.9)

Conclusion: Pharmachild showed that MTX and biologics increase the risk of infection in JIA patients. This risk is significantly enhanced by the addition of steroids to immunosuppressive therapy. We recommend monitoring for infections in JIA patients on immunosuppressive therapy.

Session Title: ACR/ARHP Combined Abstract Session: Pediatric Rheumatology

Session Type: ACR Concurrent Abstract Session
Session Time: 9:00AM-10:30AM

Background/Purpose: Neonatal Lupus (NL) is a model of passively acquired autoimmunity conferred by exposure to maternal anti-Ro antibodies. This study was initiated to address the development of de novo autoimmunity in these children and identify associated genetic risk factors. Of relevance, the initial NL congenital heart block (CHB) GWAS revealed associations with HLA class I genes of the PSORS1 region that are linked to psoriasis.

Methods: In a retrospective cohort study of enrollees in the Research Registry for Neonatal Lupus, 346 children exposed to anti-Ro in utero responded to a follow up questionnaire focused on symptoms of autoimmunity. Self-reported diseases were confirmed via medical record review. Bivariate analyses were performed with potential risk factors for autoimmune disease development including NL manifestation, a disease severity score based on mortality risk factors, and maternal diagnosis of systemic lupus erythematosus (SLE) or Sjogren's syndrome (SS). In a substudy of these children (188 with CHB and their parents), DNA was interrogated using the Immunochip, a 196,806 SNP array that maps 200 regions containing known autoimmune diseases. Findings were compared to published SNPs outside of the HLA region in cohorts of rheumatoid arthritis (RA), Type 1 Diabetes (T1D) and psoriasis.

Results: Of the respondents, 134 had CHB, 74 cutaneous NL and 138 were unaffected siblings. Females comprised 54% and 81% were Caucasian. The mean age was 11.3±8.3; 10% age 0-2 years, 49% 2-13, and 40% > 13. An autoimmune disease developed in 24; 17 had CHB, 2 cutaneous NL and 5 unaffected (Table 1). The most prevalent disease was psoriasis. The presence of CHB was significantly associated with autoimmunity vs the cutaneous or unaffected children (12% vs 3%, p=0.002). An association between higher NL severity score and autoimmune disease was also found (5.0±4.7 vs 2.5±4.2, p= 0.003). The development of autoimmunity was not significantly different in children whose mother had SLE or SS vs those with asymptomatic mothers (7% vs 7%, p=1.0). No mother had psoriasis. Genetic analysis revealed that for significant associations of CHB vs. controls ($p<0.01$), overlaps were observed with other autoimmune diseases: 2 SNPs associated with RA, 0 T1D, and 178 psoriasis. For the latter, gene regions at B3GNT2-TMEM17, TRAF31P2 and KEAP-SLC9A8-SPATA2-RNF114 were of particular interest as these were significant in CHB offspring but not mothers.

Conclusion: Genetic risks factors in NL may predispose affected offspring to autoimmune diseases later in life, including psoriasis. That the development of an autoimmune disease is most apparent in those with CHB and more severe disease may relate to an inherent susceptibility to inflammation, manifest both in utero and later in life. The absence of certain SNPs in the mothers and independence of maternal clinical disease suggests that NL offspring may occupy a unique place in the spectrum of autoimmunity.

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016
Session Title: ACR/ARHP Combined Abstract Session: Pediatric Rheumatology
Session Type: ACR Concurrent Abstract Session
Session Time: 9:00AM-10:30AM

Background/Purpose: Several epidemiologic surveys have documented a remarkable, yet unexplained, disparity in the prevalence of juvenile idiopathic arthritis (JIA) subtypes among different geographic areas or ethnic groups. Moreover, the therapeutic approach to JIA is not standardized and the availability of the novel and costly biologic medications is not uniform throughout the world. This disparity may have significant impact on disease outcome. The multinational study of the EPidemiology, treatment and Outcome of Childhood Arthritis (EPOCA study) is aimed to obtain information on the variability of JIA phenotypes in different geographic areas, the therapeutic approaches of pediatric rheumatologists practicing in diverse countries, and the disease status and outcome of children with JIA currently followed worldwide.

Methods: Participation in the study was proposed to all pediatric rheumatology centers that are part of the Pediatric Rheumatology International Trials Organization (PRINTO), and to several centers in the US and Canada. Each center was asked to enroll 100 consecutive JIA patients or all consecutive patients seen within 6 months. Each patient received a retrospective and cross-sectional assessment. Parent- and child-reported outcomes were recorded through the administration of the Juvenile Arthritis Multidimensional Assessment Report (JAMAR). Participating countries were grouped into 6 geographic areas. Patients were then grouped according to their country's gross domestic product per capita (GDP) and the total expenditure on health per capita (HE) (source www.who.org).

Results: Currently, 8,325 patients from 44 countries have been entered in the web database. Comparison of main epidemiology, treatment, and outcome features across the different geographic areas is presented in the table. Patients living in countries with GDP or HE below the median had lower frequency of remission, higher median cJADAS, higher frequency of damage, and were less frequently prescribed biologic DMARDs. These results were confirmed when analyses were conducted by disease category.

	Africa N = 261	Asia N = 874	Eastern Europe N = 2587	Latin America N = 814	North America N = 422	Western Europe N = 3367
Median (IQR) age at onset, years	7 (3.6-10.5)	5.7 (2.9-9.2)	6.4 (2.9-10.5)	6.6 (3.6-10.3)	8.1 (3.7-11.1)	4.1 (2-8.7)
Systemic arthritis	17.2	26.5	8.1	17.7	4.7	6.9
Oligoarthritis	23	31.9	44.1	31.7	33.9	49.2
Uveitis	4.6	5.5	10	6.6	10.4	16.9
Use of biologics	22.6	23.6	28.9	34.2	47.6	39
Median (IQR) cJADAS10	7 (2-11)	2.5 (0-7.8)	4.5 (1-9.5)	2.5 (0-9.5)	2.3 (0-7)	2 (0-6)
Median (IQR) JAFS score	4 (0-8)	1 (0-5)	1 (0-4)	1 (0-5)	1 (0-4)	0 (0-3)
JADI-Articular > 0	27.6	19.2	23.7	31.9	15.2	12.2
JADI-Extraarticular > 0	24.5	16.8	14.8	14.5	5.9	9.1

Data are percentages unless otherwise indicated. cJADAS: clinical (3-item) JADAS; JAFS: Juvenile Arthritis Functionality Scale; JADI: Juvenile Arthritis Damage Index

Conclusion: These results provide further evidence of the wide difference of JIA characteristics across geographic areas in terms of age at disease onset, subtype prevalence, and frequency of anterior uveitis. Overall, patients living in countries with lower GDP or HE had higher levels of disease activity and cumulative damage than patients living in wealthier countries. This disparity may be partially related to differences in the availability or affordability of biologics.

Session Type: ACR Concurrent Abstract Session
Session Time: 9:00AM-10:30AM

Background/Purpose: RA FLS display a unique aggressive phenotype with a distinctive DNA methylation profile that marks genes involved with cytokine signaling, cell recruitment, and matrix regulation. In this study, the epigenetic and transcriptomic signature was expanded by adding multiple omics technologies to the integrative analysis. Patterns that distinguish RA and osteoarthritis (OA) FLS lines were identified using RNA-seq, ChIP-seq and DNA methylation datasets from the same cell lines. This analysis allowed us to create the first high-resolution functional genomic map of aggressive RA FLS.

Methods: Genome-wide data were collected from 11 RA and 11 OA FLS lines: (i) gene expression using RNA-seq for differentially expressed genes (DEGs); (ii) epigenetic modifications of six histone marks by ChIP-seq for differentially modified histone regions (DMHR) (H3K4me1, H3K4me3, H3K27ac, H3K27me3, H3K36me3, H3K9me3); (iii) DNA methylation by Illumina chip for differentially methylated genes (DMGs) previously reported on the same FLS lines (Genome Medicine, 2013). One RA and one OA FLS were filtered because they overlapped in principle component analyses (PCAs). Unbiased hierarchical clustering and PCA assessed the relationships between RA and OA. Integrative analysis was performed with overlapping gene sets and identified multi-evidence genes (MEGs), i.e., found in more than one dataset. Enriched pathways were determined with Ingenuity Pathway Analysis.

Results: 997 DEGs for RA compared with OA were identified by RNA-seq, with 43 enriched pathways including RA-specific pathways “Osteoblasts, Osteoclasts and Chondrocytes in RA” and “Macrophages, Fibroblasts and Endothelial Cells in RA”. Hierarchical clustering and PCA showed that RA and OA FLS transcriptomes significantly separated. For histone marks, 18,642 DMHRs between RA and OA were identified for six histone marks; H3K27ac, H3K4me1 and H3K4me3 showed far more DMHRs than the other marks. Multiple histone mark-enriched pathways were identified in inflammation, immune response and cell migration processes. When combined with the previously identified 2375 DMGs, integrative analysis of the 3 datasets revealed MEGs with overlapping DEGs, DMGs with H3K27ac, H3K4me1 and H3K4me3 histone marks. 19 biological pathways among the MEGS were enriched including “Macrophages, Fibroblasts and Endothelial Cells in RA”, “JAK family kinases in IL-6-type Cytokine Signaling”, “Cytokine Regulation in Macrophages and Th Cells by IL-17A/F”.

Conclusion: This is the first genome-wide analysis of the RA FLS transcriptome, methylome and histone marks. Pathogenic gene expression and epigenetic marks identify a distinctive RA signature that sheds light on the pathogenesis RA. The MEGs participate in immune networks, which enables strategies to modulate the unique aggressive phenotype of RA FLS. The data also permit development of *in silico* models that prioritize non-obvious targets for drug discovery.

Background/Purpose: Rheumatoid arthritis (RA) remains a significant unmet need despite improved therapy. Defining the interlaced nature of gene regulation and disease pathogenesis using integrative systems biology analysis is a powerful approach that can lead to experimentally verifiable predictions of novel therapeutic targets. We have developed a network that can potentially predict gene interactions that contribute to the pathogenic behavior of RA FLS and identify drug synergy to restore homeostasis.

Methods: Rheumatoid arthritis (RA) remains a significant unmet need despite improved therapy. Defining the interlaced nature of gene regulation and disease pathogenesis using integrative systems biology analysis is a powerful approach that can lead to experimentally verifiable predictions of novel therapeutic targets. We have developed a network that can potentially predict gene interactions that contribute to the pathogenic behavior of RA FLS and identify drug synergy to restore homeostasis. **Methods:** A novel computational systems biology method, known as RAnet, was designed and builds a probabilistic network model capturing the key regulations pertaining to the disease state of imprinted RA FLS. By comparing RA and osteoarthritis (OA) FLS, we curated genes that are critical in RA based on those that satisfied two of the three conditions: 1) differentially methylated genes (DMGs) in RA cells from 28 FLS lines, 2) differentially expressed genes (DEGs) in RA from 37 public microarray FLS lines, and 3) risk genes identified from GWAS studies. A set of 140 genes was selected to create a RA regulatory network. The network was determined by maximizing and adding or removing edges between randomly selected pairs of nodes. Using two and three gene combinations, predicted effects on gene expression were determined by calculating the Pearson and Spearman rank correlation coefficients.

Results: 403 gene-gene interactions were identified in RA Net. Because of the large number of potential combinations, we ranked and prioritized them in terms of the frequency in 1574 predicted models. The top gene/gene interactions included NFkB/GCLC, TP53/MDM2, CACL10/LINC0043, CYSLTR1/BHLHE22, and CARD16/C2orf88 because all were identified in at least 75% of the predicted models. We were also able to identify genes that regulate pathogenic pathways and cytokines in RA. For TNF regulation, top hits included TP53, PSMA4, IL1RN, CCR2, AIRE, JUN, and BMX. For IL-1 regulation, top hits included IL2RA, BMX, TNF, AIRE, and TP53. These core gene sets represent possible therapeutic targets that regulate these cytokines in RA. To determine combinations of genes that could be targeted to convert the RA FLS phenotype to a non-RA phenotype, we predicted the effect of knocking down combinations of genes. The maximum efficacy achievable with three-gene recipes ($r_{avg} = 0.576$) is significantly improved compared with two-gene recipes ($r_{avg} = 0.517$). The best three gene combination was the knockdown of genes the ring finger protein RNF144B (E3 ubiquitin-protein ligase), UGT2A3 and PLCH2. Interestingly, RNF144B expression is decreased by NSAIDs and RNF144B inhibitors are being developed as therapeutic agents.

Conclusion: This approach identifies synergistic therapeutic targets in RA using systems biology. The genes that regulate pathogenic pathways repeatedly appear in top gene “recipes” and could be promising candidates for combination therapy. This novel *in silico* method could offer a new way to determine disease mechanisms in RA.

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016
Session Title: Genetics, Genomics and Proteomics II
Session Type: ACR Concurrent Abstract Session
Session Time: 9:00AM-10:30AM

Background/Purpose: Antibody to citrullinated peptides/proteins (ACPA) is specific feature of rheumatoid arthritis (RA) and seen in 50 to 70% of RA patients. Amino acid (AA) position 11/13 in the HLA-DRβ1 is the strongest genetic risk factor in the HLA locus to ACPA(+) RA. We previously showed that HLA-DRB1 alleles interact to confer risk of ACPA(+) RA (Lenz et al Nat Gen 2015). However, genetic architectures underlying individual ACPA are still poorly understood. Here, we investigated the extent to which different individual ACPA are driven by distinct genetic factors within HLA locus.

Methods: We phenotyped RA cases with a multiplex peptide array to quantify 18 fine-specific ACPA as well as 2nd generation cyclic ctrullinated peptide antibody (CCP2), the representative method to quantify ACPA. We queried 6,267 patients and 12,054 controls across 3 independent cohorts. We performed clustering and principal component analysis to identify subgroups of ACPAs. We imputed HLA genotypes and tested for MHC associations with specific ACPA with logistic regression models correcting for 10 principal components and cohort effects. We also evaluate interactive effects of combinations of HLA-DRB1 alleles on fine-specific ACPA(+) RA susceptibility to assess whether allelic interactions influence expression of specific ACPAs.

Results: Clustering and principal component analysis of 18 fine ACPAs and CCP2 demonstrated that ACPAs could be classified into 2 distinct clusters, which we refer to as ACPA-A and ACPA-B. ACPA-A consisted of a total of 12 antibodies including CCP2 and an antibody recognizing a peptide derived from fibrinogen beta AA position 60 to 74 with positions 60, 72 and 74 citurillnated (Fibbeta60-74Ab) which was more strongly correlated with CCP2 than any other ACPA. ACPA-B contained a total of 7 antibodies including Fibbeta62-81cit72Ab, which reacts to a peptide sharing 12 AA sequences to the Fibbeta60-74Ab peptide but differs only in citrullination at one AA position. Position 11 of HLA-DRβ1 protein, which has six possible AA residues, showed the strongest associations in 14/18 ACPAs in intra-case analysis (omnibus $p \leq 1.1 \times 10^{-33}$). Intriguingly, Fibbeta62-81cit72Ab showed distinct association patterns of AA residues at the position 11 ($p=1.1 \times 10^{-50}$) from CCP2 associations. When we examined the subset of 175 case individuals that were positive for ACPA-B, but negative for all ACPA-A antibodies, we observed only weak evidence of association to position 11 ($p=0.066$), but did observe a significant association with HLA-B AA position 9 ($p=1.2 \times 10^{-7}$). We identified two novel allelic combinations specifically showing interactive effects on fine-specific ACPAs, for example DRB1*13:01 and 11:01 interact to influence expression of an antibody recognizing a peptide derived from heterogeneous ribonucleotide protein ($p=3.1 \times 10^{-4}$).

Conclusion: These findings suggest that specific HLA-DRB1 alleles, and their interacting combinations lead to a different repertoire of antibodies, with reactivities to different citrullinated peptide sequences. They suggest that reactivity to multiple antigen sets might independently lead to RA.

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016
Session Title: Genetics, Genomics and Proteomics II
Session Type: ACR Concurrent Abstract Session
Session Time: 9:00AM-10:30AM

Background/Purpose: Heritability of hand osteoarthritis (OA) has been estimated to be as high as 65%. Despite having a strong genetic component, genome-wide linkage and association studies of hand OA have identified few replicated genetic loci. Other mechanisms such as DNA methylation, which affects gene expression without altering the DNA sequence, may be involved. We therefore aimed to identify differentially methylated loci across the genome that are associated with hand OA.

Methods: Analyses were based on the Framingham Study, a community-based study in the US in which subjects were studied irrespective of OA status. Peripheral blood samples were collected on 2,846 individuals from the second generation cohort. Genomic DNA was extracted from the buffy coat, bisulfite converted, and assayed with the Illumina Infinium Human Methylation450 Beadchip. Standard quality-control procedures were conducted, leaving 2,648 samples and 485,513 CpG probes for analysis. There were 1,261 individuals from this generation cohort without rheumatoid arthritis who obtained bilateral posteroanterior hand radiographs. We derived a summary index score for hand OA by summing semi-quantitative Kellgren-Lawrence (KL) scores at the 2^{nd}-5^{th} distal interphalangeal, 2^{nd}-5^{th} proximal interphalangeal, 1^{st}-5^{th} metacarpophalangeal, thumb interphalangeal, and 1st carpometacarpal joints (possible range=0 to 120). We implemented linear mixed effects regression models to test the effect of a hand OA summary index score on DNA methylation level at each CpG probe. All regression models were adjusted for age, sex, principal components, and estimated cell counts as fixed effects, and familial relationships and chip identifiers as random effects.

Results: A total of 1,073 individuals with hand OA assessments and DNA methylation data were included in the analysis. Mean age was 66±8 years and 57% were women. Mean summary index score for hand OA was 8±12. We applied a conservative Bonferroni correction for ~490,000 probes and identified 7 differentially methylated regions that met genome-wide significance ($p<1x10^{-7}$), including cg12762517, cg21838477, cg05400732, cg04299389, cg20277504, cg13225177, and cg20205818 (Table 1). Our top finding, cg12762517, is located in *PARP3*, which catalyzes poly-ADP-ribosylation of nuclear proteins needed for DNA repair and regulation of apoptosis. None of the other findings has been previously associated with hand OA; however, cg0500732 resides within *ARHGEF3*, a Rho gunanine nucleotide exchange factor that may play a role bone cell biology.

Conclusion: We identified 7 differentially methylated regions associated with hand OA at genome-wide significance. None of these regions has been previously associated with OA, though *ARHGEF3* has been implicated in osteoporosis, suggesting that regulation of bone mineral density may play an important role in hand OA pathogenesis.

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016
Session Title: Genetics, Genomics and Proteomics II
Session Type: ACR Concurrent Abstract Session
Session Time: 9:00AM-10:30AM

Background/Purpose: Ankylosing spondylitis (AS) is a highly heritable inflammatory arthritis common in both Turkish and Iranian populations. Familial Mediterranean Fever (FMF) is an autosomal recessive autoinflammatory disease that usually occurs in people of Mediterranean origin. MEFV, a known FMF-associated gene, is a candidate gene for AS, because of increased co-familiality of AS and FMF, and suggestive association of MEFV with AS in candidate gene studies. Here we studied Turkish and Iranian case-control cohorts to identify AS susceptibility loci and also examine the association between MEFV and AS.

Methods: A genome wide association study was performed in 1001 Turkish AS patients and 1011 Turkish controls and also 479 Iranian AS patients and 830 Iranian controls, using Illumina Infinium CoreExome chips. Standard quality control and population stratification identification and control measures were applied (lambda1000 in Turkish, Iranian and combined datasets 1.039, 1.025 and 1.025 respectively).

Results: In this study we identified two non-MHC loci, MEFV and USP8 reaching genome-wide significance ($p < 5x10^{-8}$), and fourteen suggestive loci ($10^{-5} < p < 5x10^{-8}$), in the combined cohort. The lead MEFV SNP rs61752717 (M694V, $p = 7.6x10^{-12}$, OR = 5.3) is a rare coding variant (MAF=0.011 in Turkish controls) and also the most penetrant FMF-associated variant. This lead SNP also shows significant association with AS in Iranian cohort (p = 0.042, OR = 2.9), and in the combined dataset is very strongly AS-associated ($p = 1.5x10^{-13}$, OR = 4.9). Three coding variants in MEFV were significantly associated with AS (P369S, R408Q and M694V). AS cases with MEFV rs61752717 variants did not themselves have FMF, and had similar disease manifestations to non-carriers. This study confirms the previous identification of USP8 as an AS-associated locus (exm1161045, $p = 8.0x10^{-14}$, OR = 0.58 in combined dataset), and at previously reported AS-associated loci including HLA-B, ERAP1 and 2p15.

Conclusion: This study provides definitive evidence of the association of rare MEFV variants with AS, and confirms that FMF and AS have overlapping aetiopathogenic mechanisms. The association of MEFV in these populations has the highest odds ratio for AS of any non-MHC genetic variant confirmed at genome-wide significance to date. Functionally important MEFV mutations such as M694V have been demonstrated to lead to dysregulated inflammasome function and excessive IL-1b function. Given that IL-1 inhibition is effective in FMF, it will be interesting to study whether AS cases carrying FMF-associated MEFV variants also benefit from such therapy.

Huntingtin Interacting Protein 1 (Hip1) Is a New Arthritis Severity Gene

Teresina Laragione[1], Percio Gulko[1] and Max Brenner[2], [1]Medicine/Rheumatology, Icahn School of Medicine at Mount Sinai, New York, NY, [2]Feinstein Institute for Medical Research, Manhasset, NY

SESSION INFORMATION
Session Date: Wednesday, November 16, 2016
Session Title: Genetics, Genomics and Proteomics II
Session Type: ACR Concurrent Abstract Session
Session Time: 9:00AM-10:30AM

Background/Purpose: *Cia25/Pia42* is an arthritis severity and joint damage quantitative trait locus on rat chromosome 12 previously identified in an intercross between MHC identical but disease discordant DA (arthritis-susceptible) and ACI (resistant) rats. DA.ACI(Cia25/Pia42) congenic rats were significantly protected in both Pristane and Collagen-induced arthritis (PIA and CIA) compared with DA. This study aimed at positionally identifying the gene accounting for *Cia25/Pia42* gene.

Methods: Recombinant subcongenics covering the *Cia25/Pia42* interval were generated by backcrossing the original congenic strain with DA using a genotype-guided strategy. Recombinants sharing identical intervals were then intercrossed to homozygozity. PIA was induced in 8-12 week-old subcongenic rats and disease scored for 31 days using a system that correlates with histological damage. Fibroblast-like synoviocytes (FLS) from rats and patients with rheumatoid arthritis (RA) were studied in *in vitro* invasion assays previously shown to correlate with radiographic damage.

Results: Analyses of 12 different recombinant (R) subcongenic strains reduced the gene-containing interval from 33Mb to a 1.2MB region contained within subcongenic R6. R6 subcongenics had significantly 92% lower median arthritis severity score compared with DA ($P<0.001$) and were significantly protected from developing cartilage or bone damage ($P<0.002$). Sequencing of the 36 genes in the 1.2MB critical interval identified three genes with amino-acid changing SNPs with predicted protein functional consequences based on SIFT and PolyPhen2 analyses. These three genes were expressed in FLS from arthritic rats and patients with rheumatoid arthritis (RA). Huntingtin-interacting protein 1 (Hip1), a gene implicated in clathrin-mediated endocytosis, was one of these genes and was expressed in increased levels in DA FLS compared with R6. FLS from protected DA.ACI(Cia25/Pia42) subcongenic R6 were less invasive than those from DA rats, suggesting that the *Cia25/Pia42* gene operates via the regulation of FLS invasion. siRNA Hip1 significantly reduced the invasive properties of FLS obtained from DA rats and from patients with RA. Hip1 knock-out mice were obtained and were protected in KRN serum-induced arthritis, confirming the importance of this gene in arthritis.

Conclusion: Hip1 is a new arthritis severity and joint damage gene that mediates disease at least in part via the regulation of the invasive properties of FLS. The identification of this new gene is the first step towards developing new therapies and a new prognostic biomarker for RA.

Session Title: Metabolic and Crystal Arthropathies II: Clinical Practice
Session Type: ACR Concurrent Abstract Session
Session Time: 9:00AM-10:30AM

Background/Purpose: Gout and rheumatoid arthritis (RA), the two most common inflammatory arthritides, are both associated with premature mortality. General population-based studies have found substantially reduced premature deaths in RA patients in recent years (likely due to improved RA care), including our own study spanning 1999-2014 (1). However, no equivalent secular trend data in gout are available. Given the well-documented suboptimal gout care, opposing mortality trends may exist between RA and gout, as was recently shown in their hospitalization rates (2). We evaluated this hypothesis by examining mortality trends of gout patients over the same period (i.e., 1999-2014) as in our recent study based on the same general population database (1).

Methods: Using an EMR database representative of the UK general population, we identified incident gout cases and up to 5 non-gout controls matched on sex, age, and entry time between Jan 1 1999 and Dec 31 2014. The gout cohort was divided into two sub-cohorts based on the year of diagnosis, forming the early (1999-2006) and late (2007-2014) cohorts. We calculated mortality rates and hazard ratios (HRs) using a Cox proportional hazard model to adjust for demographics, lifestyle factors, comorbidities, medications, and healthcare use. We then compared the HRs from the early vs. late cohorts using interaction analyses. We repeated these analyses limited to those who received at least one prescription for urate-lowering therapy or colchicine, which has been found to have a validity of 90%.

Results: Both the early and late cohorts (N = 44,783 and 58,478, respectively) had the same mean age (62 years) and sex proportion (~74% male) between the gout and comparison group. In both the early and late cohorts, gout patients showed similar levels of excess mortality compared to their corresponding comparison cohort (i.e., 29.1 vs. 23.5 deaths/1000 person-years (PY) in the early cohort and 23.0 vs. 18.8 deaths/1000 PY in the late cohort) **(Figure)**. The corresponding univariate mortality HRs (95% CI) were 1.25 (1.21-1.30) and 1.24 (1.20-1.29), and the multivariable mortality HRs were 1.10 (1.06-1.15) and 1.09 (1.05-1.13), respectively (both P for interaction >0.72). Our analysis limited to those who received a prescription for anti-gout medication showed similar findings (both P for interaction >0.88)

Conclusion: This population-based cohort study indicates that the level of excess mortality among gout patients remains unchanged over the past 16 years, contrasting the aforementioned substantial reduction in excess mortality observed among RA patients during the same period (1). This unclosing gap in premature mortality among gout patients calls for improved management of gout and its comorbidities. **References:**

Session Title: Metabolic and Crystal Arthropathies II: Clinical Practice

Session Type: ACR Concurrent Abstract Session

Session Time: 9:00AM-10:30AM

Background/Purpose: A compensated polarizing microscopy has been used for detecting monosodium urate (MSU) or calcium pyrophosphate dihydrate (CPPD) crystals to confirm the diagnosis of gout or pseudogout for more than 50 years. However, accuracy of the methodology is affected by crystal concentration, time invested reading the slide and operator skill. As the procedure is only billable through a Clinical Laboratory Improvement Amendments (CLIA)-certified lab, its bedside use has waned over the years. There is a need for a more efficient and accurate method. Herein, we present a novel method to detect birefringent crystals in synovial fluid by designing a lens-free on-chip polarizing microscope.

Methods: Lens-free on-chip microscopy based on digital in-line holography is a novel imaging technique that has achieved wide field of view (>20 mm^2) and high-resolution biomedical imaging in a simple, cost-effective and field-portable design. We modified this technology with a circular polarizer and an angle-mismatched analyzer so that the partially-coherent light that is passed through

the birefringent crystals can be enhanced and detected by a digital image sensor. Two images of every sample are taken with the sample rotated by 90 degrees to eliminate any non-birefringent objects. An image processing algorithm and post image color-coding was applied to enhance the quality and to reproduce the similar color images to those of a compensated polarizing microscope. Imaging of CPPD crystals are in progress at the time of this abstract submission.

Results: Figure 1 shows the comparison of MSU crystal images taken by a compensated polarizing microscope (A), a lens-free differential grayscale image (B) and a lens-free color-coded image (C). The images taken by the novel technique was able to accurately demonstrate the direction and the strength of birefringence and the shape of MSU crystals. Two independent experts reviewed multiple images and determined that they were comparable to those from a conventional polarizing microscope.

Conclusion: We developed a digital lens-free on-chip polarizing microscope that can detect birefringent crystals over a wide field of view. It uses a computerized image analysis algorithm and a digital image sensor, which overcomes the weakness of time-consuming, operator-dependent property of the conventional polarizing microscope. Its time-efficiency, small size and low cost could make it more easily used in a daily practice, to facilitate synovial fluid examination for the diagnosis of crystal arthropathy. The process is currently completed for MSU crystals. Validation of CPPD crystal images taken by this novel technology is currently in progress.

Session Time: 9:00AM-10:30AM

Ultrasound Evaluation of the Achilles Tendon in Tophaceous Gout: A Case-Control Study

Background/Purpose: Tendon involvement in the lower limbs in gout is frequent. Tophus deposition to the Achilles tendon (AT) has been reported, however, data describing ultrasound (US) lesions to specific anatomical zones of the AT is limited. The aim of the study was to investigate frequency and distribution of US lesions of the AT in people with tophaceous gout compared to age and sex matched controls.

Methods: Twenty-four participants with tophaceous gout and 24 age- and sex-matched control participants without gout or other arthritis were recruited. All participants underwent US examination, using both greyscale and power Doppler (PD) technique by a musculoskeletal radiologist who was blinded to diagnosis. The AT was divided into three anatomical zones (zone 1: insertion, zone 2: pre-insertional and zone 3 proximal to the mid-section). US lesions were scored using a semi-qualitative scoring system assessing tophus, tendon echogenicity, tendon vascularity, tendon morphology, enthesis, bursal morphology and entheseal bone profile. All US scanning techniques and lesion definitions were used as proposed by the OMERACT ultrasound task force. Scans were scored independently by two musculoskeletal radiologists, blinded to diagnosis and each other's scores, with kappa levels of agreement ranging between 0.77 to 1.00. As lesions were nested within participants, a general estimating equation approach was used to data analysis. All tests were two-tailed, with $p < 0.05$ considered significant.

Results: The table shows the percentage of US lesions present in each group and defined by the zone of the AT. Tophus deposition was observed in the AT of 73% of participants with tophaceous gout and not observed in control participants ($p < 0.01$). Intratendinous hyperechoic spots and intratendinous PD signal were also more frequent in participants with tophaceous gout compared to control participants ($p < 0.01$ for both). Frequency of entheseal lesions, calcaneal lesions and AT thickness did not differ between groups. In participants with gout, there was no significant difference in distribution of tophi or intratendinous power Doppler signal at different zones. In contrast, intratendinous hyperechoic spots were most commonly observed in zone 1 and were least commonly observed in zone 3 of the AT.

Conclusion: The Achilles tendon is frequently involved in people with tophaceous gout. Ultrasound features of intratendinous urate deposition and inflammation are commonly observed. Table: Percentage of ultrasound lesions present between case and control participants

US lesion	Gout participants US lesions present %	Control participants US lesion present %	P	US lesions present in AT of gout participants %		P for between zones in gout participants
Tophus	73	0	<0.01	Zone 1	54	0.07
				Zone 2	52	
				Zone 3	29	
Intratendinous hyperechoic spots	98	19	<0.01	Zone 1	46	<0.01
				Zone 2	35	
				Zone 3	21	
Intratendinous power Doppler signal	81	19	<0.01	Zone 1	35	0.60
				Zone 2	31	
				Zone 3	35	
Entheseal echogenicity: calcifications	59	40	0.43			
Entheseal vascularity	21	15	0.65			
Calcaneal bone cortex irregularities	27	19	0.43			
Calcaneal enthesophytes	69	60	0.64			
Tendon thickness, mm, mean (SD)	4.65 (0.81)	4.32 (0.74)	0.85

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016
Session Title: Metabolic and Crystal Arthropathies II: Clinical Practice
Session Type: ACR Concurrent Abstract Session
Session Time: 9:00AM-10:30AM

Background/Purpose: Dual energy computed tomography (DECT) allows reliably detecting and quantifying tophus burden in patients with chronic gout. Longitudinal studies on the effect of uric acid lowering drug therapy on tophus burden assessed by DECT are currently lacking with the exception of a small study performed in patients treated with Pegloticase (1). Aim: To assess and compare the effects of uric acid lowering drugs on reducing tophus volume in patients with chronic gout by means of dual energy computed tomography scans

Methods: Follow-up DECT scans were performed in 94 patients with initially DECT positive chronic gout receiving stable treatment with either Allopurinol, Febuxostat, Benzbromaron or Pegloticase or had solely life-style intervention with no concomitant uric acid lowering drug therapy. Baseline and follow-up scans of both feet captured automatically the urate volume (Somatom Definition Flash/Force CT; Syngo DE Gout software; Siemens). Artefacts were manually excluded. Changes in tophus volume were calculated in a descriptive (tophus volume at baseline minus tophus volume at follow-up) and inferential way (Wilcoxon signed-rank test). Demographic data, medication and blood values (CRP, creatinine, serum urate) were recorded at the time of each DECT scan.

Results: 94 patients (75 men and 19 women) were analyzed. Mean disease duration until the first DECT examination was 3.3 years and mean interval between both DECT examinations was 17 months. The overall baseline serum uric acid level decreased from 7.3 ± 2.5 mg/dl to 5.9 ± 2.8 mg/dl at follow up (- 19%). Baseline tophus volume decreased by 77% with Allopurinol ($p < 0.001$, $r = -0.50$), 35% with Febuxostat ($p = 0.001$, $r = -0.51$) and 90% with Pegloticase ($p = 0.005$, $r = -0.58$). Only 2 patients were treated with Benzbromaron showing numerical decrease of tophus volume at a similar range as seen with Allopurinol (- 75%). Life-style intervention also led to a moderate (- 31%), though significant ($p = 0.007$, $r = -0.40$), decrease in tophus burden. Complete tophus resolution was found in 46,4% of the patients treated with Allopurinol, 34,8% treated with Febuxostat and 8,3% with Pegloticase.

Conclusion: Sustained uric acid lowering drug therapy leads to significant reduction of DECT tophus burden in patients with chronic gout. The effectiveness of urate lowering therapies on reducing serum urate concentration is not necessarily transferable on the resolution of monosodium urate crystal depositions (see in table 2). While Febuxostat led to the greatest change in serum uric acid levels with a reduction of 36%, its effect on reducing tophus burden was rather low (- 34 %). At present, it is common clinical practice to monitor gout treatment based on the uric acid level. However, in order to assess and monitor the real effect of urate lowering therapies on the resolution of monosodium urate depositions, dual energy CT is more accurate.

Session Title: Metabolic and Crystal Arthropathies II: Clinical Practice

Session Type: ACR Concurrent Abstract Session

Session Time: 9:00AM-10:30AM

Background/Purpose: Allopurinol is recommended as a first-line pharmacologic urate-lowering therapy in gout. Oxypurinol, the active metabolite of allopurinol, is entirely cleared by the kidneys. Oxypurinol clearance decreases in proportion to glomerular filtration rate (GFR) in chronic kidney disease. However, the pharmacokinetics of oxypurinol in dialysis patients is not known. We hypothesised that oxypurinol clearance in patients receiving haemodialysis will be comparable to patients with a glomerular filtration rate (GFR) of 10-20 ml/min. The purpose of this study was to describe oxypurinol pharmacokinetics in people with gout treated with hemodialysis.

Methods: The pharmacokinetics of oxypurinol was assessed in a group of patients with gout receiving intermittent haemodialysis three times weekly for five hours per session (Hemoflow F8HPS Polysulfone dialyser). The blood flow for dialysis was 200mL/min and the dialysate flow was 500 mL/min. All subjects were taking long-term allopurinol 100 mg daily. During the study allopurinol was taken after dialysis on dialysis days. Six blood samples were collected from each subject at 0, 1, 2, 3, 4, and 5 hours after the start of dialysis for the measurement of oxypurinol plasma concentrations. Urine was collected from each subject over a 24 hour period. A further eight blood samples were collected from each subject across a non-dialysis dosing interval at 0, 0.5, 1, 1.5, 2, 4, 6 and 24 hours after the dose. Serum urate was measured at baseline, post-dialysis (6 hours), and at the end of the study (48 hours). Oxypurinol was measured by liquid chromatography–mass spectrometry and oxypurinol clearance was calculated from the area under the concentration time curve (AUC).

Results: Six patients were recruited; five male and one female. Their median age was 63 years (28-72 years). All had been taking allopurinol for > 1 year, were taking no other medicines for gout, and were not taking diuretics. Two patients were anuric and four had some residual renal function (urine output 0-260 ml/24 hrs). One patient was excluded after sample analysis as their results showed they were not adherent with treatment. At steady state, the oxypurinol median AUC was 30 umol/L*hr (range 23-50). The median oxypurinol clearance was 1.0 L/hr (0.60-1.3). This was higher than expected and comparable to the clearance in patients with normal kidney function. The median plasma urate concentration pre-dialysis was 5.9 mg/dL (4.7-8.9mg/dl). Serum urate dropped precipitously during dialysis and is either back to baseline (n=2) or within 80% of baseline (n=3) by 42 hours post-dialysis.

Conclusion: Allopurinol is likely to be more effective if administered after, rather than before, dialysis. Serum urate should be measured prior to dialysis to ensure target urate is maintained between dialysis. Hemodialysis was more effective at removing oxypurinol from the circulation than predicted. The dose of allopurinol in dialysis patients does not need to be restricted to 100mg daily. Further studies of allopurinol to treat gout in dialysis patients should examine conventional urate targeted dosing.

SESSION INFORMATION
Session Date: Wednesday, November 16, 2016
Session Title: Metabolic and Crystal Arthropathies II: Clinical Practice
Session Type: ACR Concurrent Abstract Session
Session Time: 9:00AM-10:30AM

Background/Purpose: Recent management guidelines for gout have identified several unmet educational needs in gout patients. Qualitative studies have documented the paucity of patient-focused materials which facilitate ongoing patient-physician communication. Our objective was to develop and test a web-based interactive educational resource (electronic platform) for gout patients tailored to improve their knowledge and help facilitate communication with their physicians.

Methods: The website was developed in four phases: 1. Two advisory panels - 30 gout patients and 10 gout experts iteratively a) reviewed pre-identified content areas of modifiable gaps in pathogenesis, natural history and treatment goals from previously conducted focus groups[1] and b) evaluated the design (graphics and lay out) of the website. 2. Incorporation of a validated Gout Knowledge Questionnaire (GKQ)[2] on gout and a 5-minute post-survey to assess knowledge about critical take-home messages and satisfaction with their physician's care. 3. A team of web designers and health informatics experts tailored the content areas on the website to create a patient journey to learn various aspects of gout such as triggers of flares, comorbidities, pharmacologic and non-pharmacologic treatments, healthy gout diet, and lifestyle choices. 4. Beta testing was performed by 10 patients with gout in clinics for clarity and usability. The website is called MyGoutCare® and in the pilot study, the patient completes a baseline survey of demographics and gout knowledge, reviews the website and generates a list of customized questions (MyGoutReport®) to discuss at the upcoming visit with their physician. They next complete a post-survey within two weeks of the physician visit. Data was analyzed using a paired t-test and presented as mean change in scores between post and baseline surveys.

Results: The pilot study recruited 50 subjects with gout from general medicine, podiatry, and rheumatology clinics. The mean age was 54 years, 88% were males, 82% Caucasian, and 68% consumed 7.5 drinks per week. Disease duration was 9.5 years and they reported 3-5 flares per year. All subjects were extremely receptive of the e-learning tool that was accessible 24/7. Post-survey scores on GKQ (mean score= 9.06, 0-10) improved significantly (20%) when compared to pre-survey scores (mean score= 7.12) with mean (SD) at 1.95 (1.93), $p<0.0001$ and effect size of 0.95. All subjects reported satisfaction with discussion on the natural history of disease and treatment choices with their physicians. They reported significant actionable changes moving forward, such as changing urate-lowering therapy (72%) and dietary/alcohol changes (28%-38%) to achieve flare-free status.

Conclusion: Our pilot study suggests that web-based patient-focused materials can serve as a practical tool to positively impact the ongoing educational needs of patients in a busy clinical practice setting. Prospective adequately powered studies are needed to evaluate if this online tool will lead to better long term outcomes by improving patient-physician communication. References:

Pregabalin Is More Effective in Treating Hand Osteoarthritis Pain Than Duloxetine or Placebo: A Double-Blind Randomized Controlled Trial

Nidhi Sofat[1], Abiola Harrison[2], Salma Ayis[3], Patrick Kiely[4], Thomas Richard Barrick[5] and Franklyn Howe[6], [1]Basic Medical Sciences, St. George's, University of London, London, United Kingdom, [2]Rheumatology, Mailpoint J1A, St George's, University of London, London, United Kingdom, [3]Department if Statistics, Division of Health & Social Care Research, Guy's Campus, King's

Session Title: Osteoarthritis – Clinical Aspect II: Treatment and Imaging

Session Type: ACR Concurrent Abstract Session

Session Time: 9:00AM-10:30AM

Background/Purpose: Pain is a major symptom in hand osteoarthritis (OA), with many patients taking analgesics including acetaminophen, non-steroidal anti-inflammatory drugs (NSAIDs) and even opioids. Patients with OA who do not respond to conventional analgesics may have 'sensitization', or heightened pain symptoms which are centrally mediated. We hypothesized that patients with hand OA who have features of sensitization may improve with centrally-acting analgesics including duloxetine or pregabalin.

Methods: A prospective, randomized, double-blind, placebo-controlled trial from 42 primary care and rheumatology clinics in the UK. We recruited 85 participants: 65 with hand OA confirmed by ACR criteria (mean age 62 years) and 20 age-matched non-OA controls. Patients were assigned 1:1:1 to treatment with duloxetine (up to 60 mg), pregabalin (up to 300 mg) or matched placebo. The primary endpoints were the Australian and Canadian Hand Osteoarthritis Index (AUSCAN) pain score change and the Visual Analogue Scale (VAS) pain rating 0-10 from baseline to 12 weeks treatment. Secondary endpoints were AUSCAN function, Hospital Anxiety and Depression Scale (HADS) and pain pressure thresholds (PPTs) for sensitization measured by algometry (Wagner).

Results: All participants were randomised and included in the intention-to-treat analysis. The highest mean reduction in AUSCAN pain scores was achieved for the pregabalin group (mean change -132.1, 95% confidence interval -181.1 to -82.9) followed by duloxetine (mean change -62.5, 95% confidence interval -141.6 to 16.6) and placebo (mean change -47.1, 95% confidence interval -93.9 to 11.7). The most significant improvement after treatment was in the pregabalin group compared with placebo (p=0.013), Figure 1. AUSCAN pain reduction for duloxetine was not significant (p=0.90). VAS pain outcome was significant for pregabalin (p<0.00001) and duloxetine (p=0.029) respectively with no change in depression or anxiety scores in any group. PPT were lower in hand OA than non-OA controls at baseline (p<0.05). Side effects were similar in pregabalin and duloxetine groups, although more neurological side effects occurred in the pregabalin group including dizziness, dry mouth, sleepiness and loss of balance. PPT were useful for screening for sensitization, but did not change significantly after treatment (p>0.05).

Conclusion: Pregabalin has significant efficacy at 300 mg in improving pain and function after 12 weeks compared with duloxetine or placebo in hand OA. VAS pain outcomes for pregabalin and duloxetine both showed significant efficacy over placebo. PPTs are useful for screening for sensitization and identifying participants who are likely to respond to centrally-acting analgesics. Our results demonstrate evidence for pregabalin as an alternative for OA pain in sensitized patients and clinical trials that examine the balance between efficacy and side effects should be encouraged.

Protective Effects of Replacing Sedentary Time with Light and Moderate to Vigorous Physical Activity on Functional Limitation in Knee OA

Daniel White, Department of Physical Therapy, University of Delaware, Newark, DE
First publication: September 28, 2016

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016
Session Title: Osteoarthritis – Clinical Aspect II: Treatment and Imaging
Session Type: ACR Concurrent Abstract Session
Session Time: 9:00AM-10:30AM

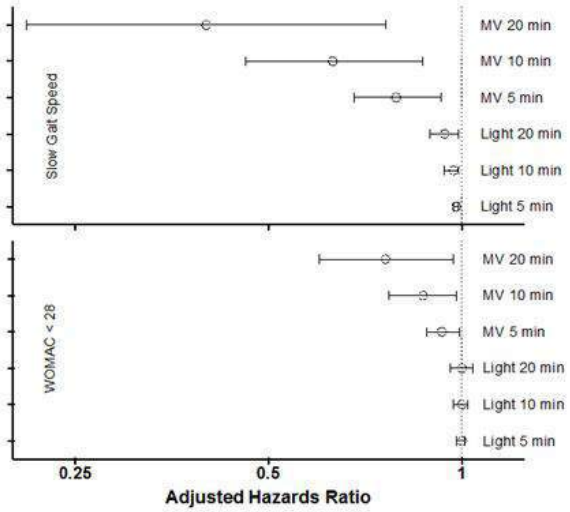
Background/Purpose: Physical activity protects the development of functional limitation in knee osteoarthritis (OA). But little is known about the protective effects of physical activity intensity, i.e., light and moderate to vigorous physical activity (MVPA). Knee OA-related pain may limit higher intensity activity, and the benefit of light intensity activity is not known. Moreover, it is unclear what amount of light intensity activity may be necessary to equal the health benefits attained from MVPA. The purpose of this study was to investigate the association of replacing sedentary time with light intensity and MVPA with the development of functional limitation two years later in people with or at high risk of knee OA.

Methods: Physical activity was objectively measured with an accelerometer in a subcohort of adults from the Osteoarthritis Initiative (OAI) at the 48- and 72-month visits (our study baselines). We included participants with at least four 10-hour days of valid monitoring and classified time in sedentary, light, and MVPA using established thresholds. Incident functional limitation over two years was assessed by: 1) Slow gait speed (< 1.0 meters/sec during a 20-meter walk), 2) Low WOMAC physical function (≥ 28; range 0-68) and 3) Low SF-12 (<40; range 0-100). We evaluated the association of replacing sedentary time with light or MVPA with incident functional limitation risk over two years using isotemporal substitution models. Hazard ratios were estimated from discrete survival models. All analyses were adjusted for potential confounders.

Results: We included 1873 study subjects (mean age (sd) = 65.0 years (9.0), 54.6% women, mean BMI (sd) = 28.4 kg/m^2 (4.7). Replacing 5 minutes of sedentary time with 5 min of light activity reduced the incident risk for slow gait function by 2%. Replacing with 5 min of MVPA reduced the risk by 21%. 78 min of light activity is necessary to achieve the same protective benefit of 5 min of MPVA. Replacing sedentary time with MVPA but not light activity significantly reduced the incident risk of low WOMAC. The protective effect of replacing sedentary time with light activity or MVPA was amplified with longer replacement periods. See Figure

Conclusion: Replacing sedentary time with light or MVPA reduced the risk of incident functional limitation. The protective effects of MVPA outweighed light activity.

Figure: Adjusted* hazard ratios of protective benefits of replacing sedentary time with an equal amount of light and moderate to vigorous (MV) physical activity.



* Adjusted for age, sex, race, education, BMI, radiographic knee OA, comorbidity, depressive symptoms, knee pain, and lower body pain

SESSION INFORMATION
Session Date: Wednesday, November 16, 2016
Session Title: Osteoarthritis – Clinical Aspect II: Treatment and Imaging
Session Type: ACR Concurrent Abstract Session
Session Time: 9:00AM-10:30AM

Background/Purpose: Infrapatellar fat pad (IPFP), a local adipose tissue, may have important contributions to knee osteoarthritis (OA). IPFP signal intensity alterations on MRI may represent pathological changes such as inflammation and oedema. This study aims to describe the associations between quantitative measures of infrapatellar fat pad (IPFP) signal intensity alterations and knee structural and symptomatic abnormalities in patients with symptomatic knee OA.

Methods: 261 participants (mean age 63.0 ± 7.2 years) with symptomatic knee OA (assessed according to American College of Rheumatology criteria) were selected from a randomized controlled trial. IPFP signal intensity alteration was quantitatively measured on T2-weighted fat-saturated MRI using MATLAB. These included the mean value [Mean (IPFP)] and standard deviation [sDev (IPFP)] of whole IPFP signal intensity, median value [Median (H)] and upper quartile value [UQ (H)] of high signal intensity, volume of high signal intensity regions [Volume (H)] and the ratio of Volume (H) to volume of whole IPFP [Percentage (H)] and Clustering factor (H) representing clustering effect of high signal intensity. Signal intensity alteration (SIA) was also measured semi-quantitatively (grade 0-3). Cartilage defects, bone marrow lesions (BMLs) and radiographic OA (ROA) were

measured. All measures except ROA were performed at both baseline and 24 months later. Linear regression analyses were performed after adjustment for age, sex, BMI, and/or intervention.

Results: Two hundred and sixty one participants (mean age 63.0 ± 7.2 years) participated in this study. There were no significant differences in demographic factors (age, sex, and BMI) between these participants and those unselected. sDve (IPFP), Median (H), UQ (H), Volume (H), Percentage (H) and Clustering factors (H) were associated with increased ROA at baseline in multivariable analyses. In the linear mixed-effects model, these measures were significantly and positively associated with cartilage defects and BMLs over 2 years in multivariable analyses. Mean (IPFP), sDev (IPFP), Median (H) and UQ (H) were also significantly associated with increased knee pain over 2 years (Table 1).

Conclusion: Quantitative measures of signal intensity alteration in IPFP were associated with knee structural and symptomatic abnormalities in patients with symptomatic knee OA, suggesting that IPFP signal intensity alterations may have a role to play in knee OA progression. Table 1. Associations of IPFP signal intensity alteration with cartilage defects and bone marrow lesions

Session Title: Osteoarthritis – Clinical Aspect II: Treatment and Imaging
Session Type: ACR Concurrent Abstract Session
Session Time: 9:00AM-10:30AM

Background/Purpose: Synovitis is prevalent in OA and associated with pain. Hydroxychloroquine (HCQ) is used routinely for treating synovitis in inflammatory arthritis. The primary aim of the HERO RCT was to determine the effectiveness of HCQ as an analgesic treatment for hand OA, and secondarily to determine if synovitis was associated with treatment response, effects on structural progression and cost-effectiveness.

Methods: 248 participants with symptomatic (VAS pain ≥4/10) and radiographic hand OA recruited across UK primary and secondary care were randomized to HCQ or placebo for 12 months. Daily HCQ dose ranged from 200-400 mg according to ideal body weight. The primary endpoint was average hand pain during the previous 2 weeks (numerical rating scale, NRS) at six months. Secondary endpoints included other self-reported pain and function (NRS and VAS scales, AUSCAN), grip strength, quality-of-life measures (OAQol, SF-12) and radiographic structural change (on Kallman score) at 12 months. The effects of baseline radiographic severity were also assessed. In a sub-study, n=143 participants had ultrasound performed at baseline on small joints of a single hand. Longitudinal mixed models compared changes between groups. Analyses were conducted on intention-to-treat basis. A health economics analysis was also performed.

Results: Follow-up was 84.7% at 6 months and 76.6% at 12 months. The mean initial HCQ dose for the intervention arm (n= 114) was 320 mg. At the primary endpoint, the treatment difference estimate between HCQ and Placebo was -0.16 points on the NRS pain scale (95% CI: -0.72 to 0.41, p=0.584, Table 1). There were no significant treatment differences at 3, 6 or 12 months for any secondary outcomes including radiographic outcomes (Table 1). Baseline structural damage did not affect response to HCQ. On ultrasound, 94% had ≥1 joint positive for greyscale synovitis, 59% were Power Doppler positive; synovitis did not impact on treatment group differences. The economic analysis found that HCQ was less costly but produced a smaller quality-adjusted life year (QALY) gain than placebo, saving £6,545 per QALY lost, and was not considered to be cost-effective.

Conclusion: HCQ was not more effective than placebo in reducing symptoms or radiographic progression in people selected for moderate to severe hand pain and radiographic OA; HCQ is therefore not recommended for this patient group. Given the analgesic benefits of other anti-inflammatory therapies, these findings may reflect the mild anti-inflammatory action of HCQ, differing drug effects on certain OA pathologies, and also inclusion criteria in hand OA trials. Table 1: Adjusted group means and differences from longitudinal mixed models

	HCQ Mean (95% CI)	Placebo Mean (95% CI)	Between-group Difference (95% CI)

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016
Session Title: Osteoarthritis – Clinical Aspect II: Treatment and Imaging
Session Type: ACR Concurrent Abstract Session
Session Time: 9:00AM-10:30AM

Background/Purpose: In the treatment of meniscal damage in the setting of mild to moderate osteoarthritis (OA), several randomized trials found that both arthroscopic partial meniscectomy (APM) and physical therapy (PT) led to substantial pain relief. Whether certain subgroups of patients have worse outcomes with APM vs. PT is unknown. We hypothesize that increased baseline cartilage damage and presence of bone marrow lesions (BML) on magnetic resonance imaging (MRI) modifies the efficacy of APM compared to PT.

Methods: We used the data from the Meniscal Tear in Osteoarthritis Research (MeTeOR) Trial of APM vs. PT. Subjects were ≥45 years old and had meniscal damage on MRI, evidence of OA changes on imaging, and knee symptoms. Patients who were randomized to APM generally had surgery within three weeks after randomization. Patients who crossed-over between treatment groups were excluded from this analysis. MRIs were read using the MRI OA Knee Score (MOAKS). All 15 subregions were analyzed. Maximum, cartilage damage in any subregion (% of loss that is full thickness) was dichotomized at <10% vs. ≥10% and maximum BML in any subregion (% of subregion occupied) at none vs. any. The outcome was change from baseline to 6 months in the Knee Injury and Osteoarthritis Outcome Pain Score (KOOS, scored 0-100, 100 worst). We investigated the interaction between the imaging variables (cartilage damage, BML), treatment type (APM, PT) and change in KOOS Pain. We then calculated the difference in mean change between those receiving APM and PT for each imaging category.

Results: The sample consisted of 223 knees (one per person); 129 (58%) had APM and 94 (42%) PT. The baseline KOOS Pain in all imaging categories ranged from 44-45 points. Patients with ≥10% cartilage damage had similar improvement in pain with PT and APM (23 points), while patients with <10% cartilage damage had greater improvement with APM than with PT (28 vs 20 points). Those with BML also had similar improvement with APM and PT (24 vs 23 points), while those with no BMLs had greater improvement with APM than with PT (29 vs 16 points). While these difference in efficacy of APM vs. PT were clinically relevant (MCID~8 points) they did not reach statistical significance. (p-value for interaction =0.17 for cartilage damage and 0.11 for BML).

Conclusion: These data suggest that for patients with more extensive baseline cartilage damage and BMLs there is no clinically meaningful difference in pain outcomes between management with APM vs. PT. However, though not statistically significant, our data suggest that patients with less cartilage damage and those with no BMLs at baseline may receive more symptomatic benefit from APM than from PT. These relationships should be pursued in larger cohorts to further assess the role of APM in management of meniscal tear in those with less cartilage damage or no BMLs.

Table 1

	N (%)	Baseline KOOS Pain, mean (SE)	ΔKOOS Pain (95% CI) at 6 months		
			APM	PT	P interaction

Session Title: Osteoarthritis – Clinical Aspect II: Treatment and Imaging
Session Type: ACR Concurrent Abstract Session
Session Time: 9:00AM-10:30AM

Background/Purpose: OA is a leading cause of disability in the US. Although no disease-modifying therapies exist, patients with knee OA who walk 6,000 steps/day or more reduce the risk of developing a functional limitation within the next 2 years by half.[1] The purpose of this study is to demonstrate the impact of a mobile application (OA GO) plus wearable activity monitor/pedometer in increasing the mobility of knee OA patients who were treated with hylan G-F 20.

Methods: This was a multicenter, open-label study in knee OA patients treated with a single 6-ml injection of hylan G-F 20 and randomized 1:1 to unblinded wearable activity monitor and OA GO (Group A; n=107) or blinded wearable activity monitor only (Group B; n=104). Participants were aged 30 to 80 years, were eligible to receive hylan G-F 20 per US labeling, and were familiar with smartphone technology. Outcome measures included mean number and percent change from baseline in steps/day, pain and distance of 6-minute walk test, patient/physician satisfaction surveys, Patient Activation Measure (PAM-13), and adverse events (AEs) at 90 days. Descriptive statistics were used to compare baseline characteristics and least square means were used to compare changes from baseline.

Results: Baseline characteristics were similar between groups. In both groups, significant increases in mean number and percent change of steps/day from baseline were observed; a significantly greater improvement in both outcomes was observed for Group A versus Group B (1199 vs 467, *P*=.0345 for number of steps/day; 35.81 vs 11.48, *P*=0.0189 for percent change of steps/day). In the 6-minute walk test, there was a greater improvement from baseline for Group A versus Group B in reducing pain (−55.3% vs −33.8%, *P*=0.0068) and increasing distance (18.2% vs 6.3%, *P*=0.9583). There was a greater number of patients (65.4%)/physicians (67.3%) who would be likely/very likely to use/recommend the devices than those who would be unlikely to do so. In both groups, PAM-13 scores improved from baseline however, no statistically significant differences were observed between

groups (5.0% vs 6.9%, *P*=0.9931). The AE profiles were similar for the two arms.

Conclusion: In this study, both groups were treated with hylan G-F 20 and showed significantly increased mobility and reduced pain, however, patients using the wearable activity monitor and OA GO mobile application had significantly improved mobility over controls without adding safety concerns. Overall, patient use of a novel smartphone application in conjunction with a wearable activity monitor enhanced the efficacy imparted by hylan G-F 20 treatment for knee OA in steps per day and pain with walking in the 6-minute walk test. Sanofi provided funding for the study. [1]White DK, Tudor-Locke C, Zhang Y, Fielding R, LaValley M, Felson DT, et al. Daily walking and the risk of incident functional limitation in knee OA: An observational study. *Arthritis Care Res (Hoboken)*. 2014;66:1328-36.

Session Title: Quality Measures and Quality of Care II

Session Type: ACR Concurrent Abstract Session

Session Time: 9:00AM-10:30AM

Background/Purpose: The Arthritis Alliance developed a set of 6 performance measures to evaluate timely access to care and treatment for inflammatory arthritis. A national study is currently underway to test these measures in different data sources. The objective of this study was to examine 3 of these measures in early rheumatoid arthritis (ERA) patients receiving usual care in rheumatology clinics participating in a national longitudinal early arthritis study.

Methods: This study included ERA patients enrolled between January 1st 2007-January 31st 2015 who met 1987 or 2010 ACR/EULAR RA criteria and had < 1 year of symptom duration at cohort entry. Patients who died or moved away within 1 year of the baseline visit or who had <1 year of follow-up were excluded. Each measure was computed annually. Measures included: i) percentage of patients with RA seen in yearly follow-up (operationalized at fixed 12 and 14 month windows from the patient's

baseline visit), ii) annual percentage of RA patients treated with a disease-modifying drug (DMARD, calculated as the proportion of patients with RA with at least one record of DMARD or biologic use) and, iii) time from new RA diagnosis to initiation of DMARD therapy (defined by the time between the date of diagnosis of RA to the date of first starting a DMARD and reported as 50th and 90th percentile times as well as the percentage prescribed DMARDs within 2 weeks of diagnosis).

Results: 1927 RA patients were included. The mean age of the cohort was 54, with 73% female and 82% Caucasian. The average disease duration was 5.8 months and the mean DAS28 was 5.1 at baseline. Over 8 years 72% of patients were seen in yearly follow-up; when using a 14-month window this increased to 76%. The yearly percentage of newly diagnosed RA patients on a DMARD ranged between 92-100%; however, considering the whole cohort overtime the total proportion on DMARDs declined from 94% in 2007 to 70% in 2015. Between 2007 and 2015 the percentage of RA patients who received DMARD treatment within 14 days of diagnosis increased from 74% to 90%. Median time to DMARD therapy was 0 days (50th percentile) during all years of measurement indicating treatment occurred at time of diagnosis; and the 90th percentile decreased from 89 to 6 days between 2007 and 2015.

Conclusion: Between 2007-2015 the percentage meeting benchmarks for time to DMARD therapy increased in CATCH from 74% to 90%. A drop-off in yearly follow-up is typical of many observational studies though less in this study, perhaps due to benefits of universal access to care. This may not necessarily reflect a gap in care as patients may have returned to usual follow-up with the rheumatologist. The decline in percentage on DMARD over time likely represents a number of factors including: DMARD-free remission associated with earlier diagnosis and treatment, patient engagement and non-adherence and a possible care gap. Analysis of medication use over time is an ongoing goal of this study. This study represents a best-case scenario for capturing performance measures from systematically collected data demonstrating the feasibility of rapid DMARD initiation. Our findings may be useful as a benchmark while testing the measures using other settings and data sources.

Session Title: Quality Measures and Quality of Care II

Session Type: ACR Concurrent Abstract Session

Session Time: 9:00AM-10:30AM

Background/Purpose: Hypertension (HTN) is the most prevalent comorbid cardiovascular disease (CVD) risk factor among adults with rheumatic conditions. However, we previously found that high blood pressures (BP) were addressed in <1/3 of rheumatology visits, even when severely elevated (≥160/100 mmHg). In this range, only 11 patients need to be treated for HTN to prevent one CVD event. In primary care, HTN protocols executed by nurses or medical assistants during vital sign assessment have improved control of high BP. In a prior six-month pilot study, we had tested a theory-based staff protocol intervention to facilitate timely (<4 weeks per a US quality measure) primary care follow-up for patients with high blood pressures at rheumatology visits, and had reported two-fold higher odds of timely follow-up. Here, our objective is to assess the 18-month sustainability of those improvements.

Methods: We conducted a pre-post study in three academic rheumatology clinics. All eligible adult (≥18 years-old) rheumatology visits with BP ≥140/90 mmHg (Dec. 2014-May 2016) were compared to pre-intervention visits (Jan. 2012-Sep. 2014). Our multi-dimensional intervention included (1) education of frontline staff on HTN and CVD risk in rheumatologic diseases, (2) electronic health record (EHR) alerts for staff to re-measure BPs if ≥140/90 and (3) cuing brief patient education and scheduling primary care follow-up if 2nd BP ≥140/90, and (4) monthly audit and feedback with staff about performance. We gave in-person feedback between months 1 and 6, then by email months 6-18. We assessed timely primary care follow-up for high BPs among patients who received primary care in our system using EHR data. We performed multivariable logistic regression and compared the odds (OR, 95%CI) of timely primary care follow-up before and during intervention, controlling for baseline socio-demographics, comorbidities, and utilization.

Results: We compared 1,737 intervention period visits to a comparable group of 4,683 pre-intervention visits with BPs ≥140/90. Staff initiated the protocol with BP re-measurement in 57%, 73%, and 69% of eligible visits during intervention months 0-6, 6-12, and 12-18 respectively, compared to <1% pre-intervention, with 66% overall improvement, p<0.0001. Months 4-6 showed peak improvement in BP re-measurement at 80% during monthly in-person audit-feedback. More patients received timely follow-up for HTN during the entire 18-month intervention period (46% vs 29% before, p<0.0001). Multivariable analysis showed that eligible visits during the intervention had two-fold higher odds of timely follow-up compared to pre-intervention (OR 2.1, 1.4-3.0 in months 0-6; OR 2.16,1.72-2.71 across entire intervention), indicating sustained improvement.

Conclusion: Our intervention with usual staff in rheumatology clinics doubled odds of timely BP follow-up, and these improvements were sustained over 18 months. Future studies should examine this intervention in other rheumatology clinics to evaluate its impact on HTN control and CVD event risk across rheumatology populations.

Session Title: Quality Measures and Quality of Care II

Session Type: ACR Concurrent Abstract Session
Session Time: 9:00AM-10:30AM

Background/Purpose: Despite available effective treatment options and published guidelines for gout management, many patients suffer from recurrent gout attacks. Increases in gout prevalence and continued suboptimal gout care result in an increase in hospitalizations and health care utilization. We analyzed admissions due to gout in a community teaching hospital in order to ascertain whether these hospitalizations were preventable and to identify deficits in care prior to admission.

Methods:

We identified adult patients hospitalized at our institution from 01/01/2011 to 12/31/2014 with a primary discharge diagnosis of gout. A preventable admission was defined as a final diagnosis of gout without any coexisting conditions on presentation warranting admission, determined by chart review. We reviewed demographic characteristics, diagnosis on admission, prior history of gout, risk factors for gout, gout medication use prior to hospitalization, serum uric acid levels on admission, date and time of admission including overnight and weekend admissions, history of outpatient follow-up for treatment of gout, use of arthrocentesis, and duration of inpatient stay.

Results:

Ninety one patients were discharged with a primary diagnosis of gout, 71 (78%) of whom met criteria for preventable admission. Diagnosis on admission included pain 27 (38%), pain and joint swelling 4 (5%), joint effusion 4 (5%), acute gouty arthritis 26 (36%), cellulitis 10 (14%), osteomyelitis 2 (3%), and one patient was admitted to rule out deep vein thrombosis. Twenty four patients underwent arthrocentesis, but only 5 of these procedures were done in the Emergency Department (ED) prior to admission. Fifty patients (70%) had a prior history of gout, although 35 (70%) of them had no documentation of any outpatient provider managing their gout. 12 (23%) were managed by primary care providers, 3 (5%) by a rheumatologist. Risk factors for gout included hypertension 63 (88%), chronic kidney disease 27 (38%), aspirin therapy 34 (47%), and diuretic therapy 46 (64%). 20 (28%) were receiving urate lowering therapy (ULT), and 8 (11%) chronic colchicine. Seventeen (85%) of the patients treated with allopurinol received no prophylactic therapy. Only 10 (14%) had serum uric acid levels at target of <6 mg/dL, 27 (59%) had a uric acid level between 8-10 mg/dL, and 15 (21%) above 10 mg/dL. Ten (14%) had no documentation of their uric acid level. Twenty (28%) of the admissions were during the weekend, and 33 (46%) were admitted between the hours of 5pm and 7am. Overall aggregate length of stay for the preventable admissions was 179 days (mean 2.59 days).

Conclusion: Our findings demonstrate that 78% of the hospitalizations with a primary discharge diagnosis of gout were preventable. Lapses in the outpatient management of gout were apparent, as most of the patients did not have ongoing outpatient gout management, and few received concomitant prophylactic therapy when treated with ULT or had serum uric acid levels at target. A significant number of patients were admitted via the ED at night and on weekends. Arthrocentesis appeared to be underutilized in the ED. Interventions to address gaps in outpatient and ED care for gout are needed to prevent unnecessary admissions and decrease hospitalization-related costs.

Assessment of American College of Rheumatology Gout Quality Measures at a University Practice Plan

Soo Choi[1], John FitzGerald[1], Robin Clarke[2] and Andrew Hackbarth[3], [1]Rheumatology, UCLA, Los Angeles, CA, [2]Faculty Practice Group, UCLA, Los Angeles, CA, [3]UCLA, Los Angeles, CA
First publication: September 28, 2016

SESSION INFORMATION
Session Date: Wednesday, November 16, 2016
Session Title: Quality Measures and Quality of Care II
Session Type: ACR Concurrent Abstract Session

Session Time: 9:00AM-10:30AM

Background/Purpose: Gout is the most common chronic inflammatory arthritis. Gout prevalence has been rising over the past several decades, and gout is associated with significant health and financial burden. Numerous guidelines including 2012 American College of Rheumatology (ACR) guidelines have been published for management of gout. However, compliance with these practice guidelines remains poor. To promote adherence to management guidelines and improve quality of care for gout, ACR has developed a set of quality measures. We evaluated the performance of these quality measures at our university practice group.

Methods: We established a registry of patients receiving care for gout at our university practice group since 6/2013 using electronic medical record (EMR) and administrative database (ICD-9 codes 274.XX). Using a subset of this population being followed for gout over the past 12 months, we tested the three quality measures developed by ACR including: (1) Treat to Target: percentage of patients aged 18 and older with a diagnosis of gout treated with urate-lowering therapy (ULT) for at least 12 months whose most recent serum urate result is less than 6.8mg/dL; (2) ULT indications for therapy: percentage of patients aged 18 and older with a diagnosis of gout and either tophus/tophi or at least two gout flares (attacks) in the past year who have a serum urate level >6.0mg/dL, who are prescribed ULT; (3) serum urate monitoring: percentage of patients aged 18 and older with a diagnosis of gout who were either started on ULT or whose dose of ULT was changed in the year prior to the measurement period and who had their serum urate level measured within 6 months.

Results: From the university practice, 4988 patients were identified, 18 years of age or older with a diagnosis of gout. For the Treat to Target measure, 1183 (47.7%) of 2478 patients on ULT met the serum urate target of <6.8mg/dL. For the ULT indications measure, 329 (70.9%) of 464 patients with tophaceous gout or recurrent flares and serum urate level >6.0mg/dL were appropriately prescribed ULT. For the serum urate monitoring measure, 1259 (35.8%) of 3517 patients with new start or modification of ULT had serum urate level measured within 6 months. Several potential challenges in implementation were identified in our evaluation of the ACR quality measures. The Treat to Target measure appeared to be the most straightforward measure to implement, but outside labs not captured by the EMR posed a problem. For the ULT therapy measure, we encountered difficulties with establishing reliable criteria for capturing gout flares. Accurate recognition of modification of ULT dose was the primary challenge for the serum urate monitoring measure.

Conclusion: Analysis of gout patients at our university practice using the ACR quality measures confirms suboptimal adherence to available practice guidelines. Our analysis also identifies potential challenges in implementation of the ACR quality measures. Some of these challenges are practice specific (higher prevalence of outside labs at university referral practice), and others (identification of flares and medication changes) are amenable to modification of specifications to best match varying structures and available data from different EMR systems. Ability to accurately assess quality measures using EMR is an essential step in promoting adherence to practice guidelines. Continued efforts at optimizing quality measure assessments will help provide the foundation for design and implementation of future quality improvement projects.

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016
Session Title: Quality Measures and Quality of Care II
Session Type: ACR Concurrent Abstract Session
Session Time: 9:00AM-10:30AM

Background/Purpose: Glucocorticoids (GC) are associated with substantial treatment morbidity. New immunomodulatory agents offer the possibility of limiting GC exposure. To assess the comparative benefits of such agents, investigators must accurately measure their ability to prevent or reverse GC-related toxicity. No comprehensive instrument for measuring GC toxicity has previously been developed. We aimed to develop a GC Toxicity Index (GTI) to assess GC-related morbidity and GC-sparing ability of new agents.

Methods: Nineteen experts from 11 subspecialties participated. Ten experts were from the United States; 9 from Canada, Europe, or Australia. Group consensus methods and multi-criteria decision analysis were utilized. The development process included ten 1-hour conference calls, group work between calls and a 12-hour face-to-face meeting. *GTI components* The GTI is composed of the Composite GTI (CGTI) and the Specific List. The CGTI reflects GC toxicity that is likely to change over the course of a clinical trial. The toxicities included in the CGTI occur commonly, vary with GC exposure, and are weighted and scored. The Specific List is designed to capture GC toxicity not included in the CGTI. The CGTI was evaluated by application to paper cases by the investigators and an external group of 17 subspecialists.

Results: *Item inclusion and definitions* Thirty-one toxicity items derived from the literature were included in the CGTI, and 23 were included in the Specific List (Table). Definitions were developed by experts using group consensus methods. The CGTI items reflect both improvement and worsening of GC toxicity and account for medication effects (e.g., anti-hypertensives) in scoring. The 31 mutually-exclusive CGTI items are organized in order of severity within nine domains. Only one item in each domain can be scored. *Weighting and evaluation of the CGTI* Relative weights for each item in the CGTI were derived at a face-to-face meeting utilizing multi-criteria decision analysis. CGTI evaluation showed high inter-rater agreement (investigators kappa 0.88, external raters kappa 0.90). To assess the degree to which the CGTI corresponds to expert clinical judgment, participants ranked 15 cases by clinical judgment in order of highest to lowest GC toxicity. Expert rankings were then compared to case ranking by the CGTI, yielding excellent agreement (investigators weighted kappa 0.87, external raters weighted kappa 0.77).

Conclusion: We describe the development and initial evaluation of the GTI - a comprehensive instrument intended primarily for use in prospective, randomized clinical trials for the assessment of GC toxicity. The GTI can be used across clinical disciplines in trials that employ GCs to assess the comparative value of GC-sparing therapies, and to measure the impact of GC toxicity. **Table – Composite GTI and Specific List**

Composite GTI	Item Weight	Specific List

SESSION INFORMATION
Session Date: Wednesday, November 16, 2016
Session Title: Quality Measures and Quality of Care II
Session Type: ACR Concurrent Abstract Session
Session Time: 9:00AM-10:30AM

Background/Purpose: Autoimmune and inflammatory diseases occur more often in women than in men, and often these women are of childbearing age. Many of the medications prescribed for such diseases are teratogenic. Discussions regarding contraception and pregnancy planning are crucial for patients on these medications. The use of effective contraception in these women is low. We aimed at understanding barriers to counseling, improving documentation, and increasing the use of effective contraception at our academic medical center outpatient Rheumatology clinic.

Methods: As part of the quality improvement initiative, we performed an IRB exempt chart review on women between 18-45 years on methotrexate, mycophenolate, leflunomide or cyclophosphamide seen at our outpatient Rheumatology clinic from January 2015 to January 2016. We surveyed providers to understand the barriers preventing consistent discussion and documentation of recommendations for contraception. We also surveyed patients to assess plans for pregnancy, choice of current contraception, and barriers to use of effective contraception. We used the Plan-Do-Study-Act (PDSA) methodology to implement cycles of change using input from stakeholders. These PDSA cycles include standardized documentation tools, templates, targeted alerts and nursing-led education.

Results: At baseline, 182 women took at least one teratogenic medication. Most women received methotrexate (76%), followed by leflunomide (13%), mycophenolate (9%) and cyclophosphamide (2%). We sampled 25% of the women on methotrexate (n=30) and found that only 33% used highly effective contraception (tubal ligation or intrauterine device), 24% used hormonal methods (contraceptive pills or implants) and 43% did not have a form of contraception documented. Of the 17 patients on mycophenolate, 29% used highly effective contraception (tubal ligation or intrauterine device), 24% used hormonal methods (contraceptive pills or implants) and 47% did not have a form of contraception documented. Surveying the providers (n=13) we found that 46% had a patient who got pregnant while on a teratogenic medication ,even though the majority felt that they were consistently counseling their patients (85%). Of all clinic providers, only 23% were registered on the mycophenolate risk evaluation mitigation strategy (REMS).

Conclusion: We have identified a cohort of patients on teratogenic medications who are either not using, or have no documentation of contraception type in the electronic medical record. There is room for improvement in documentation of contraception type, counseling about the use of contraception, and the rate of use of highly effective contraception. Effective intervention strategies to improve these parameters are discussed.

The Caspase 8/RIPK3 Signaling Axis in Dendritic Cells Controls Joint Homeostasis Under Steady-State and Arthritic Conditions

Salina Dominguez[1], Harris R. Perlman[2] and Carla Cuda[1], [1]Northwestern University, Chicago, IL, [2]Department of Medicine, Division of Rheumatology, Northwestern University Feinberg School of Medicine, Northwestern University, Chicago, IL

SESSION INFORMATION
Session Date: Wednesday, November 16, 2016
Session Title: Rheumatoid Arthritis – Animal Models II

Session Type: ACR Concurrent Abstract Session
Session Time: 9:00AM-10:30AM

Background/Purpose: Rheumatoid arthritis (RA) manifests in persistent synovial inflammation, cellular infiltration and pro-inflammatory cytokine production, and results in progressive joint destruction. Dendritic cells (DCs) have been implicated in RA progression and persistence through either antigen presentation to autoreactive T cells or differentiation into synoviocytes, yet the mechanisms underlying these activities are not fully elucidated. We identified that caspase 8, an enzyme that initiates apoptosis and suppresses necroptosis by inhibition of RIPK1/3 signaling in a multitude of cells, is a novel DC-specific inhibitor of inflammatory processes independent of its known role in cell survival. Further, a genome-wide association study identified an RA risk single nucleotide polymorphism within the locus that contains the gene encoding for caspase 8. However, the impact of DC-specific loss of caspase 8 on arthritis progression has yet to be examined.

Methods: Mice with caspase 8 flanked by *loxP* sites ($Casp8^{fl/fl}$, WT) were bred to mice expressing Cre under control of the CD11c gene promoter (Cre^{CD11c}) to generate $Cre^{CD11c}Casp8^{fl/fl}$ mice. $Cre^{CD11c}Casp8^{fl/fl}$ mice were crossed with $RIPK3^{-/-}$ mice to determine the involvement of this signaling partner. The K/BxN serum-transfer model of arthritis was utilized and clinical severity was assessed. Ankle sections were stained with H&E and scored by a pathologist blinded to the study to assess pathology. Flow cytometric analysis was used to characterize naïve and arthritic joints.

Results: $Cre^{CD11c}Casp8^{fl/fl}$ mice showed accelerated initiation of arthritis, as evidenced by increased changes in ankle width and clinical scores on day 2 and 4, as well as increased joint damage compared to WT. DC-specific deletion of caspase 8 affects not only synovial DCs but also synovial macrophage populations in both the naïve and arthritic joint. $Cre^{CD11c}Casp8^{fl/fl}$ synovial DCs show elevated expression of costimulatory molecule CD86 compared to WT. Further, we previously demonstrated that naïve mouse joints contain MHC II^{+} and MHC II^{-} macrophages, the majority being MHC II^{-} tissue-resident macrophages that can limit arthritis initiation, and $Cre^{CD11c}Casp8^{fl/fl}$ joints exhibit a reduced proportion of these disease limiting tissue-resident macrophages compared to WT. $Cre^{CD11c}Casp8^{fl/fl}$ MHC II^{+} and MHC II^{-} macrophage populations express reduced CD36, a scavenger receptor for oxidized low-density lipoprotein and apoptotic neutrophils, and CD206, a protein active in endocytosis/phagocytosis, compared to WT. Strikingly, these alterations are a function of overactive RIPK3 signaling, as knockout of RIPK3 in $Cre^{CD11c}Casp8^{fl/fl}$ mice is sufficient to reverse all effects of caspase 8 deletion on joint homeostasis under steady-state and arthritic conditions.

Conclusion: The caspase 8/RIPK3 signaling axis in the joint plays a vital role in controlling arthritis pathogenesis, as global knockout of RIPK3 prevents the pathogenic phenotypes within the joint initiated by DC-specific caspase 8-deletion. These data have implications for RA by elucidating previously unknown cell-specific functions of a potentially useful target for therapy.

Session Time: 9:00AM-10:30AM

Abstract

Background/Purpose: Genetics alone cannot explain most cases of rheumatoid arthritis (RA). Thus, investigating environmental

factors such as the gut microbiota may provide new insights into the initiation and progression of RA.

Methods: In this study, we performed 16S rRNA sequencing to characterize the gut microbiota of DBA1 mice that did or did not develop arthritis after induction with collagen.

Results: We found that divergence in the distribution of microbiota after induction was pronounced and significant. Mice susceptible to collagen-induced arthritis (CIA) showed enriched operational taxonomic units (OTUs) affiliated with the genus *Lactobacillus* as the dominant genus prior to arthritis onset. With disease development, the abundance of OTUs affiliated with the families Bacteroidaceae,Lachnospiraceae,and S24-7 increased significantly in CIA-susceptible mice. Notably, germ-free mice conventionalized with the microbiota from CIA-susceptible mice showed a higher frequency of arthritis induction than did those conventionalized with the microbiota from CIA-resistant mice. Consistently, the concentration of the cytokine interleukin-17 in serum and the proportions of CD8+T cells and Th17 lymphocytes in the spleen were significantly higher in the former group, whereas the abundances of dendritic cells, B cells, and Treg cells in the spleen were significantly lower.

Conclusion: Our results suggest that the gut microbiome influences arthritis susceptibility. **Figure Legends Figure 1. Differences in microbiome composition between CIA-susceptible and -resistant mice.**

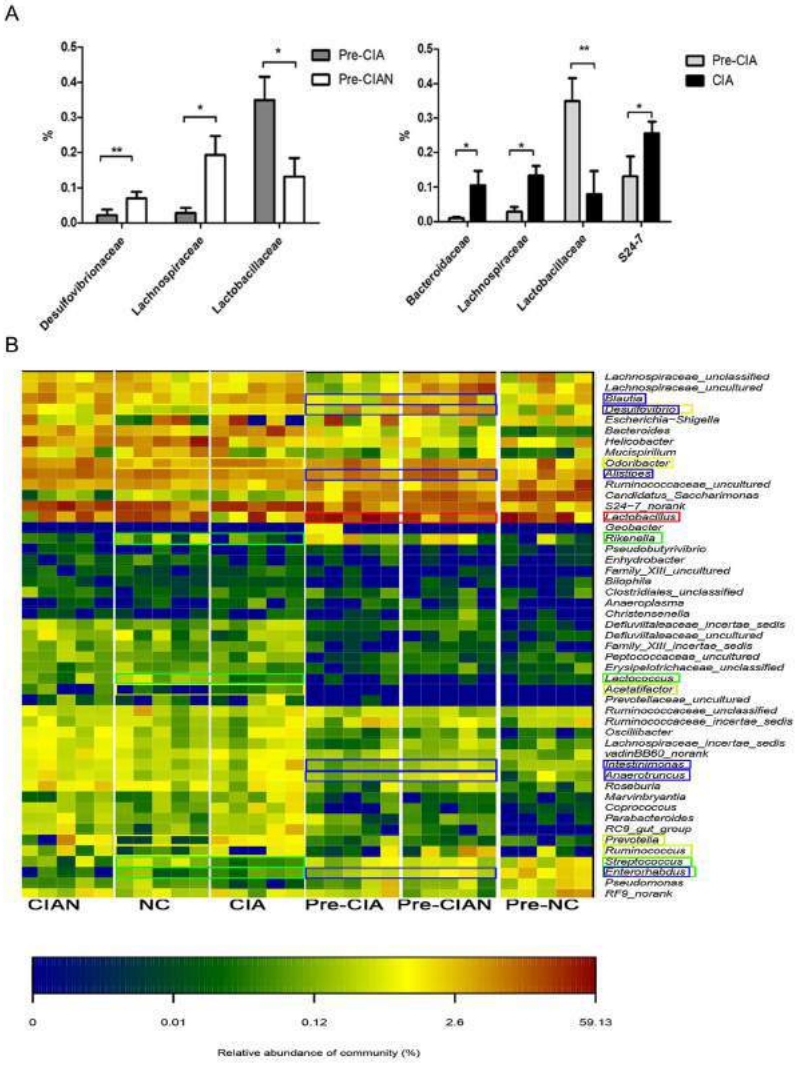

Figure 2. Analyses of faecal microbiomes of germ-free mice conventionalized with **CIA-susceptible or CIA-resistant mice.**

SESSION INFORMATION
Session Date: Wednesday, November 16, 2016
Session Title: Rheumatoid Arthritis – Animal Models II
Session Type: ACR Concurrent Abstract Session
Session Time: 9:00AM-10:30AM

Background/Purpose: Despite their role as key effector cells driving synovial inflammation and joint damage, fibroblast like synoviocytes (FLS) have yet to be targeted therapeutically. Fibroblast activation protein (FAP) is a cell surface serine protease, known to be expressed at a low level in resting FLS but up-regulated during inflammation (1). Genetic deletion of FAP has been shown to protect against cartilage damage despite no protective effect on inflammation or bone erosion (2). The pathogenic role of FLS expressing FAP is currently unknown. To determine the pathogenic role of FAP expressing FLS in inflammatory arthritis we selectively deleted these cells using a conditional cell deletion stratergy during the effector phase of inflammatory arthritis.

Methods: We utilized a transgenic mouse in which FAP expressing cells were conditionally ablated (FAP-DTR[3]) by administration of diphtheria toxin in either in a prophylactic or therapeutic regime. Inflammatory polyarthritis was induced by the passive transfer of K/BxN serum into naïve mice. Mice were scored for clinical signs of arthritis and flow cytometry of digested synovial tissue was performed to determine the expression of fibroblast subsets .

Results: We found that FAP expression in the human synovium predicts disease persistence in patients with early synovitis .FAP was dynamically expressed by FLS during inflammatory arthritis and defined a population of activated fibroblasts that co-express the lining layer marker Podoplanin (gp38). Therapeutic deletion of FAP+ cells during either the induction or peak phases of inflammatory arthritis significantly attenuated synovial inflammation leading to a reduction in the clinical severity of arthritis, reduced inflammatory cell infiltration and protection against inflammatory bone changes as measured by micro CT. In contrast, prophylactic deletion of FAP expressing cells led to a delayed onset of inflammatory arthritis, but did not impact on subsequent clinical severity.

Conclusion: These data support a pathogenic role for a subset of FAP expressing FLS in inflammatory arthritis and provide a rationale for the selective targeting of FAP+ fibroblasts as a novel therapeutic approach.

Remote Inflammation Triggers Autoimmune Arthritis through Th17 Distribution

Session Title: Rheumatoid Arthritis – Animal Models II
Session Type: ACR Concurrent Abstract Session
Session Time: 9:00AM-10:30AM

Background/Purpose: Autoimmune diseases, such as autoimmune inflammatory arthritis, result through breakdown of immune tolerance and development of self-reactive T cells, or autoantibody-producing B cells. Tolerance breakdown and progression to autoimmune disease is multifactorial and usually involves a complex interplay between both genetic and external environmental factors. While past studies have extensively studied genetic associations, less attention has been paid to defining environmental factors that precipitate disease, or flares. For autoimmune inflammatory arthritis strong links have been reported for intestinal inflammation, bronchial stress and various infections. Nevertheless underlying molecular pathways whereby such remote challenges precipitate arthritis or flares remain unclear.

Methods: Here, we used a transfer model of self-reactive arthritis-inducing $CD4^+$ cells from KRNtg mice that, upon transfer, induce a very mild form of auto-inflammatory arthritis in recipient animals. Transfer of gene-deficient KRNtg $CD4^+$ cells and manipulation of the recipient animals allowed us to identify external factors that aggravated disease and to examine underlying mechanisms.

Results: We show that several distinct challenges precipitated full-blown arthritis, including intestinal inflammation through DSS-induced colitis, and bronchial stress through *Influenza* infection. Both challenges result in locally increased IL-1β levels what triggers strong IL-17 expression primarily in self-reactive $CD4^+$ cells in local lymph nodes draining the site of inflammation. Moreover, treatment of mice with IL-1β greatly exacerbated arthritis, while transfer of KRNtg $CD4^+$ cells lacking IL-1R significantly reduced disease and IL-17 expression. Thus, the results of this study suggest that IL-1β enhances the autoaggressive potential of self-reactive $CD4^+$ cells, through increased Th17 differentiation, and this influences inflammatory events in the joints. As $IL\text{-}17^+$ autoreactive CD4 T cells express high levels of CCR6 we speculate this may drive their migration to the joints, enriched in the chemokine ligand CCL20. In addition to that, our results suggest that IL-1β may exert direct inflammatory effects to the joints. In search of common downstream mechanisms for IL-1β production, we could demonstrate that Caspase-1/NLRP3 activation did not impact on inflammation-induced Th17 differentiation of autoreactive KRNtg $CD4^+$ cells, nor influence arthritis in our model. We therefore speculate that e.g. serine proteases secreted by locally infiltrating neutrophils, may be able to trigger Caspase-1-/NLRP3-independent IL-1β activation. Alternatively, Caspase-8 (possibly in concert with Caspase-1) may induce non-canonical IL-1β maturation.

Conclusion: We propose that diverse challenges including intestinal inflammation and bronchial stress/infection, result in IL-1β-driven Th17 differentiation, and this precipitates arthritis in genetically susceptible individuals. Thus the etiology of autoimmune inflammatory arthritis likely involves numerous challenges, that ultimately converge on a common pathway involving IL-1β/Th17. This may also explain why a single etiological factor for arthritis has been difficult to identify.

Session Title: Rheumatoid Arthritis – Animal Models II
Session Type: ACR Concurrent Abstract Session
Session Time: 9:00AM-10:30AM

Background/Purpose: The presence of anti-citrullinated protein antibodies in rheumatoid arthritis points to a potential role for citrullination in disease pathogenesis. Peptidylarginine deiminases (PADs) catalyze the conversion of peptidylarginine to peptidylcitrulline. PAD2 and PAD4 are expressed in immune cells, but it is not known if either of these PADs is required for the increased citrullination seen in inflammatory arthritis. Neutrophil extracellular traps (NETs) may be a source of citrullinated proteins in inflammation. PAD4 is critical for NETosis and inflammatory arthritis, but the role of PAD2 is unknown. Here we use mice with TNFα-induced arthritis, an inflammatory, destructive arthritis similar to rheumatoid arthritis, to determine if PAD2 and/or PAD4 are required for joint citrullination and if PAD2 is required for NETosis and inflammatory arthritis.

Methods: Joint lysates from wild type, TNFα overexpressing (TNF^+), $TNF^+PAD4^{+/+}$, $TNF^+PAD4^{-/-}$, $TNF^+PAD2^{+/+}$, and $TNF^+PAD2^{-/-}$ mice were assessed for citrullination by western blot using an anti-peptidylcitrulline antibody. PAD2 levels were determined by qPCR in $PAD4^{+/+}$ and $PAD4^{-/-}$ spleens and by western blot in $TNF^+PAD4^{+/+}$ and $TNF^+PAD4^{-/-}$ joints. NETs formed by LPS-stimulated $PAD2^{+/+}$ and $PAD2^{-/-}$ neutrophils were detected by immunofluorescent staining with DAPI and anti-citrullinated histone H4 and quantified. Killing of Candida by $PAD2^{+/+}$ and $PAD2^{-/-}$ neutrophils was determined by a modified XTT assay. In $TNF^+PAD2^{+/+}$ and $TNF^+PAD2^{-/-}$ mice, bone marrow plasma cells were identified by flow cytometry, serum IgG detected by ELISA, and arthritis assessed by blinded clinical and pathological scoring.

Results: TNF^+ ankles had increased citrullination compared to wild type. $TNF^+PAD2^{-/-}$ ankles had less citrullination than $TNF^+PAD2^{+/+}$ ankles, but citrullination was not reduced in $TNF^+PAD4^{-/-}$ compared to $TNF^+PAD4^{+/+}$ ankles. There was no compensatory increase in PAD2 in PAD4 deficient spleens or arthritic ankles. NETosis and killing of Candida were not reduced in $PAD2^{-/-}$ compared to $PAD2^{+/+}$ neutrophils. Plasma cells, IgG, and arthritis were reduced in $TNF^+PAD2^{-/-}$ compared to $TNF^+PAD2^{+/+}$ mice.

Conclusion: PAD2 contributes to TNFα-induced arthritis, plasma cell numbers, and IgG levels. Also, PAD2 is required for TNFα-induced joint citrullination, but not NETosis. In contrast, PAD4, which has been shown to be critical for NETosis, does not play a major role in TNFα-induced joint citrullination. Thus, NETs may not be the main source of citrullinated protein in arthritic mice.

Session Title: Rheumatoid Arthritis – Clinical Aspects VI: Management of Early Rheumatoid Arthritis
Session Type: ACR Concurrent Abstract Session
Session Time: 9:00AM-10:30AM

Background/Purpose:

Optimal treatment for moderate-severe early rheumatoid arthritis involves using a methotrexate-based, treat-to-target strategy aiming for remission. Achieving remission without using biologics may be preferable due to their high cost and potential risk of infection. However, it is still unknown which initial treatment strategy is preferable. Our objective was to compare effects of initial treatment with MTX oral monotherapy, MTX subcutaneous (sc) monotherapy, and MTX combination therapy on time to first use of biologic DMARDs in a large national early RA cohort.

Methods:

Data were obtained from a multi-center prospective cohort study of patients with early RA. The present analysis included participants who met 1987 or 2010 ACR criteria for RA, with <12 months symptom duration, moderate or high disease activity based on the DAS28 at baseline and treated with MTX. Patients treated with a biologic at baseline were excluded. Patients were followed until they started a biologic or they were censored due to loss to follow up or the end of the 3-year study period. Cox proportional hazards survival analysis was used to estimate effects of oral MTX monotherapy, sc MTX monotherapy, and MTX combination therapy adjusting for age, gender, education level, symptom duration, comorbidities, baseline erosions, baseline DAS28, and corticosteroid use. Logistic regression analysis was used to determine predictors of ever vs. never biologic use.

Results: 1189 patients were included and 212 first events of biologic use. At baseline, 865 (71%) were female with mean (sd) age of 54 (15) years, symptom duration 6 (3) months, and DAS28 of 5.45 (1.2). Oral MTX monotherapy was used as initial treatment in 230 (20%), sc MTX monotherapy in 226 (20%), and MTX combination therapy in 664 (60%). In fully adjusted Cox regression models, patients treated with subcutaneous MTX monotherapy had a significantly delayed time to first biologic use (HR = 0.53, p = 0.02). There was no difference between MTX combination therapy and oral MTX monotherapy (HR = 0.95). In logistic regression models of ever vs. never biologic use, there were no significant differences between treatment strategies. Predictors of biologic use included younger age, use of corticosteroids, longer symptom duration, and higher baseline DAS28.

Conclusion:

Treatment with sc MTX monotherapy was associated with a delayed time to biologics. This may be due to increased treatment efficacy compared to oral MTX. Combination DMARD therapy was not associated with longer time to biologic initiation, potentially due to provincial regulations requiring a trial of combination DMARD therapy before initiating biologics. This study suggests that early use of sc MTX can potentially delay the need for more expensive biologic therapies.

Session Title: Rheumatoid Arthritis – Clinical Aspects VI: Management of Early Rheumatoid Arthritis

Session Type: ACR Concurrent Abstract Session

Session Time: 9:00AM-10:30AM

Background/Purpose: Methotrexate (MTX) is considered as the anchor disease modifying antirheumatic drug (DMARD) in treatment of rheumatoid arthritis (RA). However, there is no advice concerning individualized dosing. We aimed to study whether the initial dose of MTX/weight is predictive for disease activity and remission over the first 6 months in early RA patients in usual care.

Methods: Patients with DMARD-naive newly diagnosed inflammatory arthritis were recruited in 5 Finnish sites for a longitudinal follow-up (FIN-ERA) study. Patients fulfilling ACR/EULAR classification criteria for RA and positive for rheumatoid factor (RF) were divided by tertiles of MTX dose/weight. The linearity for baseline characteristics was tested and a multivariate regression analysis was adjusted for age, sex and positivity for anti citrullinated antibodies (AntiCCP). Repeated measures were analyzed using mixed models approach with appropriate distribution and link function.

Results: Out of 611 recruited patients, 336 patients who started with MTX at baseline (65% F, mean age[SD] at diagnosis 57[15] yrs) were analyzed. The baseline characteristics are depicted in Table 1. Males had lower mean(SD) dose/kg of MTX than females (0.24[0.09] vs 0.22[0.07] mg/kg, P=0.007). Both heavier males and females received lower dose/weight of MTX. A concomitant therapy with hydroxychloroquine (HCQ), and combination with sulphasalazine and HCQ were more common in patients receiving higher dose of MTX/weight. Patients with higher dose/weight of MTX met lower disease activity early and higher DAS28-3 remission rates at 6 months than patients with lower dose after adjusting by confounding variables (Figure 1).

Conclusion: The initial dose of methotrexate per weight is determinant of disease activity and early remission of DMARD-naive early, RF positive RA patients in usual care.

Tertile of MTX dose/weight (mg/kg)	I <0.19 N=112	II 0.19-0.26 N=112	III >0.27 N=112	*p*-value

Session Title: Rheumatoid Arthritis – Clinical Aspects VI: Management of Early Rheumatoid Arthritis

Session Type: ACR Concurrent Abstract Session

Session Time: 9:00AM-10:30AM

Background/Purpose: Anti-acetylated-peptide antibodies (AAPA) have recently been described in rheumatoid arthritis (RA)

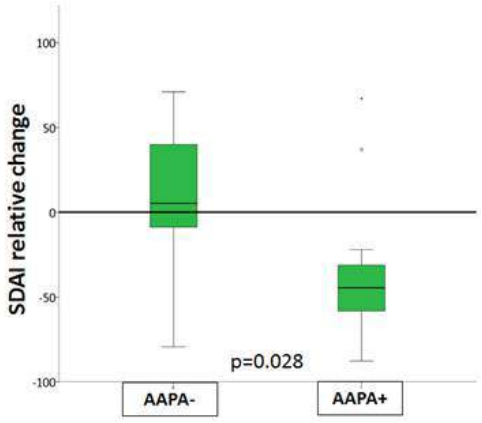
patients and may be used as a further diagnostic marker in patients with early arthritis. In this study we aimed to determine the prevalence of AAPA in a cohort of RA patients starting their first conventional synthetic DMARD treatment (csDMARD) and additionally evaluated the usefulness of AAPA as potential predictors of clinical response to methotrexate (MTX) therapy.

Methods: We measured IgG and IgA AAPA by ELISA using two acetylated peptides derived from vimentin. We tested by regression, parametric and non-parametric analyses of disease activity measures if AAPA show potency for predicting response to MTX.

Results: IgG and/or IgA AAPA were detected in 74.5% of the 110 RA patients who stated MTX treatment: 49% were positive for either IgA or IgG antibodies and 25.5% were IgA/IgG double positive. In the AAPA positive patients, 73.6% were positive for IgG AAPA while 26.4% showed IgA antibodies. Importantly, of the 36.4% of patients negative for both RF and ACPA (double negative), 55% were positive for IgG and/or IgA AAPA, and the remaining patients (i.e. 16% of the total cohort) were completely seronegative (triple-negative), see **Table**. When comparing triple negative patients with the AAPA positive double-negative ones, no significant difference in baseline characteristics was found but a trend that patients with more seroreactivities showed higher composite disease activity scores. Analyzing the clinical response to MTX, IgG-AAPA positive double-negative patients showed a significantly greater relative SDAI change after 6 months compared to triple-negative patients (p=0.028; median (IQR): -44.6% (-58.5 - -28.90) vs. 5.26% (-23.9 - 55.5%) (**Figure**). In addition, there was a significantly greater relative change in CRP (p=0.035) and erythrocyte sedimentation rate (p=0.003) in AAPA positive double-negative patients . **Table:** Crosstable of status of RF, ACPA and antiacetylated peptide antibodies

	Anti-acetylated peptide antibodies			
	Negative	**IgA or IgG positive**	**IgA and IgG positive**	Total
Negative	16.4%	16.4%	3.6%	36.4%
RF	3.6%	3.6%	2.7%	10%
ACPA	.9%	1.8%	0.9%	3.6%
RF+ACPA	4.5%	27.3%	18.2%	50%
Total	25.5	49.1	25.4	100%

Figure: Boxplots of relative changes of simplified disease activity score (SDAI) in RF and ACPA negative patients, shown for anti-acetylated (AAPA) positive and negative patients



Conclusion: AAPA commonly occur in RA patients . Measuring AAPA in addition to RF and ACPA reduced the prevalence of seronegative patients by more than 50 %. These AAPA positive but RF and ACPA negative patients responded significantly better to MTX. Therefore, AAPA positivity in RF and ACPA negative patients identifies a subgroup of patients with a more favorable response to MTX.

Session Title: Rheumatoid Arthritis – Clinical Aspects VI: Management of Early Rheumatoid Arthritis
Session Type: ACR Concurrent Abstract Session
Session Time: 9:00AM-10:30AM

Background/Purpose: The treatment of RA has changed dramatically in the past several decades with the advent of a large number of new biologic agents as well as trials that have shown the benefits of optimizing the use of conventional disease modifying agents (DMARDs) alone or in combinations. It is not clear how the large number of clinical trials and treatment recommendations related to these issues have influenced RA management. This analysis considers two aspects of DMARD choice and delivery for RA: 1) use of biologic agents as initial DMARD treatment; and 2) use of subcutaneously (SC) administered methotrexate (MTX) in patients who cannot be managed with oral drug. To evaluate trends, these questions were addressed in two patient cohorts, one that started treatment in 2009 and a second that initiated therapy in 2012.

Methods: The analysis used Symphony Health Solutions' anonymized patient-level claims data which captures ~274 million US patients and 92% of all prescription drugs dispensed in the United States. The analysis included RA patients identified by ICD-9 codes 714.0 and 714.30 who initiated treatment with oral MTX or a biologic in 2009 or 2012 and were then followed through to 2014. Treatment in the year prior to these treatments was also evaluated. This analysis focused on patients who had a biologic agent as their initial DMARD in 2009 or 2012 and those in whom SC MTX was employed after initiation of therapy with oral drug.

Results: The study included 48,910 patients who started oral MTX or biologic treatment in 2009 and 107,536 who initiated such treatment in 2012. In the 2009 cohort, 13,270 patients (27.1%) initiated treatment with a biologic vs 38,209 (35.6%) in the 2012 cohort ($p<0.0001$). This difference did not appear to result from differences between groups in baseline demographic or clinical characteristics (Table). A higher percentage of patients in the 2012 cohort received a non-MTX DMARD in the year prior to biologic initiation vs the 2009 cohort (25.4% vs 15.3%, $p<0.0001$), but even when these patients are excluded from the analysis, the higher initial use of a biologic in the 2012 remained significant ($p<0.0001$). There was also significantly increased employment of SC MTX in the 2012 cohort. 35,640 patients in the 2009 cohort initiated oral MTX and 20,041 (56.2%) switched away from this treatment over 5 years. Of these, 2,513 (12.5%) were switched to SC MTX. 69,327 patients in the 2012 cohort started oral MTX and 18,989 (27.4%) switched away from this treatment over 2 years. Of these, 3,976 (20.9%) switched to SC MTX ($p<0.0001$ vs the 2009 cohort).

Conclusion: This analysis indicated three significant trends in the treatment of RA in the US: 1) increasing use of non-MTX DMARDs prior to the initiation of a biologic; 2) increasing use of a biologic without prior administration of any conventional DMARD; and 3) increasing, but not optimal, employment of SC MTX after use of oral MTX.

Session Title: Rheumatoid Arthritis – Clinical Aspects VI: Management of Early Rheumatoid Arthritis

Session Type: ACR Concurrent Abstract Session

Session Time: 9:00AM-10:30AM

Background/Purpose: Remission targeted treatment of early RA requires frequent monitoring. However, in clinical practice monitoring frequency is not always optimal due to factors like limited resources. Therefore, to ensure successful initiation of anti-rheumatic therapy and adherence to treatment during the crucial 6 months after the diagnosis, we have developed an automated text

message (SMS) based monitoring system for early RA called SandRA. Here we present the results of a randomized study comparing SMS-based follow-up to routine care.

Methods: We randomized 166 patients with early, untreated RA fulfilling the EULAR 2010 classification criteria to intensive SandRA-based follow-up (visits at 0, 3, and 6 months and 13 SMSs at 1–2 week intervals) and to routine follow-up (visits at 0, 3, and 6 months) in 2014–2015. The SandRA software sent questions about medication use, adverse effects, and disease activity (patient global assessment [scale 0–10]). Treatment was administered at the *physician's discretion.* The SandRA follow-up aimed to improve medication adherence and to identify early the patients responding poorly to treatment. If responses suggested medication problems or insufficient reduction in disease activity, the system alarmed and the patient was contacted. The primary outcome was a strict Boolean remission at 6 months, defined as no tender or swollen joints (46 joint count), and normal CRP.

Results: Follow-up data at 6 months were available for 162 patients. The randomization groups were nearly identical at baseline (Table 1). All patients started intensive therapy; 96% started MTX, and 89% started a combination of 2–3 conventional DMARDs. At 6 months, 62% of patients in the intervention, and 53% in the control group were in remission (p=0.34). DAS28 levels decreased similarly, 2.18 in the intervention group, and 2.21 in the control group (p=0.18). Alarms from SandRA increased the number of nurses telephone contacts in the intervention group (p=0.027 for scheduled calls; p<0.001 for non-scheduled calls). No differences were observed for other visit types. Of the patients in the intervention group, 94% found the monitoring messages easy to answer, >80% felt secure and were satisfied with their treatment, and 100% would recommend SandRA monitoring for other RA patients.

Conclusion: The vast majority of RA patients were satisfied with the SMS-based monitoring system. The remission rate was higher in the SandRA group than in the control group but the difference did not reach statistical significance. Overall, remission rates were remarkably high in both groups, possibly due to successful efforts to optimize the rheumatology service (1). Despite our study failing the primary outcome, SMS-based monitoring may be beneficial in less resourced settings, and may facilitate medication adherence. Reference: Vare P, et al. Session Title: Rheumatoid Arthritis – Clinical Aspects VI: Management of Early Rheumatoid Arthritis

Session Type: ACR Concurrent Abstract Session

Session Time: 9:00AM-10:30AM

Background/Purpose: This cross-sectional study aimed to assess the agreement between Magnetic Resonance Imaging (MRI) and ultrasound (US) findings of bone erosions in the metatarsalphalangeal (MTP) joints of patients with early rheumatoid arthritis (RA).

Methods: Men and women with early RA (DMARD naïve) according to ACR criteria were recruited. Each patient underwent an MRI scan (1.0 Tesla peripheral MRI) and an US scan of MTPs 2-5 of the most symptomatic foot. MRI scans were scored by a musculoskeletal trained radiologist using OMERACT RAMRIS criteria for erosions (0-10). Using OMERACT criteria, US images were assessed for erosions (present/absent) on each joint by an experienced rheumatologist. To assess agreement using kappa statistics, MRI erosions which scored 0 were considered to have no erosions while those ≥1 were considered to have an erosion.

Results: The study included 39 patients (n=33 women), mean (standard deviation(sd)) age = 51.6 (10.3) yrs. MRI detected an erosion with a score ≥1 on 30 MTP2 joints, 28 MTP3 joints, 25 MTP4 joints and 15 MTP5 joints. US detected an erosion on 2 MTP2 joints, 1 MTP3 joints, 0 MTP4 joints and 6 MTP5 joints. The proportion of erosions detected by MRI that were also detected by US in MTPs 2, 3, 4, and 5 were 6.5%, 3.5%, 0% and 37.5%, respectively. In MTPs 2, 3 and 4, there were no erosions detected by US that were not also detected by MRI. However, in MTP5, there were 3 erosions detected by US that were not detected by MRI. Kappa statistics of agreement are presented in Table 1. Table 1: Agreement in Erosions detected by MRI and Ultrasound

Joint	kappa	95% CI	Prevalence Index	Bias Index
MTP2	0.0301	-0.0150, 0.0752	-0.1750	-0.7250
MTP3	0.0193	-0.0196, 0.0581	-0.2500	-0.7000
MTP4	0.0272	-0.0269, 0.0814	-0.3250	-0.6250
MTP5	**0.2620***	-0.0284, 0.5524	-0.3590	-0.1759

*denotes kappa is significant ($p<0.05$)

Conclusion: There was a high prevalence of bone erosions in MTPs 2-5 detected by MRI in this cohort of early RA patients. The proportion of erosions detected on MRI that were detected by US was generally very low. MRI appeared to show a greater sensitivity, detecting many more erosions than MRI which may help to explain the lack of agreement between modalities. Lack of agreement may also be explained by the physical size of the lesions that can be detected by MRI versus US due to resolution or because MRI shows more signal variation by tissue composition than US. The higher agreement for the 5th MTP may be because the US probe can almost encircle the bone allowing better visualization of the bone. In general, however, using MRI as the gold standard, the agreement between these two imaging modalities is poor, suggesting that US detected erosions likely underestimate the true prevalence of erosions in MTPs 2-5.

Zygapophyseal Joint Fusion in Ankylosing Spondylitis Assessed Using Computed Tomography: Associations with Syndesmophytes and Spinal Motion

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016

Session Title: Spondylarthropathies and Psoriatic Arthritis – Clinical Aspects and Treatment V: Imaging of Spondyloarthritis

Session Type: ACR Concurrent Abstract Session

Session Time: 9:00AM-10:30AM

Background/Purpose: Both zygapophyseal joint (ZJ) fusion and syndesmophytes contribute to structural spine damage in Ankylosing Spondylitis (AS). However, because ZJs are difficult to visualize on radiographs, little is known about the prevalence of ZJ fusion and its relationship to other features of spinal damage in AS. In particular it is not known if ZJ fusion occurs before syndesmophytes and which feature contributes most to spinal rigidity. We used computed tomography (CT) to visualize the ZJ and investigate those questions.

Methods: 50 patients (84% men) underwent thoracolumbar CT scans (Table 1). Six vertebral levels were examined (T10-T11 to L3-L4). Anonymized scans were read for the presence of ZJ fusion at each level after digitally masking the vertebral bodies to blind readers to the presence of syndesmophytes. Using a validated semi-automated computer algorithm, we quantitated syndesmophytes at the same vertebral levels. We measured syndesmophyte height in 72 angular sectors of 5 degrees around the vertebral rim. We then summed the results of the 72 angular sectors to yield the circumferential height. We used Pearson correlations to evaluate the association between ZJ fusion and the lumbar range of motion and multiple regression analysis to evaluate the relative contributions of ZJ fusion and syndesmophytes to spinal motion.

Results: Agreement on the presence of ZJ fusion between the two physicians' readings was good (kappa=0.84). 56% of patients had ZJ fusion at 1 or more vertebral levels. The median number of vertebral levels with ZJ fusion was 1 (range 0 -6). The 3 most superior vertebral levels were more often fused (39% of patients) than the lower 3 (15% of patients). Fusion was most often bilateral. Syndesmophytes were often present in vertebral levels without ZJ fusion. In all levels with syndesmophytes, only 35% had ZJ fusion. ZJ fusion was present in only 7% of vertebral levels without syndesmophytes. Bridging was also often present in levels without ZJ fusion. In levels with an extent of bridging < 50 degrees, only 35% had ZJ fusion. These results suggest that ZJ fusion most often follows the development of syndesmophytes. The number of levels with ZJ fusion correlated with the Schober test ($r=-0.58$, $p<0.0001$) and lateral thoracolumbar flexion ($r=-0.58$, $p<0.0001$). Syndesmophytes and ZJ fusion were equally associated with the Schober test (Table 2). Syndesmophytes were more strongly associated with lateral thoracolumbar movement.

Conclusion: ZJ fusion is common in AS, particularly in the T10-T11to T12-L1 levels. Although syndesmophytes seem to occur first, ZJ fusion is also important and contributes to spinal rigidity.

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016

Session Title: Spondylarthropathies and Psoriatic Arthritis – Clinical Aspects and Treatment V: Imaging of Spondyloarthritis

Session Type: ACR Concurrent Abstract Session

Session Time: 9:00AM-10:30AM

Background/Purpose: The ASAS definition of a positive MRI is solely based on inflammation in the sacroiliac joints (SI), although spinal inflammatory lesions on MRI suggestive of axial Spondyloarthritis (axSpA) may also occur. It is not well established yet how often inflammation in the spine is present in absence of inflammation in the SI and consequently if it is useful to change the definition of a positive MRI to include inflammation in the spine. The aim is to analyze the prevalence of spinal inflammation on MRI in patients with chronic back pain at baseline, and to evaluate the yield of adding MRI-spine as imaging criterion in the ASAS classification criteria for axSpA.

Methods: The SPACE-cohort includes patients with chronic back pain (≥3 months, ≤2 years, onset <45 years) in six participating Rheumatology centers. All available baseline radiographs (X-SI), MRI of SI (MRI-SI) and spine (MRI-spine) were independently scored by 3 well-calibrated readers for each method. MRI-SI was scored according to the ASAS definition. Bone marrow edema suggestive of axSpA was assessed in the entire spine and only counted if visible on ≥2 consecutive slices. For the definition of a positive MRI-spine two cut-off values for inflammatory lesions were used: **≥3 inflammatory lesions** (ASAS consensus definition) and **≥5 inflammatory lesions** (defined as the optimal cut-off value). All modalities were considered positive if 2/3 readers agreed.

Results: All patients with X-SI, MRI-spine, and MRI-SI available at baseline (n=487) were included in the analysis. Of the 487 patients, 73 (15.0%) patients had a positive MRI-SI, of which 23/73 (31.5%) patients had a positive MRI-spine (≥3 inflammatory lesions) and 17/73 (11.4%) patients had a positive MRI-spine defined by ≥5 inflammatory lesions. In total, 50/414 (12.1%) and 18/414 (4.3%) patients with negative MRI-SI had a positive MRI-spine according to ≥3 and ≥5 inflammatory lesions, respectively.

Addition of MRI-spine to the classification criteria by ≥5 inflammatory lesions would lead to classification of 16 additional patients via the imaging arm, with 8 patients already fulfilling the clinical arm. The newly classified patients (n=8) had a mean number (SD) of SpA-features of 1.5 (1.1) of whom 3/8 (37.5%) were HLA-B27 positive. Furthermore, one patient had inflammatory bowel disease and two patients were positive for peripheral arthritis. Most reported SpA-features were inflammatory back pain, good response to NSAIDs, and positive family history for SpA.

Conclusion: In this cohort, a positive MRI-spine in the absence of sacroiliitis on MRI was rarely seen. Addition of MRI-spine as an imaging criterion to the ASAS axSpA criteria had a low yield in number of classifications, and included mostly patients with a low probability of having axSpA. Therefore, performing MRI of the spine is of little value in the classification of patients with short duration CBP and suspicion of axSpA.

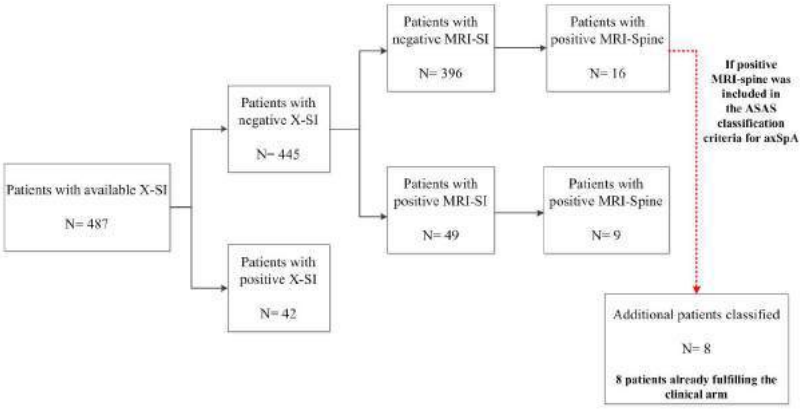

Figure 1 ASAS classification of chronic back pain patients with negative MRI-SI and positive MRI-spine defined by ≥5 inflammatory lesions, and the effect of adding positive MRI-spine as an imaging criterion to the ASAS axSpA criteria on classification of patients in the SPACE-cohort.

Session Title: Spondylarthropathies and Psoriatic Arthritis – Clinical Aspects and Treatment V: Imaging of Spondyloarthritis

Session Type: ACR Concurrent Abstract Session

Session Time: 9:00AM-10:30AM

Background/Purpose: Enthesitis is a common clinical finding and a key pathogenic feature in psoriatic arthritis (PsA). Ultrasound is emerging as a preferred method to assess enthesitis. Little is known about the relation between the presence of enthesitis and the severity of joint damage in patients with PsA. Our aim was to examine the association between sonographic enthesitis and the severity of radiographic features of damage in the peripheral and axial joints.

Methods: A cross-sectional analysis was conducted in patients from a large PsA cohort. The MAdrid Sonography Enthesitis Index (MASEI) scoring system was used to quantify the extent of sonographic entheseal abnormalities in 12 entheseal sites adjacent to large joints. Total MASEI was further categorized into: bone scores (enthesophytes, erosions) and soft tissue scores (structural entheseal changes, vascularization, bursitis). Radiographic joint damage in the peripheral joints and spine was assessed independently of the ultrasound results using the modified Steinbrocker score, Modified New York Criteria for sacroiliitis and the modified Stoke Ankylosing Spondylitis Spine Score (mSASSS). Additionally, the presence of ankylosis, arthritis mutilans and periostitis in the hands or feet was determined. Linear and logistic regression models were used to assess the association between MASEI score and the radiographic features of joint damage after controlling for age, sex, body mass index, PsA duration and the use of DMARDs and biologic medications.

Results: Two hundred and twenty two patients were included. 58% were males, with mean (s.d.) age of 55.9 (12.9) years and PsA duration of 16.7 (12.4) years. The mean MASEI score was 15.6 (12.6). The mean modified Steinbrocker score was 18.1 (32.3), *mSASSS* was 1.7 (7.3) and 37% had sacroiliitis. Multivariate regression analyses found an association between higher scores of MASEI scores and peripheral joint damage: modified Steinbrocker score (β 9.26, p<0.0001), joint ankylosis (Odds Ratio (OR) 2.09, p=0.0001) and arthritis mutilans (OR 1.73, p=0.005). The association between MASEI scores and periostitis was of borderline statistical significance (OR 1.29, p=0.06). Similarly, an association was found in multivariate analyses between higher MASEI scores and axial damage as measured by mSASSS (β 1.55, p=<0.0001) and sacroiliitis (OR 1.36, p=0.02). Sub-analysis showed that the MASEI bone score were more strongly associated with radiographic damage outcomes than the MASEI soft tissue score.

Conclusion: The severity of sonographic enthesitis is a marker of radiographic peripheral and axial joint damage in PsA. The association was found with both destructive and bone formation lesions. These findings highlight the potential role of enthesitis in the pathogenesis of articular damage in PsA.

Session Date: Wednesday, November 16, 2016

Session Title: Spondylarthropathies and Psoriatic Arthritis – Clinical Aspects and Treatment V: Imaging of Spondyloarthritis

Session Type: ACR Concurrent Abstract Session

Session Time: 9:00AM-10:30AM

Background/Purpose: After 20 years of follow up the majority of patients with aspondyloarthritis (SpA) have developed new bone in the spine although disease may remain isolated in the sacroiliac joints (SIJ) without any new bone in the spine. Assessment of these patients may provide new insights into the factors that influence disease progression. A new hypothesis has proposed that MRI can identify a “progressive phenotype” in early SpA characterized by the appearance of fat metaplasia in the SIJ. Fat metaplasia can occur both in subchondral bone and at the site of erosion after resolution of inflammation, this being termed backfill. We aimed to determine which clinical and MRI lesions in the SIJ are associated with absence of spinal damage after prolonged duration of symptoms.

Methods: In the FORCAST prospective cohort, AS patients (n=431) attending community and academic practices were assessed

for clinical and laboratory outcomes every 6 months, radiography every 2 years, and MRI annually. MR scans of the SIJ were assessed by Spondyloarthritis Research Consortium of Canada (SPARCC) SIJ and Sacroiliac Structural Score (SSS) methods for inflammation and structural features, respectively, by 2 readers. Absence of spinal damage was pre-specified as no syndesmophytes or ankylosis on cervical and lumbar spine radiographs after ≥10 years from onset of symptoms and for the entire duration of prospective follow up. Patients with and without spinal damage were matched for age and symptom duration and compared by t-test, Mann-Whitney, and Fisher's exact tests. We used univariate and multivariate conditional logistic regression to determine which demographic, clinical, and imaging variables were associated with absence of spinal damage.

Results: Mean (SD) duration of symptoms and prospective follow up was 18.0(7.0) and 2.3 (0.49) years in cases with no damage (n=42) and 17.5(8.2) and 2.6 (1.4) years in those with damage (n=81). The group with no damage had fewer males (p=0.004), lower CRP (p=0.02), and lower MRI SIJ scores for fat (p=0.03) and ankylosis (p=0.003) while score for SIJ erosion was significantly higher (p=0.02). Definite SIJ ankylosis (SSS score ≥2 by both readers) was evident in 20.7% of cases in the no damage group versus 53.3% of those with damage (p=0.007). Univariate regression indicated that no damage was associated with female sex (p=0.002), lower ASDAS (p=0.048), and lower SSS values for fat (p=0.032), backfill (p=0.014), and ankylosis (p=0.001). Smoking and B27 were not significant. A multivariate logistic regression model that included gender, ASDAS, and MRI SIJ features indicated that lower values for SSS backfill and ankylosis were independently associated with no damage (OR [95%CI]= 0.83 [0.69-0.99] and 0.89 [0.82-0.96], respectively). When all definite MRI features (SSS score ≥2 by both readers) were included in the model, definite SIJ ankylosis was significantly less likely in those who did not develop spinal damage (OR [95%CI]= 0.24 [0.08-0.70].

Conclusion: The absence of radiographic damage in the spine after prolonged duration of symptoms is associated with the lack of fat metaplasia and ankylosis in the SIJ on MRI. This supports the hypothesis that fat metaplasia identifies a progressive phenotype.

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016

Session Title: Spondylarthropathies and Psoriatic Arthritis – Clinical Aspects and Treatment V: Imaging of Spondyloarthritis

Session Type: ACR Concurrent Abstract Session

Session Time: 9:00AM-10:30AM

Background/Purpose: MRI can detect both inflammatory and structural lesions in the sacroiliac joints (SIJ) of patients with axial SpA. However, standard MRI sequences do not directly depict bone and the appearance of erosion may vary according to the presence/absence of inflammation. Consequently, further validation using an accepted gold standard, namely, computed tomography (CT), is essential. We aimed to assess the detection of structural lesions of bone in the SIJ by MRI using CT as the gold standard.

Methods: CT scans from 44 patients (26 females, mean age 49.4 years, mean symptom duration 9.1 years) were reconstructed in the semicoronal plane parallel to the superior border of the sacrum, as for conventional MRI evaluation of the SIJ, and scoring of lesions by CT was confined to this plane. Structural lesions were scored in consecutive slices in SIJ quadrants (erosion, sclerosis)

or SIJ halves (ankylosis) on a dichotomous basis (present/absent) using the same anatomical principles for defining SIJ quadrants as developed for the SPARCC MRI SIJ inflammation and structural scores. Consecutive semicoronal slices from T1W MRI scans of the SIJ from the same cases conducted at the same time as CT were assessed independently for structural lesions (erosion, fat, backfill, ankylosis, sclerosis) blinded to CT assessments using the MORPHO modification of the SPARCC method. MRI lesions were defined according to the Canada-Denmark MRI group. An online scoring module recorded detailed scores for individual SIJ slices. Agreement between CT and MRI was assessed by kappa statistics. Sensitivity/specificity of MRI for CT lesions was calculated. The primary analysis was based on lesions detected concordantly by both readers at the level of the individual iliac/sacral joint surface (erosion, sclerosis) or the individual joint (ankylosis, backfill).

Results: With CT as gold standard and a lesion defined as being present when recorded in the same location on at least 1 coronal slice by both readers, MRI-defined ankylosis had 56.3% sensitivity and 100% specificity for CT ankylosis (Table). For erosion, sensitivity and specificity of MRI was 81.3% and 96.2%, and for sclerosis, sensitivity and specificity of MRI was 50% and 97%, respectively. Agreement between CT and MRI for erosion increased when the cut-off for presence of a lesion was set at 2 slices but only marginally for sclerosis, even when the cut-off for presence of a lesion was set at 3 slices. Lesions observed on CT corresponding to backfill on MRI were ankylosis, erosion, and sclerosis, in 66.7%, 66.7%, and 80% of backfill lesions, respectively.

Conclusion: Ankylosis and erosion on MRI correspond closely with the same type of lesion observed on CT. Both new bone formation and erosion are frequently evident on CT at locations where backfill is observed on MRI supporting the hypothesis that backfill is an intermediary tissue between erosion and ankylosis.

Concordance for 2 readers		Type of Lesion	K value	Sensitivity of MRI	Specificity of MRI
MRI lesion +	CT lesion +				
≥1 slice	≥1 slice	Ankylosis	0.67	56.3%	100%
		Erosion	0.76	81.3%	96.2%
		Sclerosis	0.47	50.0%	97%
≥2 slices	≥2 slices	Ankylosis	0.71	60.0%	100%
		Erosion	0.83	84.6%	98.1%
		Sclerosis	0.53	42.9%	99.2%
≥2 slices	≥3 slices	Ankylosis	0.83	75.0%	100%
		Erosion	0.84	90%	98.1%
		Sclerosis	0.53	42.9%	99.2%

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016

Session Title: Spondylarthropathies and Psoriatic Arthritis – Clinical Aspects and Treatment V: Imaging of Spondyloarthritis

Session Type: ACR Concurrent Abstract Session

Session Time: 9:00AM-10:30AM

Background/Purpose: Low dose Computed Tomography (CT) could potentially be more sensitive than radiographs in the follow

up of patients with axial spondyloarthritis (axSpA). First goal was to develop a scoring method for the spine and test its inter-reader variability.

Methods: Patients (pts) of the Sensitive Imaging of Axial Spondyloarthritis (SIAS) cohort fulfilled the modified New York (mNY) criteria and had at least 1 syndesmophyte in cervical or lumbar spine on radiographs. Baseline and 2 years follow up CT scans were performed. Syndesmophytes were scored in the coronal and sagittal planes for all ÔcornersÕ per view, thus scoring 8 ÒquadrantsÓ per vertebral unit (VU). Syndesmophytes were scored as absent (score 0), <50% of the intervertebral disc height (IVDH) (1), ³50% of the IVDH but no bridging (2) or as Òbridging the IDVHÓ (3). Score range 0-552. Two readers, blinded for clinical and laboratory information as well as time order, scored the 2 CT scans per patient. Scores of the 2 readers were compared using heatmaps. Inter-reader variability was assessed by (two-way average) intercorrelation coefficient (ICC) and smallest detectable change (SDC) analysis for the whole spine and per segment.

Results: In total, 58 pts (47 male, mean age 50.4) were included. The heatmap presents the similarity of baseline and change scores per reader per VU. Table 1 shows that both readers use almost the entire possible range, pick up a similar magnitude of change and have high ICCs. Most change is present in the thoracic spine. A change ³SDC is seen in 33.9% of the patients.

Conclusion: A fine-grained scoring system for CT spine was developed. Scoring syndesmophytes with good accuracy on CT images was feasible, picking up changes over a 2-year period in a high percentage of patients, especially in the thoracic spine, which is insufficiently visible on radiographs. Table 1 – Smallest detectable change (SDC) and inter-reader variability between readers on timepoint 1, timepoint 2 and for the difference between the timepoints (syndesmophyte growth).

Segment (max score)	Timepoint	Median and range reader 1	Median and range reader 2	SDC (inter-reader)	No. of patients with growth ³SDC (%) (n=58)	ICC
Whole spine (552)	Timepoint 1	144 (16 – 428)	135 (6 – 447)			0.99 (0.94 – 1.00)
	Timepoint 2	157 (18 – 428)	146 (8 – 461)			0.98 (0.92 – 0.99)
	Change score	9 (-11 – 96)	8 (-6 – 93)	12.4	19 (32.8)	0.75 (0.49 – 0.88)
Cervical (144)	Timepoint 1	8 (0 – 140)	8 (0 – 128)			0.96 (0.92 – 0.98)
	Timepoint 2	8 (0 – 140)	8 (0 – 128)			0.98 (0.95 – 0.99)
	Change score	0 (-12 – 38)	0 (-9 – 38)	5.41	9 (15.6)	0.85 (0.75 – 0.91)
Thoracic (264)	Timepoint 1	84 (2 – 250)	72 (0 – 264)			0.97 (0.92 – 0.99)
	Timepoint 2	93 (2 – 256)	81 (0 – 264)			0.97 (0.85 – 0.99)
	Change score	6 (-6 – 94)	6 (-12 – 93)	12.4	15 (25.9)	0.85 (0.75 – 0.92)
Lumbar (144)	Timepoint 1	32 (0 – 140)	36 (0 – 140)			0.91 (0.79 – 0.96)
	Timepoint 2	34 (0 – 144)	39 (0 – 144)			0.99 (0.98 – 1.00)
	Change score	2 (-10 – 14)	1 (-4 – 12)	4.51	14 (24.1)	0.56 (0.26 – 0.73)

Fig 1 
Fig 2 – Heatmap presenting per reader the location of scores 
Distribution of syndesmophytes is similar between the two readers on both time points (vertebral unit level on the y-axis). Ankylosis (score 3) is most prevalent in the thoracic spine, and syndesmophytes in general are least prevalent in the cervical spine.

Session Date: Wednesday, November 16, 2016
Session Title: Spondylarthropathies Psoriatic Arthritis – Pathogenesis, Etiology II
Session Type: ACR Concurrent Abstract Session
Session Time: 9:00AM-10:30AM

Background/Purpose: Enthesitis is an important pathophysiologic component in psoriatic arthritis (PsA). Ultrasound is emerging as an optimal method to evaluate enthesitis. HLA genes are implicated in the pathogenesis of PsA. Little is known about the relation between HLA genetic susceptibility markers and enthesitis in PsA patients. Hence, our aim was to examine the association between HLA genetic susceptibility markers and sonographic enthesitis in patient with PsA.

Methods: A cross-sectional analysis was performed in patients followed at a large PsA cohort. Sonographic enthesitis was assessed according to the MAdrid Sonography Enthesitis Index (MASEI) scoring system which quantifies the extent of sonographic entheseal abnormalities in 12 entheseal sites adjacent to large joints. Total MASEI was further categorized into: bone scores (enthesophytes, erosions) and soft tissue scores (structural entheseal changes, vascularization, bursitis). HLA genotyping was performed using sequence-specific oligonucleotide probes. The association between 6 HLA susceptibility markers of PsA and the severity of sonographic enthesitis (by MASEI) was assessed using multivariate linear regression models adjusted for age, sex, BMI and disease duration.

Results: Two hundred and twenty five patients were included, 57% male with mean (s.d.) age of 55.8 (12.9) years and PsA duration of 16.4 (12.3) years. The majority of the patients were Caucasians (88%). The frequencies of the HLA alleles were: *HLA-B*27*: 15.1%; *HLA-B*38*: 18.2%; *HLA-B*39*: 4.9%; *HLA-B*44*: 21.8%; *HLA-B*08*: 17.3% and *HLA-C*06*: 27.5%. In the univariate analysis *HLA-B*27* (β 3.8, p=0.005) was associated with more severe enthesitis while *HLA-C*06* (β -2.4, p=0.03) was associated with less severe enthesitis. The results of the multivariate regression model are shown in Table 1. The interaction between HLA-B*27 and PsA duration was statistically significant, showing an increasing effect of *HLA-B*27* with longer PsA duration (p=0.004). The results remained essentially the same after restricting the analysis to Caucasians. Other predictors of enthesitis severity included male gender (p=0.02) and BMI (p<0.001). The interaction between *HLA-B*27* and PsA duration was also associated with higher MASEI-bone scores (p=0.002). *HLA-B*27* was also associated with higher MASEI-soft tissue scores (p=0.01).

Conclusion: *HLA-B*27* is associated with the severity of sonographic enthesitis in PsA, particularly in patients with longer disease duration. This finding highlights the potential role of genetic variants to predispose to severe enthesitis in patients with PsA.

Table 1: Multivariate Regression Model assessing the association between HLA alleles and MASEI score (Total MASEI include active GS and PD abnormalities)

Variable*	Multivariate Model (N=225)		Multivariate Model (Caucasians) (N=196)	
	Estimate (95% CI)	**P value**	**Estimate (95% CI)**	**P value**
HLA-B*27	4.64 (0.39, 8.89)	0.03	4.45 (0.12, 8.87)	0.04
HLA-B*27* PsA Duration	4.78 (1.54, 8.02)	0.004	4.62 (1.38, 7.87)	0.005
HLA-C*06	-2.27 (-5.62, 1.06)	0.18	-1.52 (5.08, 2.03)	0.40
Age (10 years)	1.02 (-0.26, 2.31)	0.12	1.37 (0.01, 0.27)	0.047
Sex	3.71 (0.67, 6.67)	0.02	4.32 (1.10, 7.54)	0.008

Session Title: Spondylarthropathies Psoriatic Arthritis – Pathogenesis, Etiology II

Session Type: ACR Concurrent Abstract Session

Session Time: 9:00AM-10:30AM

Background/Purpose: HLA-B27 has been linked to sacroiliitis (SII) in psoriatic arthritis (PsA); however, the contribution to SII of other human leukocyte antigen (HLA) Class I loci encoding the major histocompatibility complex (MHC) has received little study. In particular, whether symmetric and asymmetric SII are differentially genetically determined.

Methods: Patients from two prospective PsA cohorts were genotyped for HLA-B and C alleles. Radiographs were evaluated for SII, which was defined as symmetric (symSII) or asymmetric (asymSII) without knowledge of HLA-B and C status. Associations of alleles with SII were explored in multivariable logistic regression models adjusting for potentially confounding characteristics. From these models, allele scores were constructed as the sum of an individual's positively associated alleles minus the sum of their inversely associated alleles

Results: A total of 490 PsA patients were studied [mean age=56 years, 54% female, median PsA duration=18 years]. SymSII and asymSII was observed in 44 (9%) and 75 (15%), respectively. In multivariable analysis, symSII was associated with 11 alleles (listed in Fig1). SymSII was observed in 3% of patients with a symSII allele score of -3 or -2 compared with 12% of those with a score of 0 (OR=4.05; p=0.009) and in 69% of those with a score of +2 (OR=68.4; p<0.001) (Fig1A). The area under the receiver operator curve (AUC) for detecting symSII with the allele score was 0.758 (95% CI 0.679, 0.836). Adjusting for body mass index and PsA duration did not substantially alter the associations. A different set of five alleles was associated with asymSII (listed in Fig 1). The prevalence of asymSII was 7% for those with an asymSII allele score of 0 compared with 18% for those with a score of +1 (OR=3.17; p<0.001) and 42% for those with a score of +2 or +3 (OR=10.18; p<0.001) (Fig1B). The area under the receiver operator curve (AUC) for detecting asymSII with the allele score was 0.684 (95% CI 0.624, 0.742). Adjusting for family history of psoriasis, current PASI score, and the presence of radiographic osteolysis did not substantially alter the associations.

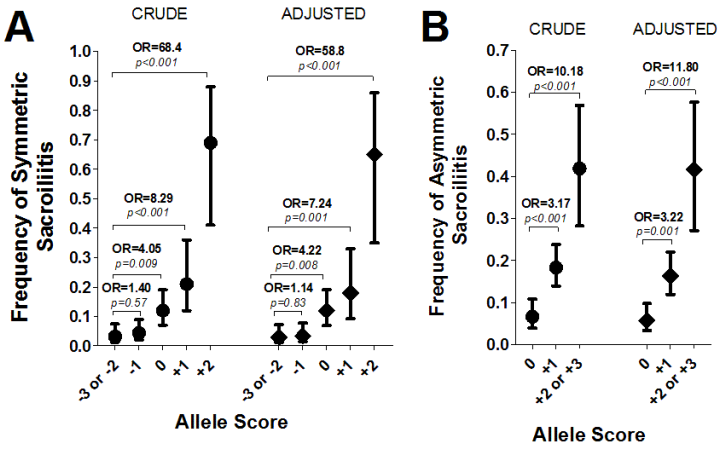

Figure. Associations of Allele Scores with Symmetric and Asymmetric Sacroiliitis in Psoriatic Arthritis. Mean and 95% confidence intervals are depicted. The symmetric sacroiliitis allele score was [B*27:05:02 + B*40:02:01 + B*44:02:01 + B*51:01:01] - [B*44:03:01 + C*06:02:01 + C*07:01:01 + C*07:02:01 + B*15:01:01 + B*37:01:01 + C*16:01:01]. The asymmetric sacroiliitis allele score was [B*08:01:01 + B*14:01:01 + B*15:01:01 + B*38:01:01 + C*05:01:01].

Conclusion: Symmetric and asymmetric SII are differentially genetically determined, such that the determination of HLA Class I alleles may be useful in predicting risk for SII within a given PsA patient.

Session Date: Wednesday, November 16, 2016

Session Title: Spondylarthropathies Psoriatic Arthritis – Pathogenesis, Etiology II

Session Type: ACR Concurrent Abstract Session

Session Time: 9:00AM-10:30AM

Background/Purpose: The pathogenesis of Axial Spondyloarthritis (AxSpA) is not well understood. A rare 9 base-pair deletion of SEC16A was recently identified to be strongly associated with AxSpA in a multiplex family. SEC16A plays an important role in endoplasmic reticulum (ER)-to-Golgi transport and the assembly of cargo carrier vesicles. We investigated if variations in SEC16A could affect the ER-Golgi transport of HLA-B27 and influence AxSpA pathogenesis.

Methods: EBV transformed B cells were isolated from 14 HLA-B27 positive members of the multiplex family. Out of 9 members with the SEC16A 9 bp deletion, 8 have been diagnosed with AxSpA and one 16-year-old was healthy. Five healthy family members had the wild-type (WT) SEC16A. C1R-B27 cells (B-lymphoblastoid cells with stable HLA-B27 expression) were used to replicate findings by knocking out (KO) SEC16A using CRISPR. Fluorescent tagged monoclonal antibodies against SEC16A and SEC31A (identifies ER-to-Golgi transport vesicle COPII) were used. The formation of ER-to-Golgi transport vesicles and the organization of ER exit sites (ERES) were studied using confocal microscopy. The vesicular stomatitis virus glycoprotein (VSVG-GFP) was

used to track ER-to-Golgi transport. In addition, Fluorescence Recovery After Photobleaching (FRAP) was performed to study the dynamics of ER-to-Golgi transport vesicles. Changes in surface and intracellular HLA-B27 and free heavy chain (FHC) expression were tested by flow cytometry. Activation of unfolded protein response (UPR) was measured using PCR and western blot for BiP, CHOP and ATF-6.

Results: EBV-B cells with the SEC16A mutation had a significantly ($P<0.001$) lower number of secretory vesicles at ERES (co-localization of SEC16A and SEC31A in Figure 1A) and impaired ER-to-Golgi transport (decreased VSVG-GFP trafficking). By FRAP, there was poor recruitment of SEC31A to ERES. There was significantly lower surface expression of intact HLA-B27 and FHC ($P<0.01$) and accumulation of both intracellularly ($P<0.01$). All findings were replicated in C1R-B27 cells after 90 % SEC16A suppression. UPR was significantly elevated due to the insufficient ER-Golgi transport in the SEC16A knock out C1R-B27 cells (Figure 1B).

Conclusion: Thus SEC16A is an important factor that can influence HLA-B27 trafficking, surface and intracellular expression and UPR. Abnormal SEC16A-HLA-B27 interaction may play an important role in the pathogenesis of AxSpA. **Figure 1. A 9-bp deletion of SEC16A (MUT) decreases COPII vesicle formation compared to wild Type SEC16A (WT) (A). SEC16A knockout (90%) leads to increased unfolded protein response (B).**

Session Title: Spondylarthropathies Psoriatic Arthritis – Pathogenesis, Etiology II

Session Type: ACR Concurrent Abstract Session

Session Time: 9:00AM-10:30AM

Background/Purpose: HLA-B27 and human b_2m expression in rats induces a spontaneous inflammatory disease resembling human spondyloarthritis (SpA). While aspects of rat SpA have been studied in detail, understanding of gut inflammation remains limited. We recently showed that HLA-B27 affects the gut microbiota in rats. Here, we aimed to determine the relationship between intestinal microbiota and the gut immune response in B27 rats developing SpA-like disease.

Methods: HLA-B27/human b_2m transgenic (B27) rats (33-3 transgene locus) on 3 genetic backgrounds (Dark Agouti, DA; Lewis, LEW; and Fischer, F344), and HLA-B7/human b_2m transgenic (B7) rats on the LEW background, were examined at 2, 3, and 6 months of age. In a total of 194 rats, microbiota in the ileum, cecum and colon was determined by 16S rRNA gene sequencing. Cecum and colon histology was scored for inflammation, and RNA from whole tissue was analyzed by RNA-Seq to assess gene expression. Differences in microbiota and host immune response were identified as a function of genotype, genetic background, and disease severity.

Results: DA rats are resistant to B27-induced gut inflammation, while it progresses with age in LEW B27, and occurs early and is more severe in F344 rats. LEW B7 rats remain unaffected. Disease severity correlates with increased relative abundance of *Proteobacteria* and *Verrucomicrobia* at the expense of *Firmicutes*. While disease-associated microbes are similar in B27 LEW and F344, their relative frequencies are background specific. For example, *Clostridium* and *Akkermansia* are abundant in F344, while *Prevotella* and *Sutterella* exhibit greater increases in LEW. B27 DA and B7 LEW animals exhibit different microbial profiles compared to their WT controls, yet neither develops disease. Metagenome predictions revealed perturbed glutathione and steroid hormone biosynthesis B27 LEW and B27 F344. A striking finding was that LEW and F344 rats harbor segmented filamentous bacteria (SFB) in the ileum, whereas SFB are absent from the DA background and B7 LEW rats. Transcriptome analysis revealed robust activation of the IL-23/IL-17 axis, with IFN-g as well as TNF-a pathways upregulated with concomitant downregulation of metabolic pathways in B27 LEW and F344 rats. Interestingly, DA B27 showed a transient upregulation of these pathways including IL-17, IL-22, and TNF-a, but not IFN-g. LEW B7 rats had a remarkably similar transcriptome to LEW WT rats despite dramatic differences in microbial communities.

Conclusion: Integrated analysis of the gut microbiota and host transcriptome on different genetic backgrounds provides an unprecedented picture of the relationship between HLA-B27-induced gut inflammation and microbial communities. Microbial dysbiosis varies with genetic background, but contributes to a common disruption of gut metabolic pathways with activation of the IL-23/IL-17 axis, and IFN/TNF signaling leading to gut inflammation. The lack of SFB in DA rats may protect B27 animals given the well-known requirement for SFB for Th17 development in the lamina propria. Understanding SpA-associated microbial communities may lead to a better understanding of HLA-B27-associated disease pathogenesis.

Session Title: Spondylarthropathies Psoriatic Arthritis – Pathogenesis, Etiology II

Session Type: ACR Concurrent Abstract Session

Session Time: 9:00AM-10:30AM

Background/Purpose: HLA-B27 is the strongest known genetic risk factor for ankylosing spondylitis and other spondyloarthropathies (SpAs). We have shown previously that Fisher 344 rats that express the human HLA-B27/β2m transgene (33-3 locus) develop a globally altered intestinal microbiome relative to wild type (WT) control animals. This mirrors the altered gut microbiota of SpA patient populations and indicates intestinal dysbiosis may be a functionally significant event in SpA pathogenesis. Intestinal IgA responses are known to shape the intestinal microbiota. We hypothesized that microbiota-specific IgA responses may be significantly impacted by HLA-B27 expression. Moreover, since IgA responses can regulate microbial translocation from the gut to the periphery, we examined B27-associated translocation of gut microbes to the joint – a site

predisposed to inflammation in the HLA-B27/β2m rat.

Methods: For IgA analysis, we used IgA-SEQ sequencing methodology, whereby fecal bacteria are flow-sorted based upon their coating with IgA and the IgA+ve and IgA-ve fractions subjected to 16s rRNA gene sequencing. The relative enrichment of each bacterial operational taxonomic unit (OTU) in the IgA+ve vs IgA-ve fraction was then calculated to profile the microbiota-specific IgA response in 16wk old HLA-B27/β2m or WT control rats. The frequency of IgA+ve B cells in intestinal lamina propria, mesenteric lymph node (MLN) and bone marrow (BM) was also enumerated by flow cytometry. We collected small and large intestinal contents (ileum, cecum and colon), MLN and ankle tissue from 16wk old HLA-B27/β2m rats and WT controls. DNA was extracted and subjected to 16s rRNA gene sequencing to profile microbial DNA at these intestinal and peripheral sites.

Results: HLA-B27 expression was associated with a markedly altered IgA response to the intestinal microbiota, with pronounced IgA-enrichment of many microbial OTUs vs WT animals. Amongst the most disproportionately IgA-coated fecal microbes in B27+ rats were *Prevotella, Blautia* and *Akkermansia spp.* and Segmented Filamentous Bacteria (SFB) – the latter of which is a known arthritogenic agent in rodents. These changes were accompanied by a B27-associated expansion of IgA+ve B cells specifically in the gut. Interestingly, we observed a highly polymicrobial DNA signature in joint tissue, including many microbes of putative intestinal origin. B27 expression was associated with a significant expansion of *Suturella, Roseburia, Akkermansia, Prevotella* and *Coprobacillus spp.*DNA at this tissue site.

Conclusion: The dysbiosis observed with HLA-B27 expression may be a result of highly perturbed mucosal IgA responses to the intestinal microbiota. The presence of microbial DNA in joint tissue implicates the translocation of gut microbes to joint may be a relevant mechanism in SpA pathogenesis. Further functional studies will provide valuable insight as to the relationship between these observations and their respective contribution to B27-associated spondyloarthropathy.

Session Title: Spondylarthropathies Psoriatic Arthritis – Pathogenesis, Etiology II

Session Type: ACR Concurrent Abstract Session

Session Time: 9:00AM-10:30AM

Background/Purpose: Evidence for a discrete intestinal microbiome signature in the terminal ileum (TI) of ankylosing spondylitis (AS) patients, compared to healthy controls, has recently been described. It has been hypothesised that HLA-B27 induces AS by effects on the intestinal microbiome, in turn driving spondyloarthritis by inducing immunological processes, particularly IL-23 production. Here we examine the effect of HLA-B27 on the composition of the intestinal microbiome in healthy individuals and twins, using culture independent 16S rRNA amplicon sequencing.

Methods: 135 samples from 6 intestinal sites were collected from otherwise healthy persons undergoing routine colorectal

screening (age 40-75yrs). All patients were HLA-B typed and biopsies sequenced for the bacterial marker gene 16S rRNA and analysed. Further analysis was conducted using multivariate analysis package MixMC as implemented in R.The association between HLA-B27 status and intestinal microbiome was further examined in 1392 otherwise healthy twins with matched faecal 16S rRNA and genotype status from the TwinsUK registry. Linear mixed effects models were used to examine the association between the microbiome and genotype status. These models account for the correlation between twins within a family.

Results: Intestinal biopsy studies revealed that HLA-B27 genotype (n=10 B27+ and 85 B27- samples) influences overall microbial composition with increases in bacterial families *Ruminococcaceae* and *Lachnospiraceae* in the HLA-B27+ samples. Multivariate regression analysis of all samples demonstrated distinct clustering of HLA-B27+ from HLA-B27- samples (P=0.0063; PERMANOVA). The TI also showed clear and distinct clustering of HLA-B27+ from HLA-B27- samples driven by a decrease in *Veillonellaceae* (P<0.001) and the order Clostridiales *(*P<0.05), and increases in *Bacteroidaceae (*P<0.05) and *Ruminococcaceae (*P<0.05). The effect of genotype on the microbiome was further examined in the TwinsUK cohort (n=107 B27+ and 1285 B27- samples). HLA-B27 status was again associated with the bacterial families *Ruminococcaceae*, *Lachnospiraceae* and the order Clostridiales, in the same direction as seen in the intestinal biopsy data. This is consistent with the TI microbial signature previously described in AS cases and healthy HLA-B27+ patients.

Conclusion: This study shows that healthy HLA-B27+ individuals exhibit shared microbiota changes with AS, indicating an altered microbiota may be a primary event in AS pathogenesis rather than secondary to disease or its treatment. These findings support the hypothesis that HLA-B27 operates to cause AS through interaction with the intestinal microbiome, and suggests that therapies targeting the microbiome may be effective in AS prevention and/or treatment.

Session Title: Systemic Lupus Erythematosus – Clinical Aspects and Treatment V: Damage and Morbidity

Session Type: ACR Concurrent Abstract Session

Session Time: 9:00AM-10:30AM

Total and Glucocorticoid-Related Damage Accrual in The Systemic Lupus International Collaborating Clinics Inception Cohort. **Jayne Little**[1], Mark Lunt[1], Ben Parker[1], Ian N. Bruce[1] and The Systemic Lupus International Collaborating Clinics (SLICC) Group, [1]Arthritis Research UK Centre for Epidemiology, Centre for Musculoskeletal Research, Institute of Inflammation and Repair, MAHSC, The University of Manchester, Manchester, United Kingdom

Background/Purpose:

The Systemic Lupus International Collaborating Clinics (SLICC)/American College of Rheumatology (ACR) Damage Index (SDI) assesses irreversible damage in SLE and a higher SDI score predicts further damage and mortality. Glucocorticoid (GC) use, a modifiable risk factor, has been associated with increased total SDI score and specific individual damage items. In a previous consensus exercise we categorised SDI items according to their likely association with GCs. Our aim was to explore the accrual of total and GC-related damage in a large international inception cohort.

Methods:

From 2000-11, we recruited patients within 15 months of developing four or more 1997 American College of Rheumatology (ACR) criteria for SLE. The SDI was completed at enrolment (if >6 months from diagnosis) and at each annual assessment. Total SDI scores in the cohort over time were assessed using descriptive statistics (point estimates of the mean) and the cumulative incidence of SDI items (grouped according to systems or likely steroid association) was calculated using Cox proportional hazard regression.

Results: The mean (point estimate) SDI increased over time from 0.45 at assessments occurring between 1 and 2 years from diagnosis (n=1332) to 0.86 at 5 years (n=1067) and 1.38 (n = 429) at 10 years. For each of the 12 SDI organ-based systems there was a steady accumulation of damage over time (figure 1). By year 5 the highest incidence rates of damage were seen within the musculoskeletal group and the 'other' group. When items were grouped based on their likely association with GC use, the cumulative incidence of items thought to have definite, probable/possible and no association with GC were 0.097, 0.053 & 0.203 respectively by 5 years and 0.207, 0.092 and 0.411 respectively by 10 years (figure 2). By 10 years, 42.6% of all damage was potentially related to GC use.

Conclusion: In this inception cohort, the damage accumulated over time in a linear manner, whether damage items are grouped as a total SDI, according to organ-systems or when grouped according to their likely association with steroids. A significant proportion of all damage accrued (42.6%) is related to steroid use and better therapeutic strategies to reduce steroid exposure are needed to improve long-term outcomes in SLE.

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016
Session Title: Systemic Lupus Erythematosus – Clinical Aspects and Treatment V: Damage and Morbidity
Session Type: ACR Concurrent Abstract Session
Session Time: 9:00AM-10:30AM

Background/Purpose: Little is known about the association of healthcare costs with damage accrual in SLE. We describe the costs associated with damage states across the disease course using multi-state modeling.

Methods: Patients fulfilling the revised ACR classification criteria for SLE from 32 centres in 11 countries were enrolled in the Systemic Lupus International Collaborating Clinics (SLICC) inception cohort within 15 months of diagnosis. Annual data on demographics, SLE disease activity (SLEDAI-2K), damage (SLICC/ACR Damage Index [SDI] if ≥ 6 months from diagnosis), hospitalizations, medications, dialysis, and utilization of selected medical/surgical procedures were collected. Annual health resource utilization was costed using 2015 Canadian prices. Annual costs associated with SDI states were obtained from multiple regressions adjusting for age, race/ethnicity, and disease duration. As there were relatively few transitions to SDI states 5 – 11, these were merged into a single SDI state. Five and 10-year cumulative costs were estimated by multiplying annual costs associated with each SDI state by the expected duration in each state, which was forecasted using a multi-state Markov model (*Bruce IN et al. Ann Rheum Dis 2015;74:1706-13*).

Results: 1641 patients participated, 89.2% female, 48.9% Caucasian, mean age at diagnosis 35.2 years (SD 13.4), mean disease duration at enrollment 0.5 years (SD 0.3), and mean follow up 6.1 years (range 0.1 – 13.7 years). Health resource utilization and annual costs (after adjustment using regression) were markedly higher in those with higher SDIs (Table 1).

Table 1. Predicted Annual Health Costs Stratified by SDI

SDI State	Health Care Costs, Mean, 95% CI 2015 Canadian $
0	1569 (691,2448)
1	3317 (2234, 4399)
2	4528 (2969, 6086)
3	7422 (5350, 9494)
4	14 631 (8450, 20 813)
≥5	31 692 (20 860, 42 524)

Five and 10-year cumulative costs stratified by baseline SDI were calculated by multiplying the annual costs associated with each SDI by the expected duration in that state (5-year example in Table 2).

Table 2. Expected Duration in each SDI state over 5 Years

Baseline SDI State	Expected Duration in each SDI State over 5 years					
	0	1	2	3	4	≥5
0	4.12 yrs	0.64 yrs	0.18 yrs	0.05 yrs	0.01 yrs	0.002 yrs
1		3.17 yrs	1.28 yrs	0.43 yrs	0.09 yrs	0.03 yrs
2			3.05 yrs	1.42 yrs	0.37 yrs	0.17 yrs
3				3.22 yrs	1.11 yrs	0.67 yrs
4					2.61 yrs	2.39 yrs
≥5						5 yrs

Five and 10-year costs were greater in those with the highest SDIs at baseline (Table 3).

Table 3. Predicted 5 and 10- Year Cumulative Costs Stratified by Baseline SDI		
Baseline SDI State	Health Care Costs, Mean, 95% CI 2015 Canadian $	
	5-Year Cumulative Costs	10-Year Cumulative Costs
0	7440 (2729, 12 151)	16 940 (4548, 29 333)
1	19 301 (11 991, 26 612)	54 122 (31 306, 76 937)
2	32 468 (20 557, 44 379)	92 155 (57 941, 132 368)
3	58 874 (38 022, 79 726)	157 626 (98 830, 216 422)
4	111 379 (68 987, 153 770)	250 293 (155 798, 344 789)
≥5	155 961 (101 449, 210 472)	306 919 (197 091, 416 747)

Conclusion: Patients with the highest baseline SDIs incur annual costs and 10-year cumulative costs that are approximately 20-fold higher than those with the lowest baseline SDI. By estimating the expected duration in each SDI state and incorporating annual costs, disease severity at presentation can be used to predict future healthcare costs, critical knowledge for cost-effectiveness evaluations of novel therapies.

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016

Session Title: Systemic Lupus Erythematosus – Clinical Aspects and Treatment V: Damage and Morbidity

Session Type: ACR Concurrent Abstract Session

Session Time: 9:00AM-10:30AM

Background/Purpose: Systemic lupus erythematosus (SLE) is associated with an increased risk of mortality. Despite improvements in the recognition and treatment of SLE, it remains a challenging illness to treat, and patients with SLE also frequently suffer from multiple comorbidities, including premature cardiovascular disease and infections. Rheumatoid arthritis (RA) has also been shown to be associated with increased mortality, but studies have found substantially reduced mortality rates in recent years, likely due to improved treatment for RA.[1] However, recent mortality trends in SLE are unknown. Our objective was to assess whether mortality rates in SLE patients have changed over time in a general population context.

Methods: We conducted a population-based cohort study using data from 1999-2014 in a medical record database representative of the UK general population. We identified incident cases of SLE and up to 10 controls matched on age, sex, and entry time. This cohort was divided into two subgroups based on year of SLE diagnosis, forming the early cohort (1999-2006) and late cohort (2007-2014). We compared mortality rates, hazard ratios (HRs) (using a Cox proportional hazard model), and rate differences (RDs) (using an additive hazard model) between SLE and non-SLE cohorts, adjusting for demographics, lifestyle factors, comorbidities, medications, and healthcare use.

Results: Both the early and late cohorts (N = 1,470 and 1,666) had a similar mean age (50 and 51 years, respectively) and sex proportion (18% and 17% male, respectively). In both cohorts, SLE patients had a higher risk of mortality compared to their corresponding comparison cohort (i.e., 15.9 vs. 7.9 deaths/1,000 person-years in the early cohort and 13.8 vs. 7.0 deaths/1000 person-years in the late cohort) (**Table 1**). The corresponding absolute mortality RDs were 8.1 (95% confidence interval (CI), 1.3-11.8) and 6.9 (95% CI, 3.5-10.0) deaths/1,000 person-years, and the mortality HRs were 2.51 (95% CI, 1.63-2.83) and 2.12 (95% CI, 1.61-2.80) in the early and late cohorts, respectively (both P values for interaction > 0.6). After adjusting for covariates, the HRs and RDs remained similar between the early and late cohorts (both P values for interaction >0.47), suggesting similar levels of excess mortality in SLE patients in the two cohorts.

Conclusion: This UK population-based cohort study suggests that the excess mortality among SLE patients has not improved over a recent 16-year period. This is in contrast to recent findings that RA patients have had substantially improved survival during the same study period.[1] This supports the need for improved treatment options and strategies for SLE as well as its associated comorbidities. **References:** 1. Session Title: Systemic Lupus Erythematosus – Clinical Aspects and Treatment V: Damage and Morbidity

Session Type: ACR Concurrent Abstract Session

Session Time: 9:00AM-10:30AM

Background/Purpose: Insulin resistance (IR) may contribute to an increase in cardiovascular risk. The aim of this study was to examine the association between IR and disease activity, disease phenotypes, drug exposure and subclinical atherosclerosis in patients with SLE.

Methods: Cross-sectional study that encompassed 332 non-diabetes individuals; 102 SLE patients and 220 age/sex-matched controls. IR by homeostatic model assessment (HOMA2), insulin, C-peptide serum levels and lipid profile were assessed in both groups. Activity (SLEDAI), severity (Katz) and damage (SLICC) scores, carotid intima-media thickness (cIMT) and carotid plaques were assessed in SLE patients. A multivariable regression analysis, adjusted for IR related factors, was performed to evaluate the differences between groups in IR indexes and, in SLE patients, the interrelation between IR and disease activity/characteristics.

Results: Median disease duration was 16 (IQR 9-28) years. Body mass index and abdominal circumference did not differ between groups. HOMA-IR-C-peptide (mean difference [IQR], 1.26 [0.77-1.74], p=0.00) and HOMA-%B-C-peptide (56 [4-71], p=0.00) were increased in SLE patients compared to controls. Similarly, insulin sensitivity through HOMA-S% was inferior in SLE patients (-44 [-28-61], p=0.00). Forty percent of patients were in no activity SLEDAI score, while 32, 21 and 9% were in mild, moderate and high/very high activity respectively. Patients in the SLEDAI high or very high activity category disclosed a higher HOMA-IR level (4.8 ± 4.8 vs. 2.07 ± 1.40, p= 0.00) when compared to those in the no activity category. SLICC index was also clearly associated with IR indexes; higher index values were related with higher HOMA-IR (beta coef. 0.27 [0.08-0.46], p=0.01) and lower HOMA-S% (beta coef. -6 [-10--3], p=0.00) levels. These associations remained significant after adjustment for age, gender, smoking, hypertension, and dyslipidemia. Katz severity index did not revealed relation with IR indexes. Use of prednisone was positively associated with HOMA-IR both when it was considered binary (beta coef 1.75 [1.37-2.12], p=0.00) and continuous (beta coef 0.15 [0.07-0.23] per mg, p=0.00). Hydroxychloroquine/other DMARDs use was not related with IR indexes. Patients with higher anti-DNA titers and those with lower complement serum levels did not reach higher IR levels. 28% of the SLE patients had carotid plaques. The presence of carotid plaque was associated with higher HOMA-IR-C-peptide (3.75 ± 3.62 vs. 1.86-1.19, p=0.00). This difference remained significant after adjustment for demographics or cardiometabolic risk factors (1.50 [0.34-2.66], p=0.01).

Conclusion: IR is present in a significant proportion of SLE patients. Disease activity and damage are SLE-related factors that lead to IR development IR is independently associated with subclinical artheriosclerosis in SLE patients.

The Impact of Statin Use on Mortality in Systemic Autoimmune Rheumatic Diseases

April Jorge, Na Lu and Hyon K. Choi, Rheumatology, Allergy, and Immunology, Massachusetts General Hospital, Harvard Medical School, Boston, MA

First publication: September 28, 2016

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016

Session Title: Systemic Lupus Erythematosus – Clinical Aspects and Treatment V: Damage and Morbidity

Session Type: ACR Concurrent Abstract Session

Session Time: 9:00AM-10:30AM

Background/Purpose: Individuals with systemic autoimmune rheumatic diseases (SARDs)—such as systemic lupus erythematosus (SLE) and systemic sclerosis (SSc)—have been found to have an increased risk of premature cardiovascular (CV) disease compared with healthy peers. Statins have been shown to reduce CV events and mortality in the general population as well as among those with rheumatoid arthritis (RA).[1] However, it is not known whether statins have a similar impact among those with SARDs. We examined the potential survival benefit of statin use on mortality among patients with SARDs in a general population setting.

Methods: We conducted an incident user cohort study with time-stratified propensity score matching using a United Kingdom general population database. Our population included patients with a SARD as determined by incident diagnoses of SLE, SSc, Sjogren's syndrome, dermatomyositis, polymyositis, mixed connective tissue disease, Behcet's syndrome, or ANCA-associated vasculitis between January 1, 2000 and December 31, 2014. To account for potential confounders, we compared propensity score-matched cohorts of statin initiators and comparators (non-initiators) within 1-year cohort accrual blocks. 50 variables were used to create the propensity scores, including but not limited to disease duration, socio-economic status, body mass index, lifestyle factors, and medication use.

Results: Of 2310 statin initiators, 303 died during the follow-up period (mean=5.09 years), whereas among 2310 propensity score-matched non-initiators, 335 died during the follow-up period (mean=4.89 years). This corresponds to a mortality rate of 25.77/1000 and 29.64/1000 person-years, respectively. The baseline characteristics were well-balanced between the two groups. Statin initiation was associated with a 17% reduction of all-cause mortality (HR=0.83, 95% CI 0.70-0.996). When we compared the unmatched cohorts to determine the effectiveness of our propensity score matching, the statin initiators (n=2863) actually showed an 85% higher risk of mortality (HR=1.85, 95% CI 1.58-2.16) compared to non-initiators (n=2863 randomly selected without propensity score matching) due to confounding by indication.

Conclusion: In this general population-based cohort study, statin initiation was shown to reduce overall mortality in patients with SARDs after adjusting for relevant determinates of CV risk. This is similar to what has been shown in the general population and in patients with RA.[1] These findings suggest that statins should be considered part of the optimal CV risk-reduction strategy for patients with SARDs. Rheumatologists can advocate for this beneficial treatment intervention among their patients. **References:** 1. Schoenfeld SR et al. Statin use and mortality in rheumatoid arthritis: a general population-based cohort study. Ann Rheum Dis. 2016 Jul;75(7):1315-20.

Session Title: Systemic Lupus Erythematosus – Clinical Aspects and Treatment V: Damage and Morbidity

Session Type: ACR Concurrent Abstract Session

Session Time: 9:00AM-10:30AM

Background/Purpose: Over the past half-century, diagnostic and therapeutic developments for SLE have led to dramatic improvements in the 5- and 10-year survival. Whether these achievements have improved the long-term trends in mortality in SLE is unclear.

Methods: We measured temporal trends in age-standardized mortality rates (ASMR) for SLE and non-SLE causes by joinpoint

trend analysis using county-level data abstracted from the Centers for Disease Control and Prevention database. We calculated the annual % change in mortality over the past 46 years. Logistic regression was applied to model the association of sex, race and geographic region on SLE deaths. We calculated SLE case-fatality by dividing the SLE-mortality by the estimated SLE prevalence within each demographic variable. Since no national SLE prevalence is available, we estimated these values with weighted visit data from the National Ambulatory Medical Care Survey and the National Hospital Ambulatory Medical Care Survey.

Results: SLE was listed as the primary cause of death in 50,249 individuals from 1968-2013 in the US. The crude mortality rate for SLE peaked during the 1970s-80s and declined during 2000s. Black race was associated with the highest SLE crude mortality rate in each period. While ASMR for non-SLE causes continuously declined throughout the 46 years, the SLE ASMR showed periods of sustained increase from mid-1970s-1990s followed by a decline in 2000s. The higher SLE mortality in the general population was associated with female sex, Black race, and residence in the West or South. The national estimates for SLE prevalence per 100,000 were 221.17 in females, 20.08 (males), 170.5 (Blacks), 107.44 (Whites) and 133.5 (Hispanics), and ranged from and 106.36 (Midwest) to 138.35 (Northeast). Using these national prevalence estimates, we calculated case-fatality. Analysis of the trend in SLE case-fatality showed an overall decline in rates from 1999-2013. The average annual % change in SLE case-fatality ranged from -2.5% per year to -3.1% per year in various subpopulations during 1999-2013. Analyses of case-fatality in different subpopulations revealed that in the SLE subpopulation, males had a higher mortality (odds ratio 1.94, $p<0.001$), and even after adjusting for the prevalence variability, the SLE mortality remained higher in Blacks (odds ratio 5.24, $p<0.001$), and in people living in the South (odds ratio 1.55, $p<0.001$) and the West (odds ratio 1.44, $p<0.001$) than in the Northeast. Age of death histograms showed that Blacks died from SLE at a younger age than Whites with 50% of total deaths occurring by age 45 years in Blacks versus age 59 years in Whites. Likewise, Hispanics died younger with half of the SLE deaths occurring by age 44 years versus non-Hispanics by age 54 years.

Conclusion: Mortality from non-SLE causes declined throughout the 46 years, however, SLE mortality rates had periods of increases and more recent declines. SLE deaths occur younger in Blacks and Hispanics, and SLE case-fatality is greater in males. Despite encouraging trends in overall SLE mortality, significant gender, racial, ethnic and regional disparities persist. The findings provide impetus to delineate the next steps to improve these disparities.

Session Title: Systemic Sclerosis, Fibrosing Syndromes and Raynaud's – Pathogenesis, Animal Models and Genetics II

Session Type: ACR Concurrent Abstract Session

Session Time: 9:00AM-10:30AM

Background/Purpose: Peroxisome proliferator-activated receptors (PPARs) are nuclear receptors known to modulate fibrosis. The pan-PPAR agonist IVA337 recently demonstrated efficacy in prevention and treatment of experimental skin fibrosis (1). Our objective was to evaluate the antifibrotic effects of IVA337 in preclinical mouse models of pulmonary fibrosis and related

pulmonary hypertension (PH).

Methods: IVA337 has been evaluated in the mouse model of bleomycin-induced pulmonary fibrosis and in Fra-2 transgenic mice, this latter being characterized by non-specific interstitial pneumonia and severe vascular remodeling of pulmonary arteries leading to PH. Mice received 2 doses of IVA337 (30 mg/kg or 100 mg/kg) or vehicle administered by daily oral gavage up to 4 weeks.

Results: Both 30 mg/kg and 100 mg/kg doses of IVA337 were well tolerated in all mouse models. IVA337 demonstrated at a dose of 100 mg/kg a marked protection from the development of lung fibrosis induced by bleomycin compared to mice receiving 30 mg/kg of IVA337 or vehicle. Indeed, IVA337 (100 mg/kg) strongly reduced by 61% and 28% tissue density on histological measurements and total lung hydroxyproline concentrations, respectively, as compared to vehicle. IVA337 at 100 mg/kg also significantly decreased col1, col3, fibronectin and a-smooth muscle actin mRNA levels in lesional lungs. *In vitro* in primary human lung fibroblasts, IVA337 inhibited in a dose-dependent manner TGFβ-mediated fibroblasts to myofibroblasts transition and PDGF-mediated proliferation. Similarly, Fra-2 transgenic mice treated with 100 mg/kg of IVA337 displayed reduced lung density (20% *vs.* vehicle) and significant increase of functional residual capacity (30% *vs.* vehicle) when assessed by chest micro-CT imaging. These results were emphasized by a 50% reduction of the Ascroft fibrosis score (Figure 1A) and by a 48% reduction of hydroxyproline concentrations upon IVA337 (100 mg/kg) compared to vehicle treated mice. Regarding vessel remodeling and related pulmonary hypertension, treatment with 100 mg/kg of IVA337 led to a substantial attenuation of right ventricular systolic pressure and right ventricular hypertrophy compared to mice receiving the vehicle (Figure 1B and 1C). Furthermore, IVA337 given at 100 mg/kg markedly reduced medial wall thickness (Figure 1D) and the number of muscularized distal pulmonary arteries.

Conclusion: We demonstrate that treatment with 100 mg/kg IVA337 prevents lung fibrosis in two complementary animal models and substantially attenuates PH in the Fra-2 mouse model. These findings confirm that the pan-PPAR agonist IVA337 is an appealing therapeutic candidate for systemic sclerosis both, for skin and key cardiovascular complications. **Reference:** 1/ Ruzehaji et al, Ann Rheum Dis 2016, in press. **Figure 1:** Effects of IVA 30 mg/kg and 100 mg/kg on pulmonary fibrosis (A) and related pulmonary hypertension (B-D) in the Fra-2 mouse model

Session Time: 9:00AM-10:30AM

Background/Purpose:

Systemic sclerosis (SSc) is a chronic fibrosing disorder that affects the skin and other internal organs. Inflammation, vasculopathy and fibrosis at the affected area are the major pathological aspects of SSc. Infiltration of inflammatory cells into the fibrotic lesions often occurs at an early phase of the disease; therefore, immunosuppressive therapy often prevents disease progression and accumulation of extracellular matrix (ECM) molecules. The PDE4 inhibitor, apremilast, acts on target cells as an anti-inflammatory agent by increasing intracellular cAMP levels and the subsequent activation of protein kinase A (PKA) and exchange protein directly activated by cAMP (Epac). cAMP-elevating molecules have been extensively reported to ameliorate fibrosis in various fibrotic models. Based on these findings, we hypothesized that apremilast may prevent the progression of dermal fibrosis by inhibiting inflammation and fibrosis.

Methods: Dermal fibroblasts obtained from healthy individuals and patients with diffuse cutaneous SSc were incubated with apremilast at a concentration of 1-10 μM in the presence or absence of TGF-β1. Furthermore, to assess the anti-fibrotic effect of apremilast *in vivo*, we injected BALB/c mice with bleomycin together with intraperioneal administration of PBS or apremilast (1 mg/kg or 5 mg/kg daily) for 4 weeks, and dermal fibrosis was evaluated by the degree of skin thickness, αSMA-positive myofibroblast counts and collagen content. Intracellular cAMP levels were determined by an enzyme-linked immunosorbent assay (ELISA). mRNA levels of target molecules were determined by quantitative RT-PCR. Protein levels of target molecules were determined by immunoblotting and immunostaining.

Results: PDE4A, B and D were expressed in human dermal fibroblasts, and the mRNA levels of PDE4 subtypes did not differ between fibroblasts from healthy and SSc groups. Apremilast significantly suppressed the expression of *COL1A1*, *COL1A2* and *CTGF* mRNA in SSc dermal fibroblasts and healthy dermal fibroblasts treated with TGF-β1. Similarly, apremilast decreased the protein levels of type I collagen and CTGF in SSc dermal fibroblasts. With respect to the signal transduction of TGF-β1, phosphorylated Smad3, ERK1/2 and Akt were diminished in dermal fibroblasts treated with apremilast. These findings demonstrated that apremilast inhibited the production of ECM proteins by interfering with TGF-β signaling in both a Smad-dependent and a Smad-independent manner in dermal fibroblasts. Furthermore, in an *in vivo* analysis of a mouse model of bleomycin-induced dermal fibrosis, apremilast attenuated the development of dermal fibrosis compared with PBS.

Conclusion: Apremilast has anti-fibrotic effects on experimental dermal fibrosis, at least in part, by acting on activated dermal fibroblasts. Considering that apremilast is approved for psoriatic arthritis, apremilast may serve as a well-tolerated drug for the treatment of fibrotic lesions in patients with SSc.

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016
Session Title: Systemic Sclerosis, Fibrosing Syndromes and Raynaud's – Pathogenesis, Animal Models and Genetics II
Session Type: ACR Concurrent Abstract Session
Session Time: 9:00AM-10:30AM

Background/Purpose: We previously showed patients in the inflammatory subset were most likely to demonstrate improvement in modified Rodnan Skin Score (mRSS) during mycophenolate mofetil (MMF) treatment. Here, we show that MMF abrogates the molecular inflammatory signature and that the inflammatory signature and myeloid immune cell counts rebound after treatment cessation.

Methods: Sixty-eight SSc patients and 22 healthy controls were enrolled. Clinical data and 358 independent biopsies were obtained and analyzed at baseline, 6, 12, 24, and 36 months (mo). Immunohistochemistry (IHC) was performed on skin biopsy sections using a CD163 marker for macrophages and CD1c for myeloid dendritic cells (mDCs). Genome-scale gene expression was measured. Clinical improvement was defined as a decrease in mRSS $\geq$ 25%. Subjects with longitudinal skin biopsies and at least 24 mo of follow-up were termed completers. We calculated a normalized enrichment score (NES) for the inflammatory signature on a per-biopsy basis using ssGSEA.

Results: Six of the 11 completers showed 2 distinct response patterns between 24 and 36 mo determined by MMF therapy status. Three subjects showed a significant decrease in their inflammatory signature at 12 and 24 mo, paralleling decreases in T cell, macrophage and DC gene signatures, as well as mDC/macrophage IHC counts. MMF cessation at 24 mo resulted in a return of their inflammatory signatures and mDC/macrophage IHC counts, typically with an increase in mRSS. In contrast, 3 subjects that continued MMF therapy showed decreased inflammatory signatures through 36 mo with decreasing or stable mRSS. The remaining 5 completers largely showed an absence of the inflammatory signature at baseline and no improvement during MMF therapy.

Conclusion: A subset of patients receiving MMF lose their inflammatory signatures and show decreases in skin myeloid cells. After cessation of MMF, these patients show rebounding inflammation, worsening mRSS and increases in skin mDC/macrophages. Patients remaining on MMF show stable to decreasing inflammatory signatures that coincide with stable mRSS. These results show that significant mRSS improvement during MMF occurs slowly over a 12-24 mo period, and may involve T lymphocytes, macrophage and mDC molecular pathways. These data summarize the effects of MMF on gene expression pathways and myeloid cell localization in the skin and support MMF treatment beyond 24 mo in SSc patients that demonstrate mRSS improvement.

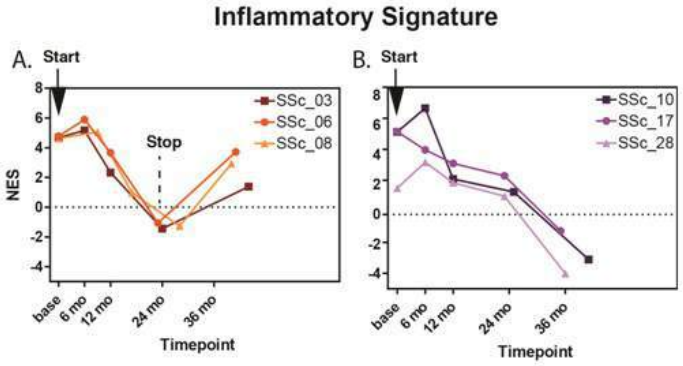

Figure 1. Kinetics of the MMF Response in SSc patients. A summary of inflammatory gene signature in six patients treated with MMF. Arrows indicate start of MMF treatment; dashed lines indicate MMF treatment cessation. **A**. Three patients that lose their inflammatory signature during (to 24 months) with improved mRSS and rebound at 36 months after MMF treatment is stopped, with a concomitant increase in MRSS. **B**. Three patients with sustained improvement in mRSS do not stop treatment and show a sustained loss of inflammatory signature.

Session Date: Wednesday, November 16, 2016

Session Title: Systemic Sclerosis, Fibrosing Syndromes and Raynaud's – Pathogenesis, Animal Models and Genetics II

Session Type: ACR Concurrent Abstract Session

Session Time: 9:00AM-10:30AM

Background/Purpose: Clinical trials in SSc have tended to be underpowered and not meet clinical endpoints. Genome-wide gene expression measured in some studies can prove challenging to analyze and interpret due to the small sample sizes. Often, few differentially expressed genes can be detected pre- and post-treatment after multiple hypothesis testing correction. Here, we have leveraged data from thousands of experiments and utilized state-of-the-art machine learning to robustly identify genes and processes that are predicted to be modulated during clinically significant response to treatment and view the processes modulated in each through the lens of a functional genomic network.

Methods: We analyzed immunomodulatory therapeutics: **abatacept** (Chakravarty et al., 2015) (CTLA4-IgG), **MMF** (Hinchcliff et al., 2013; Mahoney et al., 2015), and **rituximab** (Lafyatis et al., 2009; Pendergrass et al., 2012) (anti-CD20), as well as a tyrosine kinase inhibitor (TKI): **nilotinib** (Gordon et al., 2015), and a monoclonal antibody to the pro-fibrotic cytokine TGF-β: **fresolimumab** (Rice et al., 2015). We applied a common improvement criterion to each study: -20% *OR* -5 modified Rodnan Skin Score (mRSS) (Khanna et al., 2006). Nominally significant genes that changed in each trial were placed in the context of a skin-specific functional genomic network and their connectivity patterns learned using a support vector machine (SVM) (Greene et al., 2015) (Figure 1).

Results: Our machine learning approach captures features beyond differential expression and is better at identifying predicted gene targets of each therapy than the t-statistic alone**.** As an example, *CD86* is captured when abatacept is analyzed due to its connectivity in the network, although the gene itself is not differentially expressed. We observe the abrogation of inflammatory pathways in improvers in multiple studies regardless of the mechanism of action of a drug, which suggests high expression of immune-related genes may represent an active disease state. The framework allows us to compare different trials and ask if the patients that failed one therapy could possibly improve on a different therapy. As an example, we find that genes with high expression at baseline in fresolimumab non-improvers were downregulated in MMF improvers, suggesting that these patients might have benefited from the combination therapy.

Conclusion: This work provides a systems biology framework for analysis of therapeutic trials in rare diseases and for prediction of potentially beneficial treatment combinations. Our results suggest that if a strong inflammatory signature is present in a patient it may need to be treated with an immunosuppressive treatment, but that this may show more efficacy if paired with an anti-fibrotic drug such as anti-TGF-β therapy, especially for patients with a weak baseline inflammatory signature.

Session Title: Systemic Sclerosis, Fibrosing Syndromes and Raynaud's – Pathogenesis, Animal Models and Genetics II

Session Type: ACR Concurrent Abstract Session

Session Time: 9:00AM-10:30AM

Background/Purpose: Interstitial lung disease (ILD) is one of the main causes of systemic sclerosis (SSc)-related deaths. Since routine diagnostics such as high resolution computed tomography and pulmonary function tests often only detect ILD at disease stages with already impaired organ function and/or damage, there is an unmet clinical need for the non-invasive diagnosis of ILD at earliest, still reversible stages. Here, we assessed new radiotracers for the detection of SSc-ILD specifically targeting integrin $\alpha_v\beta_3$ and folate receptor β (FR-β) as molecular players of inflammation and inflammation-dependent fibrosis in the murine model of bleomycin-induced lung fibrosis.

Methods: Expression of integrin $\alpha_v\beta_3$ and FR-β was analyzed in lung sections from patients with SSc-ILD, idiopathic pulmonary fibrosis (IPF) (n=5-6), healthy controls (n=4-5) as well as from bleomycin-treated mice and respective controls (n=6) using immunohistochemistry. *In vivo* imaging was performed using a RGD peptide derivative and a folate derivative radiolabeled with the gamma-radiation emitting radionuclide Lutetium-177 (^{177}Lu). SPECT (single photon emission computed tomography) was performed using a dedicated small-animal SPECT/CT scanner. Animals were scanned at day 7 after intratracheal installation of bleomycin to visualize pulmonary inflammation and incipient fibrosis. The specific pulmonary accumulation of the radiotracer was confirmed by *ex vivo* SPECT/CT, biodistribution, and autoradiography studies.

Results: In lung sections of patients with SSc-ILD and IPF, the expression of integrin $\alpha_v\beta_3$ was significantly increased compared to healthy controls ($p<0.009$, $p<0.02$). In contrast, FR-β expression was only significantly upregulated in lungs from SSc-ILD

($p<0.04$), but not in IPF patients. In line with the results obtained in SSc-ILD, lungs of bleomycin-treated mice, but not of controls showed a significant increase in integrin $\alpha_v\beta_3$ expression and FR-β expression ($p<0.03$. $p<0.05$, Fig. C). Notably, at day 7 after intratracheal installation of bleomycin, SPECT/CT with ^{177}Lu-RGD targeting integrin $\alpha_v\beta_3$, successfully visualized pulmonary inflammation and incipient fibrosis in the model of bleomycin-induced lung fibrosis. Similarly, SPECT/CT of FR-β showed a higher pulmonary uptake of the ^{177}Lu-folate radiotracer in bleomycin-treated mice than in controls (Fig. A). *Ex vivo* SPECT/CT, biodistribution and autoradiography studies confirmed the *in vivo* results and validated the specific uptake of both radiotracers in lungs from bleomycin-challenged mice as compared to controls (Fig. B).

Conclusion: The here presented data provide evidence that targeting molecular players of inflammation and inflammation-dependent fibrosis using nuclear imaging methods may lead to a novel promising non-invasive approach for the early detection of lung involvement in SSc.

Session Title: Systemic Sclerosis, Fibrosing Syndromes and Raynaud's – Pathogenesis, Animal Models and Genetics II

Session Type: ACR Concurrent Abstract Session

Session Time: 9:00AM-10:30AM

Background/Purpose: Cardiac dysfunction is a significant cause of the high mortality in systemic sclerosis (SSc). Heart involvement in SSc patients resembles inflammatory dilated cardiomyopathy (iDCM) with inflammation and fibrosis. Myofibroblasts are the main players in cardiac fibrogenesis, but their origin remains unknown. Here, we aim to determine the role of specific myocardial stromal cell subsets in myocardial remodeling in SSc.

Methods: The Fos-related antigen 2 (Fra2) tg mouse model of SSc/iDCM was studied. Immunohistochemistry (IHC) and immunofluorescence (IF) were performed on endomyocardial biopsies (EMBs) from SSc/iDCM patients (n=10) and on hearts from Fra2 tg mice (n=5). Flow cytometry analysis was used to identify different subsets of myocardial stromal cells that were sorted, cultured and stimulated with TGFβ1. The differentiation potential was assessed by qPCR, IF, stress fiber staining, SIRCOL and contraction assay on sorted cells. Proliferation and apoptosis were assessed by BrdU incorporation and caspase 3/7 detection. The antisense oligonucleotide GapmeR was used to downregulate Fra2

Results: Fra2 tg mice showed increased $CD45^+$leukocyte infiltrates and massive collagen deposition in the heart tissue similarly to the myocardium of SSc/iDCM patients. Moreover, the myocardium of Fra2 tg mice revealed increased expression of pro-fibrotic markers such as αSMA, vimentin, collagen I and fibronectin compared to wild type mice. Among cardiac stromal cells ($Ter119^-CD45^-CD31^-Sca1^+CD29^+$) four specific stromal cell subsets were identified: $gp38^+CD90.2^-$, $gp38^+CD90.2^+$, $gp38^-CD90.2^+$ and $gp38^-CD90.2^-$. The frequency of $gp38^+CD90.2^-$ (single positive) cells and $gp38^+CD90.2^+$(double positive) cells was significantly higher in Fra2 myocardium compared to control mice (p= 0.009; n=11). Importantly, in the myocardium of Fra2 tg mice, the majority of $gp38^+$ cells co-expressed αSMA, vimentin, collagen and fibronectin, indicating that myocardial $gp38^+$stromal cells might proliferate and/or differentiate towards the myofibroblast phenotype. Myocardial single and double positive stromal cells were cultured *in vitro*. After TGFβ1 stimulation, both cell subsets up-regulated αSMA mRNA levels. Importantly, $gp38^+$stromal cells from Fra2 tg mice showed the presence of αSMA fibers and stress fibers, as well as a stronger contraction capability even without TGFβ1 stimulation. In addition, apoptosis and proliferation were increased in Fra2 cells compared to wild-type cells. These findings indicate that Fra2 overexpression might trigger the differentiation of these cells. Accordingly, Fra2 silencing resulted in a decreased differentiation capability of $gp38^+$stromal cells: mRNA levels of the pro-fibrotic genes αSMA and collagen I were significantly downregulated (p=0.0075 and p=0.0073; n=5). Moreover, Fra2 downregulation impaired the secretion of collagens and the formation of αSMA fibers

Conclusion: Cardiac $gp38^+$ stromal cells might serve as a cellular source of pathological myofibroblasts playing a pivotal role in TGFβ/Fra2-driven myocardial remodeling in SSc. A better understanding of the mechanisms triggering myocardial dysfunction in SSc might be helpful in developing effective therapies

Session Date: Wednesday, November 16, 2016
Session Title: Vasculitis IV: Diagnosis and Assessment of Disease Activity
Session Type: ACR Concurrent Abstract Session
Session Time: 9:00AM-10:30AM

Background/Purpose: ANCA-associated vasculitis (AAV) is an organ- and life-threatening disease. Patients present with active disease, followed by periods of remission and flare, and have impairments in mental and physical wellbeing due to disease and treatment. An international team has developed a disease- specific patient- reported outcome measure: the AAV-PRO, supported by a steering group, including four patient partners, in collaboration with the Outcome Measures in Rheumatology (OMERACT) Vasculitis Working group. Candidate questionnaire items were produced following in-depth qualitative research in the UK, US, and Canada plus cognitive interviews, extensive piloting and independent linguistic and translatability assessment.

Methods: Patients with AAV were recruited from Vasculitis UK, and the Vasculitis Patient-Powered Research Network, US. Patients completed the 35 candidate questionnaire items, plus information about their disease, at baseline and three months (included transition item charting change). Paper copies were used in the UK and an electronic online version in the US. UK patients also completed the Euro-Qol-5D (EQ-5D-5L). In the US, a test-retest exercise was completed 3-5 days following baseline. Exploratory factor analysis (EFA) and Rasch analysis defined the underlying scale (domain) structure. The following properties were determined for each domain: convergent validity, using Pearson correlations between domain scores and the EQ-5D-5L; known groups validity, using t-tests to compare mean scores for different disease states; test-retest reliability, analysing intraclass correlation coefficients (ICC), with respondents reporting “no change”; and longitudinal construct validity, analysing mean change scores and effect sizes in relation to transition item responses at three months.

Results: The survey included 626 patients with AAV**,** mean age 59.9 years (standard deviation (SD) 13.9), 29% reported current “active disease” and 43% a flare within the last 2 years. EFA and Rasch analysis supported a 29-item profile measure comprising 6 domains: “Organ-Specific Symptoms”, “Systemic Symptoms”, “Treatment Side Effects”, “Social and Emotional Impact”, “Concerns about the Future”, and “Physical Function”. Domains individually fitted the Rasch model (no significant item-trait interaction at the 1% level) and had good internal consistency (Cronbach’s alphas 0.73 to 0.93). Mean AAV-PRO domain scores were all higher for patients reporting “active disease” versus “remission” (all $p<0.001$). Correlations between domain scores and the EQ-5D-5L index ranged from r0.55 to r-0.78. In respondents reporting “no change” (n=97), ICC values were high (range 0.89 to 0.96) for comparisons of each domain’s 3-5 day test re-test scores. Comparison of mean score changes and effect sizes (ES) for each domain demonstrated stable scores in those reporting “no change” and appropriate positive and negative changes in “much better” or “much worse” disease.

Conclusion: The AAV-PRO, a new disease-specific PRO measure for use in ANCA-associated vasculitis, has good face, content, and construct validity, is reliable, feasible, and discriminates among disease states of importance.

SESSION INFORMATION
Session Date: Wednesday, November 16, 2016
Session Title: Vasculitis IV: Diagnosis and Assessment of Disease Activity
Session Type: ACR Concurrent Abstract Session
Session Time: 9:00AM-10:30AM

Background/Purpose: Prior work has shown that urinary soluble CD163 (usCD163) displays excellent biomarker characteristics for detection of active renal vasculitis using samples from patients with new diagnoses of ANCA-associated vasculitis (AAV) and highly active renal disease. This study focused on use of usCD163 in detection of the more clinically relevant state of mild renal flare, and to compare the performance of usCD163 directly to another proposed biomarker, urinary monocyte chemoattractant protein 1 (uMCP-1).

Methods: Patients with samples obtained during active AAV (n=88) with evidence of active renal involvement (n=34) or without current renal involvement (n=54) were identified within a serially-sampled longitudinal multi-center cohort. In addition, paired remission samples and samples from those with remission AAV were also identified. Creatinine-normalized usCD163 and uMCP-1 levels were measured simultaneously by ELISA. usCD163 and uMCP-1 levels during a flare of active renal vasculitis were compared to levels during remission or during active non-renal AAV.

Results: Samples were available from 320 study visits including times of active renal vasculitis (n=34), remission (n=278), and active extra-renal vasculitis (n=54). Mean creatinine levels in remission and during renal flare were 1.01 mg/dl (SD 0.47) and 1.43 mg/dl (SD 0.61), respectively. usCD163 levels were higher in patients with active renal vasculitis compared with patients in remission and those with active extra-renal vasculitis, with median values of 5.2 pg/mmol (interquartile range (IQR) 1.5-19.4pg/mmol), 0.8pg/mmol (0.1-2.5pg/mmol) and 0.6pg/mmol (0.1-1.6 pg/mmol), respectively ($p<0.001$). uMCP-1 levels were also higher in patients with active renal vasculitis compared with patients in remission and those with active extra-renal vasculitis, with median values of 12.6pg/mmol (IQR 5.1-25.1), 2.4pg/mmol (4.1-8.5) and 3.1pg/mmol (1.2-5.5), respectively ($p<0.001$, Figure 1). The optimal diagnostic cut-offs for usCD163 and uMCP-1 were 1.2pg/mmol and 10.0pg/mmol, respectively. Using these cut-offs, the specificities of usCD163 and uMCP-1 in identifying renal vasculitis flare were 91% and 80%, respectively. Specificities were the same whether comparison was made to remission or to active non-renal AAV. The corresponding sensitivities with these cut-offs were 68% and 64%. The addition of uMCP-1 to usCD163 did not further increase the specificity. usCD163 and uMCP-1 levels were moderately correlated ($r^2 = 0.36$, $p<0.001$), suggesting that additional information may be obtained from sequential modelling that incorporates traditional biomarkers.

Conclusion: In the context of subtle renal vasculitis flare, both usCD163 and uMCP1 levels are tightly associated with active renal disease in AAV. **Figure 1. Urinary sCD163 and MCP-1 levels in ANCA-associated vasculitis, stratified by disease activity**

Session Date: Wednesday, November 16, 2016

Session Title: Vasculitis IV: Diagnosis and Assessment of Disease Activity

Session Type: ACR Concurrent Abstract Session

Session Time: 9:00AM-10:30AM

Background/Purpose: The significance of persistent hematuria or proteinuria in patients with ANCA-associated vasculitis (AAV)

who are in clinical remission is still unclear. This study examined the utility of urinalysis in predicting renal relapse in AAV.

Methods: Participants enrolled in the Wegener's Granulomatosis Etanercept Trial (WGET) and the Rituximab in ANCA-Associated Vasculitis (RAVE) trial who had active glomerulonephritis due to AAV, positive ANCA, and achieved remission by month 6 were included. Exposures included persistent hematuria (or proteinuria) for the first 6 months from enrollment after onset of active renal disease and cumulative hematuria (or proteinuria) as a time-varying covariate. Renal relapse was defined as new or worsening RBC casts and/or rise in serum creatinine according to the Birmingham Vasculitis Activity Score for Wegener's Granulomatosis (BVAS/WG). In RAVE only, the relationship between worsening levels of hematuria and renal relapse was evaluated. Competing risk regression was used to examine renal relapse (with non-renal relapse and end-stage renal disease as competing events); results were expressed as subdistribution hazard ratios (sHR). All models adjusted for study, ANCA type, baseline serum creatinine, and pulmonary involvement.

Results: There were 149 patients included: 42% had persistent hematuria and 43% had persistent proteinuria beyond 6 months (**Table 1**). There was a significantly higher risk of relapse among patients with persistent hematuria beyond 6 months (sHR 3.99 [95% CI 1.20, 13.25], p = 0.02) (**Figure 1**) as well as with each additional month of cumulative hematuria (sHR per month 1.07 [95% CI 1.02, 1.13], p = 0.01) (**Table 2**). Persistent proteinuria was not associated with renal relapse (p = 0.53). Evaluation of changes in level of hematuria showed that an increase in hematuria level over the prior 6 months was associated with renal relapse (sHR 4.90 [95% CI 1.81, 13.27], p < 0.01) and larger changes in hematuria conferred greater risk.

Conclusion: Persistent hematuria and increasing hematuria, but not proteinuria, are associated with renal relapse among patients with AAV and recent renal disease. These findings suggest that the urinalysis may be a useful tool in predicting renal relapse in AAV.

Table 1. Characteristics of Study Population at Enrollment

	All (N = 149)	Persistent hematuria beyond 6 months		P-value
		Yes (N = 63)	No (N = 86)	
Age at baseline, years	55 (44, 66)	54 (43, 68)	55 (44, 63)	0.67
Female, %	41%	56%	30%	< 0.01
Achieved menopause (if female), %	62%	51%	77%	0.04
ANCA type by ELISA, %				0.45
Anti-PR3	68%	65%	71%	
Anti-MPO	32%	35%	29%	
Newly-diagnosed at enrollment, %	59%	57%	60%	0.68
Prior kidney involvement, %	98%	100%	94%	0.05
BVAS/WG at baseline	7 (5, 10)	8 (6, 10)	7 (4, 9)	< 0.01
VDI at baseline	0 (0, 1)	0 (0, 1)	0 (0, 1)	0.70
Serum creatinine at baseline, mg/dL	1.4 (1.1,2.3)	1.8 (1.1, 2.6)	1.3 (1, 2.2)	0.07
Renal disease at baseline, %				
Hematuria	100%	100%	100%	--
Proteinuria	74%	86%	66%	0.01
Red blood cell casts*	56%	62%	52%	0.24
Rise in serum creatinine*	50%	63%	41%	< 0.01
Duration of persistent hematuria, months	6 (3, 12)	17 (11, 26)	3 (2, 4)	< 0.01
Persistent proteinuria ≥ 6 months, %	43%	60%	31%	< 0.01
Pulmonary involvement at baseline, % Alveolar hemorrhage at baseline	60% 26%	54% 30%	65% 23%	0.17 0.44
Induction therapy, % Cyclophosphamide Rituximab	66% 34%	54% 46%	76% 24%	< 0.01

Values expressed as median (interquartile range) or percentage. *Based on BVAS/WG items.

AAV, ANCA-associated vasculitis. BVAS/WG, Birmingham Vasculitis Activity Score for Wegener's Granulomatosis. CI, confidence interval. ELISA, enzyme-linked immunosorbent assay. GPA, granulomatosis with polyangiitis. MPA, microscopic polyangiitis. PR3, proteinase-3. MPO, myeloperoxidase. VDI, Vasculitis Damage Index

Table 2. Risk of Renal Relapse in ANCA-Associated Vasculitis after Multivariate Adjustment for Duration of Hematuria and Proteinuria

Variable	sHR (95% CI)	P-value
Cumulative duration of hematuria (per month)	1.07 (1.02, 1.13)	0.01
Cumulative duration of proteinuria (per month)	1.04 (0.99, 1.08)	0.10
ANCA (PR3 vs MPO)	0.77 (0.30, 1.92)	0.57
Baseline pulmonary involvement	2.84 (0.34, 23.98)	0.34
Baseline Creatinine (per 1 mg/dL)	0.94 (0.48, 1.83)	0.85
Study (RAVE vs WGET)	0.30 (0.06, 1.64)	0.17

Cumulative duration of hematuria and proteinuria were analyzed as time-varying covariates. Hematuria-by-proteinuria interaction was not significant (p for interaction = 0.11).

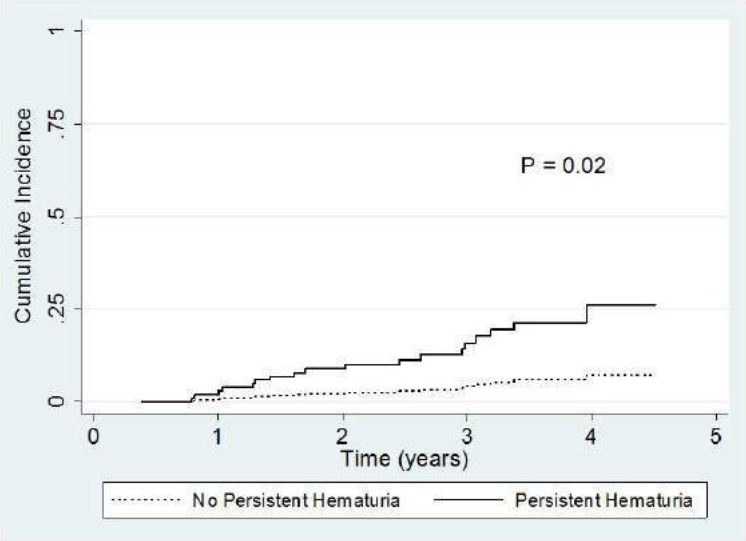
sHR, subdistribution hazard ratio. CI, confidence interval.

PR3, proteinase-3. MPO, myeloperoxidase.

WGET, Wegener's Granulomatosis Etanercept Trial.

RAVE, Rituximab in ANCA-associated Vasculitis trial.

Figure 1. Cumulative Incidence Curves for Renal Relapse in Patients With AAV With and Without Persistent Hematuria for 6 Months



Adjusted for study, ANCA type (anti-proteinase 3 vs anti-myeloperoxidase), pulmonary involvement, and baseline creatinine. Relapse without renal involvement and development of end-stage renal disease were competing events.

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016

Session Title: Vasculitis IV: Diagnosis and Assessment of Disease Activity

Session Type: ACR Concurrent Abstract Session

Session Time: 9:00AM-10:30AM

Background/Purpose: Fluorine-18-fluorodeoxyglucose (18F-FDG) PET/CT is, due to its excellent diagnostic accuracy[1], increasingly used to diagnose large vessel GCA (LV-GCA). However, PET/CT is not always readily available, which may compel the clinician to 1) either delay steroid treatment at the risk of GCA related complications, or 2) to initiate treatment at the expense of diagnostic sensitivity of the 18F-FDG PET/CT study. Therefore, evidence of a possible "18F-FDG PET/CT diagnostic window" after initiation of steroid treatment is needed.

Methods: Twenty treatment-naïve patients (14 women) with a mean age of 69 (range 56-83) years with 18F-FDG PET/CT (PET0) proven LV-GCA were randomized to repeat 18F-FDG PET/CT after either 3 (PET3, n=10) or 10 days (PET10, n=10) of treatment with oral prednisolone 60 mg daily. Prior to treatment, clinical examination and laboratory tests were performed to confirm GCA and exclude differential diagnoses. A temporal artery biopsy (TAB) was performed in all patients. An experienced nuclear medicine physician blinded to patients' clinical data reviewed the 18F-FDG PET/CT images. LV-GCA was suspected if increased 18F-FDG uptake in the wall of the aorta and/or supra-aortic branches was observed. A semiquantitative approach was applied (a.m. Meller) in which 18F-FDG uptake in 6 vascular regions (see table 1) was graded on a 5-point scale (0 = no uptake, 1 = uptake below or equal to blood pool, 2 = above blood pool but below liver, 3 = above liver, 4 = 2 times above liver). Any score ≥3 was considered consistent with vasculitis[2]. Data was either continuous or binomial. Normality was checked using QQ-plots. McNeemars and Wilcoxon signed-rank test was used to test statistical significance.

Results: Mean CRP and ESR were 77.2 (95% CI: 56.8; 97.7) mg/l and 77.3 (95% CI: 67.3; 87.3) mm/h, respectively. Fourteen of twenty patients fulfilled the ACR criteria for GCA and 13/20 had a positive TAB. Mean number of prednisolone doses before the post-therapeutic 18F-FDG PET/CT were 3.1 (95% CI: 2.9; 3.3) (PET3) and 10.2 (95% CI: 9.6; 10.8) (PET10). Vascular composite score in aorta did not decrease at PET3 whereas a significant decrease was observed in supraaortic branches at PET3 and all vascular domains at PET10 (table 1). Although, 18F-FDG uptake decreased in supra-aortic branches after 3 days, LV-GCA could still be accurately diagnosed in 10/10 patients. By contrast, LV-GCA could only be diagnosed in 5/10 patients after 10 days (PET0 vs. PET10, p=0.03).

Conclusion: In LV-GCA, high-dose steroid treatment for three or ten days differentially attenuates the regional uptake of 18F-FDG but diagnostic properties remains within the first three days. **Table 1**

Post-therapeutic LV-GCA diagnosis by 18F-FDG PET/CT

	PET3	PET10
PET positive	10/10	5/10

Median vascular composite score

	PET0	PET3	PET0	PET10
Aorta€	9 (9-9)	9 (6-9)	9 (9-9)	5 (3-6)*
Aortic branches#	6 (5-8)	4.5 (3-7)*	6.5 (6-8)	4 (3-5)*

PET positive was defined as vascular 18F-FDG uptake≥3. A vascular composite score in two different vascular domains was calculated by summarizing the grades for selected regions. Medians (interquartile range) in the two groups (PET3 or PET10, n=10 respectively) are presented. *Indicates that post-therapeutic vascular score was significantly different from pre-therapeutic score. €*Aortic: Aorta ascendens, aorta descendens and aortic arch.* #*Aortic branches: Vertebral, carotic and subclavian/axillary artery.*

Session Title: Vasculitis IV: Diagnosis and Assessment of Disease Activity

Session Type: ACR Concurrent Abstract Session

Session Time: 9:00AM-10:30AM

Background/Purpose: As published in The Lancet online, March 4, 2016, the first randomized, placebo-controlled trial (RCT) of tocilizumab (TCZ) in giant cell arteritis (GCA) showed clinical efficacy of the anti-IL-6 receptor biologic agent in the induction and maintenance of remission for up to 52 weeks. However, very little is known about inflammatory signals in the vessel walls of TCZ-treated patients. Therefore, the aim of this analysis was to evaluate the inflammation of the vessel wall as seen on magnetic resonance angiograms (MRAs) during the RCT and to compare the signals in the two treatment arms.

Methods: In this single-center RCT participants who satisfied the 1990 American College of Rheumatology criteria were randomly assigned in a 2:1 ratio to receive either TCZ (8 mg/kg of body weight) + glucocorticoids (GC) or placebo + GC. Participants

received infusions at 4-weekly intervals for 52 weeks, and GC were started at 1 mg/kg/d and then tapered down to zero. GCA was proven by positive temporal artery biopsy and/or assessed as large vessel vasculitis by MRA using a score 0 to 3; 0= no mural thickening (vessel wall diameter < 0.6 mm), no enhancement; 1= no thickening, slight mural enhancement; 2= mural thickening (> 0.6 mm), significant mural enhancement; 3= strong thickening (> 0.7 mm), strong mural and perivascular enhancement. Scores 2 and 3 were considered to represent active mural inflammation. The MRAs were analyzed by two experienced radiologists who were blinded to treatment allocation. If positive at inclusion, MRA was repeated after 3 month and at end of the study. The primary outcome for this analysis was the number of patients with complete remission on MRA based on the vasculitis score at week 12 (GC dose of 0.1 mg/kg/d). The secondary outcome was the number of patients with complete MRA remission at week 52 and the change in the vasculitis score.

Results: Twenty-eight of 30 randomized patients underwent baseline MRA, 20 in the TCZ + GC group and 8 in the placebo + GC group. 11 MRAs at baseline (9 in the TCZ + GC group and 2 in the placebo + GC group) had no signs of vasculitis. At week 12, MRAs were performed in 9 patients in the TCZ + GC group, all of whom were in clinical remission, and 4 patients in the placebo + GC group, 2 of whom were in remission. Three (33%) patients in the TCZ + GC group were in complete MRA remission, compared to 1 (25%) in the placebo + GC group. At week 52, there was additional improvement, but no complete remission, on MRA in 3 participants in the TCZ + GC group, resulting in a median change in the vasculitis score of -1.0, and no improvement in the remaining 2 participants in the placebo + GC group, resulting in a median change in the vasculitis score of -0.5.

Conclusion: TCZ induces and sustains clinical remission of GCA but does not completely suppress MR signals of vessel inflammation. Whether these signals are of prognostic importance remains to be determined and should be further evaluated in long-term studies.

Antiphospoholipid Antibodies in Giant Cell Arteritis. What Can They Tell Us?

Alojzija Hocevar, Rok Jese, Ziga Rotar, Polona Žigon, Saša Čučnik and Matija Tomšič, Department of Rheumatology, University Medical Centre Ljubljana, Ljubljana, Slovenia

First publication: September 28, 2016

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016

Session Title: Vasculitis IV: Diagnosis and Assessment of Disease Activity

Session Type: ACR Concurrent Abstract Session

Session Time: 9:00AM-10:30AM

Background/Purpose: The aim of our prospective study was to evaluate the potential impact of the antiphospholipid antibodies (aPL-Abs) on the clinical presentation of giant cell arteritis (GCA).

Methods: GCA patients diagnosed for the first time between 1 September 2011 and 30 April 2016 at our secondary/tertiary rheumatology center and in whom aPL-Abs were determined at presentation were included. Three types of aPL-Abs were studied in the patients' sera: anticardiolipin antibodies (aCL; IgG and IgM isotype), antibodies to β2-glycoprotein 1 (aβ2GP1; IgG, IgM and IgA isotypes) and lupus anticoagulants (LA). The patients were stratified according to the number of positive aPL-Abs tests into three groups: without aPL-Abs, those with a single aPL-Ab and those with two or more aPL-Abs. Medical records of GCA cases were analyzed and data compared between the three groups.

Results: During the 56-month observation period we performed aPL-Abs tests in 97/115 GCA patients (67 (69%) females, median (IQR) age 73.3 (67.2; 78.2) years). aCL, aβ2GP1 and LA were present in 47 (48%), 17 (18%) and 44 (45%) cases, respectively. 39 (40%) patients had single aPL-Ab, 28% had two and 5% had three aPL-Abs. aPL-Abs were not detected in 26 (27%) patients. Characteristics of aPL-Abs negative vs. positive (single and double or triple) groups are presented in Table 1. GCA patients with at least two aPL-Abs had more commonly had severe visual manifestations (transient and permanent visual loss) at presentation (100% vs. 22% of all visual disturbances; p=0.021), as well as symptoms (19% vs. 0%, p=0.029) and ultrasonographic signs of

large vessel vasculitis (62% vs. 33%, p=0.054) than those without aPL-Abs. At least 1 year follow-up data (median (IQR) 101 (50.4; 104.4) weeks) were available in 71 patients. 35 (49%) patients relapsed during follow-up and relapses were not associated with the aPL-Abs positivity at presentation in our group.

Table 1. GCA and aPL-Abs	*aPL-Abs* *(number of patients)*		
Clinical characteristics	*aPL negative*	*single positive*	*double or triple positive*
N	26	39	32

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016
Session Title: Epidemiology and Public Health III: Psoriatic Arthritis and More
Session Type: ACR Concurrent Abstract Session
Session Time: 11:00AM-12:30PM

Background/Purpose: Smoking is a strong risk factor for psoriasis and psoriatic arthritis, but several studies have found that smoking is inversely associated with the risk of psoriatic arthritis (PsA) among psoriasis (PsO) patients. These paradoxical findings may occur due to index event bias (a selection bias also called collider bias) that arises from selecting a group of patients (e.g., PsO) on the causal pathway (e.g., between smoking and PsA), such that the total effect of smoking on risk of PsA among PsO patients cannot be appropriately assessed using conventional methods. Moreover, the obtained direct effect (i.e., effect of smoking on the risk of PsA not through PsO) may also be biased. We sought to confirm the paradox in a substantially larger sample and conduct sensitivity analyses to quantify the potential bias on the direct effect estimate.

Methods: We used 1995-2015 data from The Health Improvement Network (THIN), an electronic medical record database representative of the UK general population. We analyzed data from adults free of PsA after at least 1 year of enrollment into THIN, and with data on factors of interest. Follow-up began with the first record of smoking status (exposure) after the enrollment period and ended at the time of PsA diagnosis, death, loss to follow-up, or the end of the study, whichever came first. Using Cox regression, we assessed the effect of smoking on incident PsA in the general THIN population and then in patients with PsO. We conducted a "bias sensitivity analysis" for a range of possible relative risks for the association between smoking and potential unmeasured confounders "U" (e.g., genetic factors) and that between U and PsA. Analyses were adjusted for baseline confounders.

Results: There were over 6.6 million subjects without PsA at baseline (mean age 42 years; 53% female; 28% current smokers, and 16% ex-smokers). Of those, 88,469 developed incident PsO, among whom 1,708 developed incident PsA. The adjusted hazard ratio (HR) of smoking for the risk of PsA among PsO patients was 0.79 (95%CI: 0.69, 0.91), but the corresponding HR for PsA in the general THIN population was 1.27 (95%CI: 1.19, 1.36) (**Table**). Results from the bias sensitivity analysis indicated that if the association between U and smoking and that between U and PsA were as low as a relative risk (RR) of 1.8 and 1.9, respectively, then it could nullify a biased protective effect (RR=0.8) **(Figure)**.

Conclusion: This large cohort study confirms that conditioning on PsO can reverse the true association between smoking and PsA. Such index event bias can produce a misleading estimate of the impact of modifiable risk factors. We suggest that investigators perform sensitivity analyses to assess how sensitive the observed effect estimate is to unmeasured confounding and its associated index event bias.

Table. Association between Smoking and Psoriatic Arthritis in the General Population and among PsO Patients

	Non-Smokers	Ex-smokers	Current Smokers
General THIN Population	3,759,554	1,035,203	1,856,542
Number of PsA	3699	1178	2180
Total Follow-up Years	26,961,014	6,599,380	12,964,215
PsA Incidence Rate (1/1000 person-year)	0.14	0.18	0.17
Crude HR (95% CI)	1.0	1.32 (1.24, 1.41)	1.23 (1.17, 1.30)
Adjusted HR* (95% CI)	1.0	1.32 (1.22, 1.43)	1.27 (1.19, 1.36)
Among PsO Patients	37,101	24,646	26,722
Number of PsA	808	457	443
Total Follow-up Years	236,657	133,102	170,186
PsA Incidence Rate (1/1000 person-year)	3.41	3.43	2.6
Crude HR (95% CI)	1.0	0.97 (0.86, 1.09)	0.76 (0.68, 0.86)
Adjusted HR* (95% CI)	1.0	1.04 (0.91, 1.19)	0.79 (0.69, 0.91)

*Adjusted for age, alcohol, BMI, sex, and trauma.

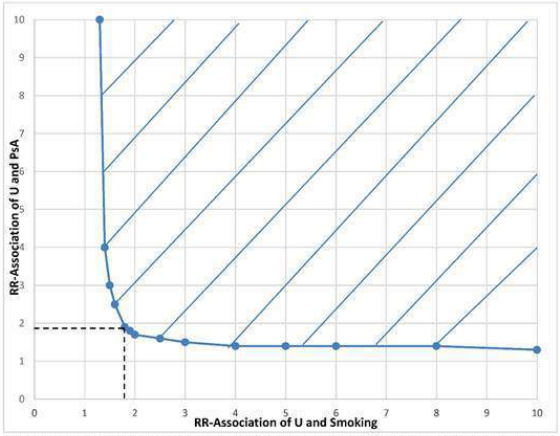

Figure. Sensitivity Analysis of Uncontrolled Confounders Contributing to the Index Event Bias behind the Association between Smoking and the Risk of PsA among PsO Patients. The areas above the curved line are the joint values of the RR of the U-smoking association and the RR of the U-PsA association for unbiased RR > 1.0 for the direct effect of smoking and PsA among PsO patients.

SESSION INFORMATION
Session Date: Wednesday, November 16, 2016
Session Title: Epidemiology and Public Health III: Psoriatic Arthritis and More
Session Type: ACR Concurrent Abstract Session
Session Time: 11:00AM-12:30PM

Background/Purpose: In the management of chronic diseases, recommendations insist on the need to work in partnership with the patient. Patient-physician discordance in global assessment of disease activity is frequent but what does it reflect? The objectives of this study were to assess patient-physician discordance in global assessment in psoriatic arthritis (PsA), predictors of discordance (including patient reported domains of health) and the frequency of discordance according to disease activity levels.

Methods: The PsAID cross-sectional multicenter European study of patients with PsA according to expert opinion was analysed. Patient- and Physician-Global Assessment (PGA and PhGA) were rated with a 0-10 numeric rating scale. Discordance was defined as the difference (PGA–PhGA) and as the absolute difference |PGA-PhGA|≥3 points in the whole population and according to Disease Activity index for PSoriatic Arthritis (DAPSA) levels. Determinants of (PGA-PhGA) were assessed by a stepwise multivariate linear regression among 12 physical and psychological aspects of impact (pain, skin problems, fatigue, ability to work/leisure, functional incapacity, feeling of discomfort, sleep disturbance, anxiety/fear, coping, embarrassment/shame, social participation and depressive affects). A sensitivity analysis was also performed with a logistic regression model using the binary variable |PGA-PhGA|≥3 as outcome. There was no imputation of missing data.

Results: In 460 patients (mean age 50.6±12.9 years, 52.2% female, mean disease duration 9.5±9.5 years, mean DAPSA 30.8±32.4), mean PGA was higher than mean PhGA with a mean absolute difference of 1.9±1.8 points. Discordance defined by |PGA-PhGA|≥3 points concerned 134 (29.1%) patients and 115 (85.8% of patients with discordance) had PGA>PhGA. Higher fatigue (β=0.14), lower self-perceived coping (β=0.23) and impaired social participation (β=0.16) were independently associated with a higher difference (PGA-PhGA). The sensitivity analysis using |PGA-PhGA|≥3 as outcome shows that coping (OR=1.34, impaired social participation (OR=1.28) and depressive affects (OR=1.18) were related with discordance. According to DAPSA, more patients with discordance were in remission (30.8%) compared to high disease activity (26.1%).

Conclusion: Discordance concerned 29.1% of these PsA patients, which is less frequent than in rheumatoid arthritis (around 43%). Mean PGA was higher than mean PhGA. Factors associated with discordance were psychological rather than physical domains of health. Unlike most published articles on patient-physician discordance in RA, pain was not a predictive factor in this study, perhaps due to links with other outcomes. The patient's ability to self-manage seems to be important. Discordance was more frequent in patients in remission, indicating the meaning of remission should be further explored in PsA.

Session Date: Wednesday, November 16, 2016
Session Title: Epidemiology and Public Health III: Psoriatic Arthritis and More
Session Type: ACR Concurrent Abstract Session
Session Time: 11:00AM-12:30PM

Background/Purpose: Psoriatic arthritis (PsA), a chronic inflammatory joint disorder typically affecting individuals with psoriasis of the skin, is associated with severe comorbidities, reduced quality of life, and increased work disability. Our study is the first to comprehensively examine PsA's comorbidties, healthcare and public transfer (allowance) costs.

Methods: A total of 10,525 PsA patients and 20,777 matched general population comparator (GPC) subjects were included in this nationwide cohort study, using data from Danish registries from January 1998 through December 2014. Societal costs, employment status, and occurrence of comorbidities in patients with PsA both before and after diagnosis were compared to GPC subjects matched on age, sex, time, and marital status.

Results: Median age of PsA patients and general population comparator subjects at study entry was 52 years (interquartile range 40 to 60 years), 41% were male. At baseline, PsA patients had significantly more comorbidities, including neoplasms (OR 1.25 95% CI 1.11 to 1.41), cardiovascular disease (OR 1.70 95% CI 1.55 to 1.86), respiratory diseases (OR 1.73 95% CI 1.54 to 1.96), infectious diseases (OR 2.03 95% CI 1.69 to 2.42), and haematological diseases (OR 1.94 95% CI 1.55 to 2.43) compared to GPC subjects. At all time-points, PsA patients had higher total healthcare costs (Figure) and public transfer costs; they also had lower income ($p<0.001$) and incurred a net average increased societal cost of 12,024 USD per patient year compared to GPC subjects following diagnosis. The relative risk (RR) for being on disability pension five years prior to PsA diagnosis was 1.36 (95% CI 1.24 to 1.49) compared to GPC subjects. The RR increased to 1.60 (95% CI 1.49 to 1.72) at the time of diagnosis and was 2.69 (95% CI 2.40 to 3.02) 10 years after diagnosis, where 21.8% of the PsA patients received disability pension.

Conclusion: The study not only demonstrates increased healthcare costs, lower income, higher unemployment rates, higher risk for disability pension, but also more comorbidities for PsA patients compared to the general population in the period prior to diagnosis. The study also clearly demonstrates attenuated socioeconomic burden as well as increased comorbidities in the years following a PsA diagnosis. **Figure**

SESSION INFORMATION
Session Date: Wednesday, November 16, 2016
Session Title: Epidemiology and Public Health III: Psoriatic Arthritis and More
Session Type: ACR Concurrent Abstract Session
Session Time: 11:00AM-12:30PM

Background/Purpose: It is speculated that gout is a risk factor for kidney disease progression. The aim of this study was to evaluate the association of gout with progression to advanced chronic kidney disease (CKD) in a national study.

Methods: This cohort study used primary care data from the UK Clinical Practice Research Datalink linked to national data on hospitalisation and mortality. From 1/01/2000 to 31/03/2013, each adult case of gout (≥18 years), based on clinical diagnosis or treatment with a urate lowering agent, was matched with up to 10 controls without gout on age, sex, and registered clinical practice. The median follow-up was 3.68 years (interquartile range 1.65-7.04 years). The incidence of advanced CKD (a composite outcome defined as progression to dialysis, kidney transplant, diagnosis of CKD stage 5 or eGFR < 10ml/min, death with CKD, or doubling of the serum creatinine) was estimated and relative risk of advanced CKD was compared in 68,897 gout patients and 554,964 matched controls. Multivariable Cox regression using marginal structural models and propensity-matching methods estimated hazard ratios (HRs) and 95% confidence intervals (CI) for the rate of advanced CKD. Analyses were adjusted for baseline demographic characteristics, 12 individual medical conditions including mild-moderate kidney disease, Charlston comorbidity index, lifestyle factors (drug use and alcohol use), socioeconomic status (Townsend score) and medication use (defined as treatment with NSAID, oral corticosteroid, angiotensin receptor blocker, angiotensin converting enzyme inhibitor, thiazide diuretic, other diuretic, statin, or aspirin).

Results: Accounting for baseline differences, patients with gout experienced significantly higher risk of advanced CKD (HR 1.29, 95 % CI (1.23-1.35) compared with those without gout (HR, 1.00 referent group). The findings were similar in the propensity-matched analysis (HR 1.23, 95% CI 1.17-1.29).

	Gout Cases (n=68,897)	95% CI	**Controls** (n=554,964)	95% CI
Incidence rate of advanced CKD per 1000 person-years	8.54	(8.26-8.83)	4.08	(4.00-4.16)
Incidence rate ratio	2.10	(2.07-2.12)	1.00 (reference)	
Adjusted hazard ratio (64,726 cases vs 489,842 controls)	1.29*	(1.23-1.35)	1.00 (reference)	
	Propensity-matched Gout Cases (n=64,420)		**Propensity-matched Controls** (n=286,110)	
Incidence rate of advanced CKD per 1000 person-years	7.58	(7.30-7.86)	4.43	(4.32-4.55)
Incidence rate ratio	1.71	(1.69-1.73)	1.00 (reference)	
Adjusted hazard ratio (60,339 cases vs 259,815 controls)	1.23*	(1.17-1.29)	1.00 (reference)	

*P < 0.001 for all

Conclusion: Gout is associated with an elevated risk of progression to advanced CKD. Future studies should investigate whether control of gout is protective and reduces future CKD risk.

Patient Perceptions of Glucocorticoid Side Effects: A Survey of Users in an Online Health Community

Ruth Costello[1], Rikesh Patel[1], Jennifer Humphreys[1], John McBeth[1] and William G Dixon[2], [1]Manchester Academic Health Science Centre, Arthritis Research UK Centre for Epidemiology, The University of Manchester, Manchester, United Kingdom, [2]Manchester Academic Health Sciences Centre, Arthritis Research UK Centre for Epidemiology, The University of Manchester, Manchester, United Kingdom

First publication: September 28, 2016

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016

Session Title: Epidemiology and Public Health III: Psoriatic Arthritis and More
Session Type: ACR Concurrent Abstract Session
Session Time: 11:00AM-12:30PM

Background/Purpose: Glucocorticoids (GC) are widely used to treat inflammatory diseases, but are known to have many side effects. Patients' perspectives of side effects are known to influence treatment decisions and adherence, yet few studies have investigated which side effects are important to patients. The aim of this study was to identify the side effects most important to GC users through a survey of a UK online health community (healthunlocked.com).

Methods: A short survey about GC use popped up when UK users viewed posts discussing steroids on healthunlocked.com. Responders were eligible if they were currently taking, or had taken GCs within the last month. Within the survey, responders had to score the importance of listed side effects from 1 to 10, with 10 being of high importance to them. The side effects shown in table 1 were listed alphabetically, with examples or descriptions as required. For each side effect, histograms were plotted, and the median rating and inter-quartile range (IQR) was determined. Side effects were ranked by median ranking (largest to smallest) and then IQR (smallest to largest) for those with the same median. The scores were categorised as low (scores 1-3), medium (scores 4-7) and high (scores 8-10) importance.

Results: There were 604 responders who completed the survey. The majority were over 50 years old (81%) and female (86%). Histograms of side effect scores showed a skew towards high importance for weight gain, a U-shaped distribution for CVD, diabetes, eye disease and infections, and a skew towards low importance for acne (Figure 1). When ranked the side effect of most importance to responders was weight gain (median score=9, IQR 6, 10) followed by insomnia and moon face with equal median score (8) and IQR (5, 10). Several side effects had the same median score of 8, but distribution across categories varied. Three clinically serious side effects: cardiovascular disease, diabetes and infection, were ranked of lower importance but had wide ranging scores (median score=8, IQR 1, 10). Acne was of least importance to responders (median score=1, IQR 1, 6) (Table 1).

Conclusion: The three most highly rated side effects were not clinically serious but remained important to patients, perhaps reflecting their impact on quality of life and their high prevalence. The importance of these less serious but potentially high impact side effects should be taken into consideration when discussing treatment options and planning future GC safety studies. Table 1: Median, inter-quartile range, rank and categories of side effect scores.

Side effect	Median(IQR)	Rank	Low (score 1-3) N (%)	Medium (score 4-7) N (%)	High (scores 8-10) N (%)
Weight gain	9 (6, 10)	1	74 (12.3)	145 (24)	385 (63.7)
Insomnia	8 (5, 10)	2	75 (12.4)	210 (34.8)	319 (52.8)
Moon face	8 (5, 10)	2	125 (20.7)	149 (24.7)	330 (54.6)
High blood pressure	8 (4, 10)	4	150 (24.8)	138 (22.8)	316 (52.3)
Reduced bone strength	8 (4, 10)	4	133 (22)	134 (22.2)	337 (55.8)
Eye disease	8 (3, 10)	6	164 (27.2)	93 (15.4)	347 (57.5)
Cardiovascular disease	8 (1, 10)	7	216 (35.8)	56 (9.3)	332 (55)
Diabetes	8 (1, 10)	7	206 (34.1)	86 (14.2)	312 (51.7)

Epidemiology of Polymyalgia Rheumatica 2000-2014: A Population Based Study

Shafay Raheel[1], Cynthia S. Crowson[2] and Eric L. Matteson[1], [1]Rheumatology, Mayo Clinic, Rochester, MN, [2]Health Sciences Research, Mayo Clinic, Rochester, MN

First publication: September 28, 2016

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016

Session Title: Epidemiology and Public Health III: Psoriatic Arthritis and More

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: To determine time trends in the incidence and survival analysis of polymyalgia rheumatica (PMR) over a 15 year period in a geographically defined population and to descriptively compare the incidence of PMR in this time period to a previous incidence cohort from the same population base.

Methods: In a geographically defined population, we retrospectively identified all incident cases of PMR between January 1, 2000, and December 31, 2014. Detailed review of all individual medical records was performed. All but 4 of these cases (who were age<50 years) fulfilled EULAR/ACR classification criteria for PMR. Incidence rates were age and sex adjusted to the US white 2010 population and were graphically illustrated using 3 year centered moving averages. Survival rates were computed using Kaplan-Meier methods and were compared with the expected rates in the population of the US State.

Results: There were 407 incident cases of PMR during the 15 year study period. Of these 64% were female and the mean age at incidence was 73.9 years. The overall age and sex adjusted annual incidence of PMR was 68.3 (95% confidence interval [CI] 61.6, 75) per 100,000 population aged ≥50 years. Incidence rates increased with age in both sexes, but incidence fell after age 80 years among women. The incidence rates fluctuated over the period of observation (Figure) with evenly spaced peaks in 1970, 1990 and 2005. Comparing the two time periods, there was a significant increase in incidence of PMR in the recent time period compared to 1970-1999 (age and sex adjusted rate: 55.8 per 100,000; p=0.011). During median follow-up of 6.4 years, 120 patients died. Mortality among individuals with PMR was not significantly worse than that expected in the general population (standardized mortality ratio: 0.73; 95% CI: 0.60, 0.87).

Conclusion: The incidence of PMR has increased slightly in the past 15 years compared to previous decades. Survival among patients with PMR is not worse than the general population. Further research is needed to understand the determinants of the increase in incidence of PMR.

Session Date: Wednesday, November 16, 2016

Session Title: Health Services Research II

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose : We have recently found that myocardial infarction (MI) risk was similar among age- and sex-matched SLE patients compared to diabetes mellitus (DM) patients within a U.S. Medicaid cohort. However, little is known about rates and relative risks of coronary revascularization (CR) procedures, such as coronary artery bypass grafting (CABG) and percutaneous coronary interventions (PCI), among SLE compared to DM patients. We compared rates and relative risks of CR procedures among patients with SLE and DM enrolled in Medicaid.

Methods : We utilized Medicaid Analytic eXtract (MAX) data, containing billing claims for Medicaid patients from 29 most populated U.S. states from 2007-2010. We identified adults aged ≥18-65 years with prevalent SLE or DM (≥3 ICD-9 codes for SLE or DM, each separated by ≥30 days) and >6 months enrollment prior to 3rd code (=index date). We performed 1:2 matching (SLE:DM) by age (month/year), sex, and index date. Sociodemographic data and medical and cardiac comorbidities were collected during the baseline period (6 months prior to and including index date). Outcomes were assessed after index date, including CABG, PCI, and combined CABG or PCI. Subjects were followed to first procedure, death, Medicaid disenrollment, or end of follow-up. We used Cox sub-distribution regression models to calculate hazard ratios (HR_{SD}) of undergoing CR procedures, accounting for the competing risk of death and adjusting for sociodemographics and cardiac and medical comorbidities.

Results : 32,089 prevalent SLE patients were matched to 64,178 prevalent DM patients. In both cohorts, 92.8% were female and mean age was 41.3 (±12.1) years. There were more Blacks (41.1 vs. 30.5%) and fewer Whites (36.3 vs 45.1%) in the SLE vs. DM cohort. Mean follow-up was 1.67 (±1.03) years for SLE and 1.79 (±1.07) years for DM. Cardiac risk factors at baseline were more prevalent among DM vs. SLE patients: hypertension (38.0 vs. 33.7%), hyperlipidemia (22.5 vs. 10.6%), and obesity (11 vs. 4.5%). PCI rates were nearly 10-fold those of CABG rates in each cohort (**Table**). Annual rates of CABG and PCI were much higher among SLE than DM patients. Age- and sex-adjusted risks of CR procedures, particularly CABG, were higher among SLE than DM patients. Multivariable adjustment attenuated relative risks slightly. The multivariable-adjusted HR_{SD} for CABG was 1.83 (95%CI 1.48-2.25) and for PCI was 1.23 (95%CI 1.15-1.31) in SLE vs. matched DM patients.

Conclusion : Despite similar MI risks among SLE and DM patients, SLE patients had substantially higher rates of PCI and CABG compared to age- and sex-matched DM patients. SLE patients had > 80% increased risk of CABG compared to DM patients. While the etiology of these differences is not clear, they suggest that underlying cardiovascular disease may more severe or more likely to come to medical attention among SLE than similar age and sex DM patients.

SESSION INFORMATION
Session Date: Wednesday, November 16, 2016
Session Title: Health Services Research II
Session Type: ACR Concurrent Abstract Session
Session Time: 11:00AM-12:30PM

Background/Purpose: To evaluate whether meteorological parameters influence pain and disease activity in patients with rheumatoid arthritis (RA).

Methods: We assessed correlations between individual meteorological variables and clinical measures of disease activity: clinical disease activity index (CDAI), self-reported pain (by visual analogue scale), tender- and swollen 28 joint counts (TJC and SJC) and patient global assessment (PGA). Assessments documented in our RA database as well as the average temperature and relative humidity, obtained from the Central Institute for Meteorology and Geodynamics, were matched on a daily basis for a period of 10 years between 2005 and 2015, and analyzed using generalized estimating equations (longitudinal data analysis). On average, an individual patient would have 3-monthly visits throughout this observation time.

Results: A total of 1437 patients with RA (average disease duration at first visit: 4.88±8.63 years; 77% female, mean CDAI 17.8±11.7,) were analyzed. Higher temperature and lower humidity were significantly associated with lower CDAI (p=0.0002, and p=0.0332, respectively). Both, temperature and humidity were significantly associated with pain (p=0.0076), PGA (p=0.0011), and SJC (p=0.0187). Temperature and humidity showed an interaction on pain: lower temperatures were associated with higher pain levels at the lower quartiles of humidity; in contrast, lower temperature corresponded to lower pain levels at the highest quartile of humidity (Figure 1).

Conclusion: In this largest association study of meteorological parameters with RA specific outcomes both temperature and relative humidity were shown to have significant effects on disease activity. Individual measures of disease activity and pain correlated either with temperature or humidity, while the composite CDAI measure correlated with both meteorological variables. These data are confirmatory of the influence of the climate environment on outcomes of an inflammatory disease.

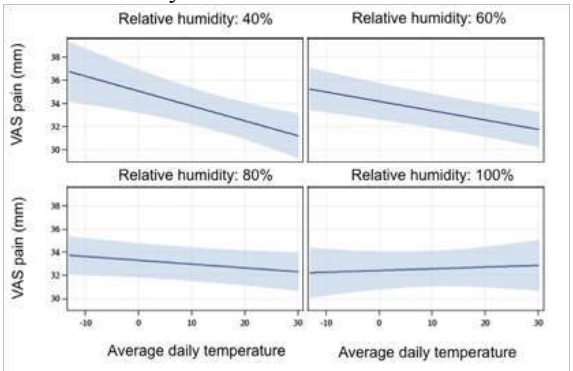

Figure 1. Effects of temperature on pain under different levels of humidity

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016

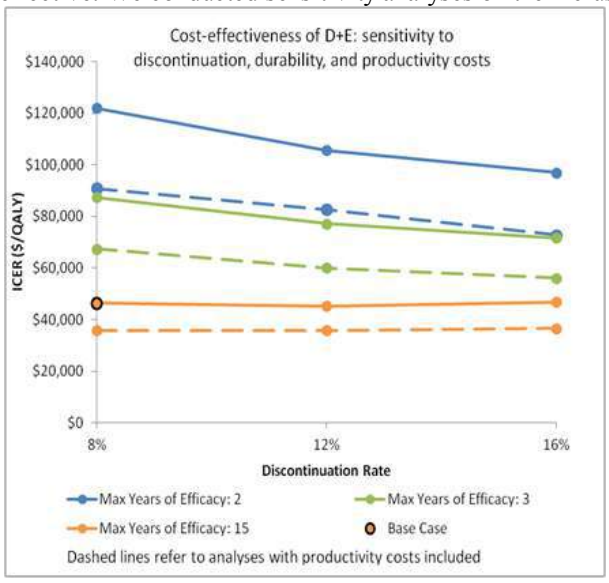
Session Title: Health Services Research II

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: About 50% of persons with knee OA are obese. Quality-adjusted life-year losses due to knee OA and obesity exceed 3.5 per person. The results of the Intensive Diet and Exercise for Arthritis (IDEA) trial showed that an intensive diet and exercise (D+E) program, consisting of meal replacements and group exercise sessions led by a professional exercise interventionist, led to a mean 10.6 kg weight reduction and 50% reduction in pain over 18 months. We sought to determine the cost-effectiveness of the D+E program in overweight and obese (BMI>27 kg/m^2) OA patients.

Methods: We combined the data from the IDEA trial with the Osteoarthritis Policy (OAPol) Model, a validated computer simulation of knee OA, to evaluate long-term clinical and economic outcomes in knee OA patients similar to those enrolled in the IDEA trial. Mean age was 66, average WOMAC score 32 (0-100, 100 worst) and average BMI 33.6 kg/m^2. We evaluated the cost-effectiveness of adding a D+E regimen to clinical management consisting of intermittent analgesia until patients are eligible and willing to have TKR. D+E efficacy and sustainability over 18 months were derived from IDEA and assessed on two domains: BMI reduction and pain reduction. 29% of subjects in D+E arm of IDEA trial had a BMI reduction between 5-10% and 8% reached a reduction of 20-25%. The discontinuation rate was estimated at 8% per year. Annual costs for the D+E regimen included costs of program ($328 in year 1, $281 in subsequent years), meal replacements during the first six months ($790) and a hypothetical (the trial subjects did not have to pay for it) gym membership ($600/year). The base-case analysis assumed maximum duration of efficacy to be 15 years. We adopted a modified societal perspective (without productivity costs), discounted outcomes at 3%/year, and assumed a willingness to pay (WTP) threshold of $100,000 per quality adjusted life year (QALY). Strategies with incremental cost-effectiveness ratios (ICERs) below WTP were considered cost-effective. We conducted sensitivity analyses on the inclusion of productivity costs, duration of efficacy and discontinuation rates.



Results: In the base case, those who were offered the D+E regimen spent 7.4 years on the regimen, on average. They spent 2.9 years with at least 5% BMI reduction. The D+E regimen led to 12.4 quality-adjusted years of life gained per every 100 participants, resulting in an incremental cost-effectiveness ratio of $46,300/QALY. Inclusion of productivity costs decreased the ICER for the D+E regimen to $35,800. Reducing the duration of efficacy to 3 years increased the ICER for the D+E regimen to $87,400/QALY when productivity costs were not included ($67,500/QALY with productivity costs). (Figure)

Conclusion: Adding D+E to clinical management of overweight and obese patients with knee OA is cost-effective. Implementation of D+E into care of OA patients should be a public health priority.

Session Date: Wednesday, November 16, 2016

Session Title: Health Services Research II

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: Rheumatologists have many choices of medications to use for patients with rheumatoid arthritis (RA), but patients may not fill a prescription (primary non-adherence or PnA). Even for those who do initiate therapy, they may discontinue treatment shortly thereafter (secondary non-adherence or SnA). The factors that underlie never starting on therapy as distinct from early discontinuation are likely to be different but have not been well characterized. This study investigated predictors of PnA and SnA to to methotrexate (MTX), biologics/tofacitinib (B/T) in RA patients.

Methods: A retrospective cohort analysis was conducted using a U.S. integrated claims and electronic health records (EHR) database. Patients were required to have a new prescription or treatment of MTX or B/T (index event) (12+ month clean period) with >=2 RA physician diagnoses (714.0, 714.2, or 714.81), no other autoimmune diseases or cancer before index, and continuous pharmacy and medical insurance coverage and EHR data availability before and after index. PnA was defined as a new written prescription of MTX or B/T (EHR data) not initiated within 90 days (linked pharmacy claims data). SnA was defined using only pharmacy data as treatment discontinuation (a gap >=90 days) within 12 months of initiation. Potential predictors (n=414 from EHR and claims data) were selected based on clinical judgment and included in separate lasso-regularized logistic regression.

Results: Of 1,117 and 744 patients with a new written prescription, 24% (MTX) and 27% (B/T) failed to initiate them. For those who started on treatment 12-month discontinuation rate was 50% for MTX and 40% for B/T. For PnA, multiple baseline treatment-based comorbidity markers positively and diagnosis-based comorbidity markers negatively impacted MTX primary adherence, whereas for B/T almost no comorbidity markers were significant. Model discrimination was good (AUC=0.81 for MTX, 0.71 for B/T). For SnA, some psychosocial issues such as depression and anxiety were associated with MTX discontinuation. For B/T, infection-related conditions at baseline were associated with discontinuation (Tables 1 and 2).

Conclusion: Using novel linked EHR and pharmacy data, approximately 25% of new prescriptions for MTX, biologics or tofacitinib were not filled by patients within 90 days. Different factors were related to primary nonadherence (never filling first Rx) vs. secondary non-adherence (early discontinuation), implying the need for different interventions to improve adherence to MTX and B/T, both at the time of first fill and over time. SESSION INFORMATION

Session Date: Wednesday, November 16, 2016

Session Title: Health Services Research II

Session Type: ACR Concurrent Abstract Session

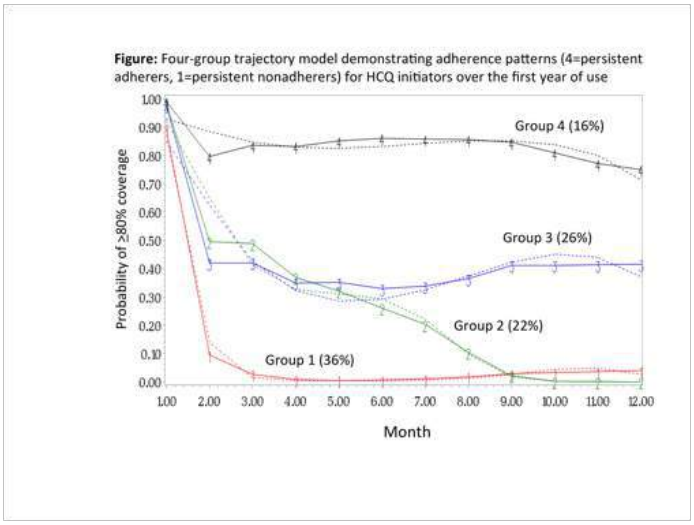
Session Time: 11:00AM-12:30PM

Background/Purpose: Hydroxychloroquine (HCQ) is the standard of care medication for most SLE patients, however cross-sectional studies suggest that nonadherence is common. Similar to the fluctuating nature of SLE, we hypothesized that adherence is dynamic and composite measures might not capture the nuances of medication use over time. We used a novel method, group-based trajectory modeling (GBTM), to investigate longitudinal patterns of nonadherence to newly prescribed HCQ, and demographic and disease-related predictors, in a U.S. nationwide SLE cohort.

Methods: We used Medicaid data with all claims and pharmacy data for beneficiaries in most states (2000-10), to identify adults 18-65 years with prevalent SLE. We restricted our cohort to new users of HCQ (≥6 months without HCQ use), and required ≥1 year of follow-up after first dispensing (index date). Predictors were collected in the 6 months pre-index date. The proportion of days covered (PDC) was used to describe overall 12-month adherence (<80%=nonadherent). We applied GBTM to examine patterns of monthly HCQ nonadherence (<80% of days/month covered), during the first 12 months post-index date. GBTM fit was assessed using Bayesian Information Criterion (BIC) and posterior probabilities. We used multivariable multinomial logistic regression models to examine predictors of nonadherence trajectories.

Results: We identified 10,900 HCQ new users with SLE. Mean age was 38 (±12) years, 94% were female, 43% black, 31% white, 19% Hispanic; 85% had a mean PDC <80%. The 4-trajectory group model had the lowest BIC and posterior probabilities >80%, suggesting the best fit (**Figure**); 36% were persistent nonadherers (group 1), 16% were persistent adherers (group 4). At 6 months, intermediate nonadherence trajectories diverged. Group 3 plateaued and group 2 declined; group 2 had fewer outpatient visits at 6 months vs. group 3 ($p<0.001$). Using multinomial regression, compared to adherers (group 4), the odds of nonadherence were increased for groups 1-3 for blacks and Hispanics vs. whites and for younger ages vs. older (**Table**). Increased SLE-related comorbidities (SLE risk adjustment index), was associated with reduced odds of nonadherence for groups 1 and 2, but not for 3.

Conclusion: Rates of HCQ nonadherence were extremely high and distinct patterns were uncovered. While younger age and black and Hispanic race/ethnicity increased odds of nonadherence overall, other predictors differed by nonadherence pattern. Six months was a critical juncture for intermediate nonadherers and utilization patterns suggest that improved access to outpatient care at this



point may improve long-term HCQ adherence.

Session Title: Health Services Research II

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: The retrieval of rheumatoid arthritis (RA) disease activity measures recorded in an electronic medical record through natural language processing (NLP) would significantly aid RA management and epidemiologic research. The Veterans Affairs Rheumatoid Arthritis (VARA) registry participants routinely collects disease activity measures including the 28 joint disease activity score (DAS28) at each site and enters these data into a VARA database. Each site uses independent methods for documenting clinical notes and placing these data into the VARA database using manual extraction (ManEx). The purpose of this work was to develop NLP code to automatically identify relevant notes and extract clinical measures of RA disease activity and determined the accuracy of the NLP in comparison to the ManEx system at three VARA sties.

Methods: All clinical notes for VARA enrollees at three VARA sites between January 1, 2015 and September 30, 2015 that contained one clinical component of the DAS 28 - tender joint count (TJC), swollen joint count (SJC), or patient global assessment (PtGA) identified by either ManEx in the VARA database or in an NLP note - were evaluated. Any ESR within two weeks before and after the clinic visit was identified and the value closest to the clinic visit combined with TJC, SJC, and PtGA to calculate DAS28. For each event/note the JTC, JSC, PtGA, and ESR was evaluated and classified as follows: correct by NLP and ManEx, correct by ManEx only, correct by NLP only, or missing data by both methods. During the same observation period, observations that allowed calculations of DAS28 (all four elements collected) were also identified. Any discrepancies between ManEx and NLP were resolved by investigator review of the clinic notes.

Results: There were 1273 notes identified on 474 patients at the three VARA sites with the percent of DAS28 elements identified by the two methods as noted in the table. Reasons for the ManEx and NLP not identifying clinical elements varied by the specific element detected but generally fell into the following categories. Reason for ManEx or NLP failure may have occurred more than once for each note. Errors for ManEx were note not identified for data extraction (basically missed by reviewer doing ManEx) (N=133, 10.4 %), and data entry errors by the ManEx reviewer (N=170, 13.6%). Reasons for NLP failure were: wrong template selected for rheumatology note (N=91, 7.1%), modified template during clinic visit(N=6, 0.4%), prose instead of numeric values entered into the template (N=5, 0.4%), and no note in the VA corporate data warehouse (electronic note source) (N=72, 5.7%) .

Conclusion: This NLP system can extract DAS28 from notes from three distinct VARA sites to aid in clinical care and research activities. Future efforts will emphasize the standardization of data collection to better support using NLP methods for more efficient and reliable collection of clinical outcomes in RA and the dissemination and evaluation of the methodology at other sites using similar electronic medical record systems.

Correct Detection of Components of Disease Activity by NLP & ManEx, ManEx only, NLP only, or neither NLP or ManEx

		Site #1 (n=439)	Site #2 (n=376)	Site #3 (n=458)	Total (n=1273)

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016

Session Title: Imaging of Rheumatic Diseases III: Crystal Arthritis, Osteoarthritis, Connective Tissue Disease and Vasculitis

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: By a Delphi process, the OMERACT Ultrasound (US) large vessel vasculitis task force has recently defined the US appearance of normal temporal arteries (TA) and normal extra-cranial large arteries (i.e. axillary arteries, AA), as well as the key elementary US-detected lesions in -giant cell arteritis (GCA) (i.e.:“halo sign” and “compression sign”; Table 1). The aim of the present study was to assess the reliability of those definitions on still images and videos in a web-based reliability exercise.

Methods: The reliability exercise was performed using a REDCap web application.One-hundred-fifty anonymized images/videos, provided by the members of the task force, were assessed: 20 videos and 20 still images of AA and 45 videos and 45 still images of TA with either no abnormality or the presence of a halo sign, and 20 videos of TA with either a positive or negative compression sign. The task force members (n26) were asked to rate all images and videos for normality/abnormality applying the definitions agreed upon in the previous Delphi exercise. In order to assess the intra-observer reliability the study was repeated two weeks later using the same images/videos presented in a different order. Cohen’s and Light’s κ were used for evaluating intra- and inter-reader reliability, respectively. K values 0–0.2 were considered slight, 0.2–0.4 fair, 0.4–0.6 moderate, 0.6–0.8 substantial and 0.8–1 excellent.

Results: The response rate was 25/26 (96%) in round 1 and 25/25 (100%) in round 2. The reliability of the 25 participants was excellent with mean inter-rater agreements over 90%, mean Lights's kappa values of >0.8 for inter-rater reliability (Table 2) and mean Cohen kappa values of 0.83-0.98 for intra-rater reliability.

Conclusion: Inter- and intra-observer agreement on the evaluation of US still images and videos from normal and vasculitis patients was excellent applying the new OMERACT definitions for key elementary US lesions for GCA. Further exercises are planned in order to test the reliability in patients with large vessel vasculitis. Table 1

Vessel	Definition of US appearance of normal arteries	Definition of US appearance of vasculitis – "halo sign"	Definition of US appearance of vasculitis - compression sign
Temporal Arteries	Pulsating, compressible artery with anechoic lumen surrounded by mid- to hyperechoic tissue. Using US equipment with high resolution, the intima-media complex presenting as a homogenous, hypo- or anechoic echostructure delineated by two parallel hyperechoic margins ("double line pattern") may be visible.	Homogenous, hypoechoic wall thickening, well delineated towards the luminal side, visible both, in longitudinal and transverse planes, most commonly concentric in transverse scans.	The thickened arterial wall remains visible upon compression, i.e. the echogenicity contrasts hypoechoic due to vasculitic vessel wall thickening in comparison to the mid- to hyperechoic surrounding tissue.
Axillary Arteries	Pulsating, hardly compressible artery with anechoic lumen; the intima-media complex presents as a homogenous, hypo- or anechoic echostructure delineated by two parallel hyperechoic margins ("double line pattern"), which is surrounded by mid- to hyperechoic tissue.	Same as for temporal arteries	The definition is not used for the axillary arteries

Table 2

Section	Mean agreement	mean Light's κ
Halo (all images & videos)	94%	0.89
Halo (images)	98%	0.95
Halo (videos)	92%	0.84
Halo temporal arteries (images & videos)	94%	0.87
Halo temporal arteries (images)	97%	0.94
Halo temporal arteries (videos)	91%	0.83
Halo axillary arteries (images & videos)	97%	0.93
Halo axillary arteries (images)	99%	0.98
Halo axillary arteries (videos)	94%	0.88
Compression sign (videos)	92%	0.83

Session Title: Imaging of Rheumatic Diseases III: Crystal Arthritis, Osteoarthritis, Connective Tissue Disease and Vasculitis

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: ultrasonography (US) has been implemented recently as a possible diagnostic method for CPPD[1]. However, data on the reliability of US in CPPD diagnosis are lacking. Aim of the study was to assess the inter-reader and intra-reader reliability of US on detecting CPP deposition in fibrocartilage(FC), hyaline cartilage (HC), tendons (T) and synovial fluid (SF)

Methods: the OMERACT “US in CPPD” group defined firstly the US CPPD identification criteria following the methods adopted by OMERACT and described at the OMERACT handbook (http://www.omeract.org/omeract_publications.html). After a systematic literature review and a Delphi survey the set of US criteria for identification of CPPD by were defined (table 1).

Structure	Shape	Echogenicity	Localization	Behavior at Dynamic scanning
Fibrocartilage	deposits of variable shape	hyperechoic (similar to the bone cortex)	localized within the fibrocartilage structure	remain fixed and move together with the fibrocartilage during dynamic assessment (i.e. joint movement and probe compression).
Hyaline cartilage	deposits varying in size and shape	hyperechoic (similar to the bone cortex echogenicity) that do not create posterior shadowing	Localized within the hyaline cartilage	the deposits remain fixed and move together with the hyaline cartilage (i.e. joint movement and probe compression)
Tendon	multiple, linear (parallel to the tendon fibrillar structure and not in continuity with the bone profile) deposits	Hyperechoic (in relation to the tendon echogenicity), that generally not create posterior shadowing. The deposits maintain their high degree of echogenicity even at very low levels of gain and are not affected by anisotropy as the surrounding tendon.	Localized within the tendon	remain fixed and move together with the tendon during movement and probe compression.
Synovial fluid	deposits of variable size (from punctuate to large)	hyperechoic (similar to the bone cortex echogenicity), that generally not create posterior shadowing.	Localized within the synovial fluid	are mobile according to joint movement and probe pressure.

Subsequently, a two steps procedure for the assessment of the reliability has been followed. Firstly, the panel gave a dichotomous score on the presence absence of CPPD in 150 photos of FC, HC, T and SF equally distributed, on a web based platform. The assessment has been carried out twice in order to calculate both inter and intra-reader reliability. In the second step, the experts met for a real life-patient based assessment of CPPD in a workshop organised in Siena-Italy. In that occasion, FC/HC/T/SF of the right knee and FC and SF of the right wrist of 8 patients were assessed twice in a day by all experts giving again a dichotomous score for CPPD. 8 US scanners (ESAOTE mylab seven) equipped with the same probe and the same preset (made ad hoc before the meeting), have been used for the workshop.

Results: Reliability values of the web based exercise and of the workshop are presented in table 2. Tendons and synovial fluid analysis did not reach sufficient strength of agreement neither on the web based nor in the patient based exercise regarding the inter-reader kappa and independently of the site. However, in the static exercise, both tendons and SF reached a good intra-reader reliability meaning that scanning technique of these structures is very important for CPPD identification. On the other hand, menisci (but not triangular FC of the wrist) and HC reached good kappa values for inter-reader and intra-reader agreement both on static and web-based exercise.

Section	K inter-reader I round	K inter-reader II round	K intra-reader
	WEB based exercise		
Fibrocartilage	0.58	0.58	**0.80**
Hyaline Cartilage	**0.73**	**0.73**	**0.85**
Tendons	0.28	0.31	**0.64**
Synovial Fluid	0.50	0.47	**0.76**
	Patient based workshop		
ALL	0.44	0.45	**0.63**
- Knee	0.47	0.52	**0.65**
--- Menisci	**0.65**	**0.64**	**0.73**
----- Medial Meniscus	**0.72**	**0.74**	**0.78**
----- Lateral Meniscus	0.57	0.48	**0.70**
--- Synovial Fluid	0.09	0.12	0.41
--- Tendon	0.25	0.3	0.44
----- Quadriceps Tendon	0.13	0.19	0.28
----- Proximal Patellar Tendon	0.09	0.19	0.47
----- Distal Patellar Tendon	0.31	0.25	0.44
--- Hyaline Cartilage	0.58	0.55	**0.68**
- Wrist	0.31	0.2	0.50
--- Triangular fibrocartilage	0.27	0.15	0.47
--- Synovial Fluid	0.15	0.1	0.36

Strength of agreement: < 0.20 Poor, 0.21 - 0.40 Fair, 0.41 - 0.60 Moderate, 0.61 - 0.80 Good, 0.81 - 1.00 Very good

Conclusion: Knee cartilage and fibrocartilage structures resulted to be reliable enough for identification of CPPD. On the other hand, CPPD identification in tendons and synovial fluid is challenging and the actual OMERACT criteria for these sites do not ensure a safe classification of patients. OMERACT US criteria for CPPD identification in knee menisci and HC allow a reliable classification of patients and should be used when CPPD is suspected. References:

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016

Session Title: Imaging of Rheumatic Diseases III: Crystal Arthritis, Osteoarthritis, Connective Tissue Disease and Vasculitis

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: Imaging and pathology studies have shown that bone erosion is closely associated with monosodium urate (MSU) crystal deposition in tophaceous gout. It is currently unknown whether bone erosion in gout occurs through an inside-out mechanism with direct intra-osseous crystal deposition, or through an outside-in mechanism, whereby crystals deposit on the surface of articular cartilage surface or within synovium and then interact with bone to promote erosion. The aim of this study was to analyse the relationship between bone and MSU crystal deposition using dual energy computed tomography (DECT) in people with tophaceous gout.

Methods: One hundred and forty four participants were recruited from rheumatology clinics. All participants had gout according to the 1977 American Rheumatism Association classification criteria and at least one palpable tophus. DECT scans of both feet were performed on a dual X-ray tube 128 detector row scanner. Two readers independently scored all metatarsal heads (1433 bones available for scoring). Each site was initially scored for the presence or absence of urate deposition within the joint. If urate was present within the joint, the presence of urate in contact with bone was then scored. For bones in contact with urate, the site was then scored for whether urate was present within an erosion, on the surface of bone or within bone only (true intra-osseous deposit). In the case of reader disagreement, agreement was reached in a consensus re-scoring exercise. Pre-consensus inter-reader kappa for all scoring was >0.93. Differences between the location of urate deposits in each and all metatarsal heads were modelled taking into account clustering of results within individuals by general estimating equations using the GENMOD procedure of SAS v9.4.

Results: Urate deposition in the joint was present in 681/1433 (47.5%) sites. Urate in contact with bone was present in 370/681 (54.3%) joints with urate deposition. For those bones in contact with urate, deposition was present on the surface of bone in 143/370 (39%, 95% CI 34, 44%) and within erosion in 227/370 (61%, 95% CI 56, 66%). True intra-osseous urate deposition was not observed at any site (0%, 95% CI 0, 1%), GENMOD P<0.0001. For all bones with apparent intra-osseous deposition in one plane, examination in other planes demonstrated urate deposition within an *en face* erosion (Figure).

Conclusion: In tophaceous gout, MSU crystal deposition is present within the joint, on the bone surface and within bone erosion, but is not observed within bone in the absence of a cortical break. These data support the concept that MSU crystals deposit outside bone and contribute to bone erosion through an outside-in mechanism. **Figure.** Example of apparent metatarsal intra-osseous urate deposit in axial plane, with images in other planes showing urate within an erosion. Urate is colour coded as green and bone as purple.

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016

Session Title: Imaging of Rheumatic Diseases III: Crystal Arthritis, Osteoarthritis, Connective Tissue Disease and Vasculitis

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: A recent randomized clinical trial in erosive osteoarthritis (OA) of finger joints with a TNF blocking agent, adalimumab, showed inhibition of radiographic progression in joints showing inflammatory signs (soft tissue swelling) at baseline (1). We anticipate the use of radio-labelled antibodies can help in identifying their *in vivo* abundance in joints (2) and might help to identify joints at particular risk for progression amenable for target therapies. The purpose of the current study is to investigate the uptake of radiolabeled Certolizumab pegol in patients with erosive OA and study associations with other markers of active disease.

Methods: Certolizumab Pegol was conjugated with S-HYNIC and radiolabeled with ^{99m}Tc. At baseline, static images of both hands of 5 patients with EOA (F/M: 4/1; median disease duration 8.4 years) were acquired at 2 time points (immediately following administration (early phase) and after 4-6 hours post injection (late phase)). All 18 IP finger joints were scored according to the anatomical phase scoring system (3) on hand radiographs. All patients underwent clinical examination (presence of tenderness and swelling) and Gray-scale and Power Doppler (PD) US one day prior to scintigraphy. Immunoscintigraphic findings were independently scored in a semi-quantitative way (uptake: 0 = absent, 1 = weak; 2 = strong). Descriptive statistics on joint level were calculated. Associations between uptake and other signs of disease activity, being presence of tenderness, soft tissue swelling and sonographic activity were calculated by Odds ratios (OR) (with 95% confidence intervals (95% CI)) with absence of tenderness/soft tissue swelling/sonographic activity as reference.

Results: In total, 90 IP joints were studied. Active tracer uptake was seen in 7 joints in early phase (7.8%) (all weak) and in at least 24 joints in late phase (26.7%) (19 weak, 5 strong). Considerably more uptake was present in joints with soft tissue swelling compared to non-swollen joints: in 14 (61.0%) of 23 swollen joints and in 10 (14.9%) of 67 non-swollen joints. Presence of soft tissue swelling is found to be significantly associated with uptake with OR = 8.9 (95% C.I. = 3.0 – 26.0). A trend towards more uptake in tender joints was seen compared to non-tender joints (OR = 2.1 (95% C.I = 0.8 -5.6). Similarly, a trend towards more uptake in sonographic active joints was seen (OR = 1.5 (95% C.I. = 0.5 -4.3)).

Conclusion: This is the first *in vivo* demonstration of TNF abundance in erosive OA. We found strong associations with presence of clinical swelling. The strongest association with TNF was found in the remodeling phases. These data further solidify the rationale for cytokine directed therapies in EOA. References: (1) Verbruggen G. et al. SESSION INFORMATION

Session Date: Wednesday, November 16, 2016

Session Title: Imaging of Rheumatic Diseases III: Crystal Arthritis, Osteoarthritis, Connective Tissue Disease and Vasculitis

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: Salivary gland dysfunction is one of the most common features of Sjögren' syndrome (SS). Sialoscintigraphy (sSC) is the only technique nowadays available to objectify salivary gland dysfunction that provides simultaneous information about type of functional defect, distribution and severity. In recent years its interpretation based mainly on qualitative indices and the appearance of the ACR criteria have shifted in favor of the biopsy (Bp). Some studies have analyzed the role of quantitative scintigraphic indices, mainly excretion fraction (EF%), in the diagnosis of SS, with mixed results. In our study we aimed to describe glandular involvement patterns and EF% values useful in SS diagnosis and to compare diagnostic accuracy of scintigraphic indices and Bp.

Methods: Patients with suspected SS and with sSC and Bp performed between 2006-2012 were included. sSC were performed in a 30 minutes protocol with 99mTc sodium pertechnetate and lemon juice stimulation. Patients already diagnosed of SS and/or with sSC or Bp requested by specialists other than rheumatologists were excluded. Correlations between glandular involvement patterns and EF% and diagnosis of SS were analyzed with Fisher exact test and Kruskal Wallis respectively. Sensitivity, specificity and receiver operating characteristic curve analysis of scintigraphic indices and Bp were performed.

Results: Among 272 patients with sSC performed in that period, 71 fulfilled inclusion criteria. Sixty-eight (96%) were women with a mean age of 52 ± 14 in the timing of sSC. Fifty-seven (80%) reported xerostomia, the majority (39%) with onset in recent months. Qualitative sSC were reported as abnormal in 51 cases (71%); data on age, xerostomia duration, xerostomia related drugs and presence of thyroid disease showed similar frequencies among normal and abnormal sSC groups. Sufficient data to apply American-European Consensus Group and ACR criteria were available in 69 and 48 patients respectively, with diagnosis of SS in 38 (54%). Uptake dysfunction (96 vs 77% p 0.134) and submandibular involvement (59 vs 30% p 0.236) were observed most frecuently in SS patients. All glands showed lower EF% medians in this group, with significant differences for submandibulary ones: right gland 29 (7-37) vs 49 (41-57) p 0.004; left gland 30 (10-45) vs 52 (29-64) p 0.007. Submandibular EF% (right gland AUC 0.793 ± 0.091 p 0.004 IC 95% [0.61-0.97]; left gland AUC 0.764 ± 0.083 p 0.007 IC 95% [0.60-0.93]) showed better diagnostic accuracy than qualitative sSC (AUC 0.601 ± 0.070 p 0.149 IC 95% [0.47-0.74]) and similar to Bp (AUC 0.789 ± 0.055 p 0.000 IC 95% [0.68-0.90]). Cutoff values of 39.5 (right gland) and 47.5 (left gland) of submandibular EF% showed a sensitivity of 95-82% and specificity of 71-67%, compared to 82% and 39% for qualitative sSC, and 58% and 100% for Bp.

Conclusion: 1) Patients fulfilling SS criteria show lower submandibular EF% compared to those who do not. 2) Diagnostic accuracy of submandibular EF% is better than qualitative sSC and similar to Bp. 3) Cutoff values of submandibular EF% of 39.5 (right gland) and 47.5 (left gland) show a sensitivity comparable to qualitative sSC but a significantly higher specificity.

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016

Session Title: Imaging of Rheumatic Diseases III: Crystal Arthritis, Osteoarthritis, Connective Tissue Disease and Vasculitis

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: Systemic sclerosis is a multisystem disease characterized by the development of microangiopathy and subsequent fibrosis of skin and internal organs. The joint involvement is common, but its prevalence and characteristics differ in the literature. Traditionally, it has been assessed by clinical examination, which may underestimate the presence of synovitis and erosions. Objective: To evaluate the characteristics of joint involvement in a cohort of patients with systemic sclerosis assessed by clinimetric and ultrasonographic (US) measures.

Methods: Observational cross-sectional study. Consecutive patients with systemic sclerosis according to ACR-EULAR 2010 criteria were included. Acute phase reactants (erythrocyte sedimentation rate and C-reactive protein), immunology laboratory, rheumatoid factor and antiCCP were measured the day of clinical examination. Disease activity was measured by DAS28, hands' functionality was assessed by Duruöz Index and modified Kapandji Test, extension of cutaneous involvement by modified Rodnan Score and disability by HAQ-A. All US examinations were performed by an experienced rheumatologist, blinded to clinical and laboratory data. The US evaluation included examination in grayscale and power Doppler with a linear transducer (10-18MhZ) in the longitudinal and transverse sections of: radiocarpal and intracarpian joint, second to fifth metacarpophalangeal joint, tibiotalar joint, 1st to 6th wrist tendon extensor compartment, 1st to 5th digital flexor tendon, Achilles tendon, peroneal tendons, posterior tibialis tendon and tibialis anterior tendon, all bilaterally. For descriptive statistics, continuous variables were described as median (IQR) and categorical variables as percentages. To analyze the differences between the groups with and without ultrasound findings, Mann Whitney test was used for continuous variables, and Fisher exact test for categorical variables. It was considered as significant a p value < 0.05.

Results: 40 consecutive patients with systemic sclerosis were included. Median age was: 53 (IQR 45-59), 87.5% were women. The median time since the first not Raynaud manifestation was 4 years (IQR 2-6). The 72.5% of patients had limited scleroderma, Barnet subtype 1, 77.5% had Raynaud, 50% of patients reported suffering from arthralgia and only 4 patients arthritis, 35% (n = 14) had pitting and 17.5% (n = 7) active digital ulcers. Only 1 patient had a history of amputation and 2 had calcinosis. The median Duruöz index was 12.7 (SD 14.3), Kapandji Test 80 (SD 23), HAQ 0.79 (SD 0.83) and DAS28: 2.77 (IQR: 2.18- 3.34). The US findings were: 47.5% (n = 19) of patients presented at least one finding by ultrasound, 32.5% (n = 13) proliferative synovitis grade II in the radiocarpal joint and 2.5% (n = 1) Grade III. Only 2 patients had PD positive grade II. At the tibiotalar joint, only 2 patients had moderate synovitis. 15% (n = 6) had extensor compartment tenosynovitis and 30% (n = 12) digital flexor tenosynovitis. The 42, 5% of patients (n = 17) had tenosynovitis and/or tendinopathy in tibialis anterior tendon, posterior tibialis tendon, peroneal tendons and Achilles tendon. 12.5% (n = 5) had erosions in styloid process (n = 4) and 2nd metacarpophalangeal (n = 1). No statistically significant differences were found between the groups with and without ultrasound findings regarding the following variables: Median HAQ, DAS28, Score Rodnan, Duruöz Index and Kapandji Test, anti centromere and Scl-70 antibodies, RF, acute phase reactants, VAS, disease duration, age or treatments ($p > 0.05$).

Conclusion: The joint involvement in systemic sclerosis is frequent, evaluated both clinically and by ultrasound. This manifestation should be considered in daily care in patients with systemic sclerosis.

Session Title: Pediatric Rheumatology – Clinical and Therapeutic Aspects III: Autoinflammatory Diseases and Juvenile Dermatomyositis

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: Cyclophosphamide (CYC) has been used as a second-line agent in the treatment of severe or refractory JDM. The published literature on the efficacy of CYC in JDM is limited to a small number of case series and case reports. The aim of this study was to describe the efficacy and safety of CYC in a large national UK patient cohort with severe or refractory JDM.

Methods: Patients treated with CYC met Bohan and Peter criteria and were recruited to the UK JDM Cohort and Biomarker Study (JDCBS). Patients received CYC at 500mg/m2 (max 500mg) every 2 weeks for first 3 doses and then 750mg/m2 (max 1.2g) every 3-4 weeks according to response for total 6-10 doses. Clinical data at baseline and 6, 12 and 24 months were recorded, including physician's global assessment (PGA) to assess overall disease activity, modified disease activity score (mDAS) to assess skin disease, and Childhood Myositis Assessment Scale (CMAS) and Manual Muscle Testing (MMT8) to assess muscle weakness. Data are presented as median [interquartile range] and were analyzed using Friedman's test for non-parametric repeated measures ANOVA, with post-hoc tests using the Wilcoxon signed rank test and Bonferroni adjustment.

Results: Of 525 patients in the JDCBS 83 patients were treated with CYC, of whom 62.7% were female. Age at diagnosis was 6.2 [4.0-10.0] years and disease duration at CYC start was 45 [26-320] days. Total duration of disease was 8.6 [5.0-12.8] years. Patients who received CYC had more severe disease compared to patients who did not receive CYC, as assessed by PGA (p=3.60e-12), mDAS (p=0.00056), CMAS (p=1.98e-9) and MMT8 (p=6.21e-5). Overall, disease activity improved over the time-points analyzed, with improvements in PGA (p=5.5e-13), mDAS (p=4.98e-10), CMAS (p=4.08e-13) and MMT8 (p=1.33e-5). For all outcome measures, the 6, 12 and 24 month time-points differed significantly from baseline. PGA reduced from 6.9 [4.1-8.0] at baseline to 2.0 [1.0-3.1] at 6 months (p=3.61e-9), 0.8 [0.3-2.3] at 12 months (p=3.89e-8) and 0.9 [0.0-1.8] at 24 months (p=4.13e-9). mDAS decreased from 4 [2.5-5] at baseline to 3 [0-4] at 6 months (p=0.00099), 2 [0-4] at 12 months (p=2.99e-5) and 0 [0-3] at 24 months (p=1.00e-7). CMAS increased from 22 [6.75-38] at baseline to 45 [38.75-49.25] at 6 months (p=9.32e-8), 47 [44-52] at 12 months (p=1.32e-7) and 49 [45-53] at 24 (p=1.77e-7) months. MMT8 increased from 52 [30.25-62.75] at baseline to 78 [67-80] at 6 months (p=9.82e-5), 76 [70-79] at 12 months (p=9.49e-5) and 80 [73-80] at 24 months (p=4.29e-5). Finally, CYC appeared to be well-tolerated with no serious adverse events including infections reported during the study period.

Conclusion: Significant improvement in both skin and muscle disease was observed in patients who received CYC at 6, 12 and 24 months after the onset of therapy. Ongoing analyses are exploring whether overall disease trajectories of patients treated with CYC differ from those of patients who were not treated with CYC.

Session Title: Pediatric Rheumatology – Clinical and Therapeutic Aspects III: Autoinflammatory Diseases and Juvenile Dermatomyositis

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: Lipodystrophy and metabolic abnormalities occur frequently in juvenile dermatomyositis (JDM) and redistribution of adipose tissue has been reported in several rheumatic diseases. Visceral adipose tissue (VAT) is closely linked to cardiovascular disease. We aimed to assess body composition, with emphasis on VAT, in JDM patients and controls, and explore the associations with cardiac function.

Methods: Fifty-nine JDM patients and 59 age- and sex matched controls from the general population, were included in a cross sectional study median 16.8 years after disease onset. Body composition including fat mass (kg) and lean mass (kg) was analyzed by total body dual-energy X-ray absorptiometry (DXA). Total body fat percentage was defined as the ratio of total fat mass/(total lean mass + total fat mass). VAT (g) was quantified by DXA only in individuals above 18 years, including 38 JDM patient and 35 controls (missing data in 3 controls). Long axis strain (LAS) and early diastolic tissue velocity (E') assessed by echocardiography were used as markers for systolic and diastolic cardiac function, respectively. Inactive disease was measured by the PRINTO criteria.

Results: In JDM patients, median age was 21.5 (IQR 15.3-35.3) years and 36/59 (61%) were female; 29/59 (49.2%) had inactive disease. Cumulative prednisolone dose was median 7.9 g (IQR 3.5-12.8). 17/59 (28%) of the patients were on prednisolone and/or DMARD at follow-up. BMI was similar between JDM patients and controls (22.3kg/m^2 (4.8) vs 22.5kg/m (4.5), p=0.752). JDM patients had higher percentage total body fat (31.2% (7.9) vs 28.2% (7.5), p=0.017) and lower lean mass (41.4kg (12.9) vs 44.9kg (13.6), p=0.008) compared with controls. Fat mass was comparable in patients vs controls (data not shown). VAT was three times higher in patients compared with controls (726g (IQR 193-1183) vs 232g (IQR 72-751), p=0.022), no difference was seen between

patients with active and inactive disease. VAT correlated negatively with LAS in all patients, and even more in patients with active disease (rsp -0.397, p=0.018 and rsp -0.750, p=0.000 respectively). VAT correlated negatively with E' in all patients and in the subgroups with active and inactive disease (rsp -0.584, p= 0.000; rsp -0.567, p=0.014 and rsp -0.554, p=0.014 respectively). VAT correlated with systolic and diastolic blood pressure (BP) in all patients, and in patients with active and inactive disease. No correlation between VAT and LAS, E', Diastolic BP was observed in controls. No correlation was found between VAT and use of medication at follow-up or cumulative prednisolone dose.

Conclusion: Patients with JDM had a higher total body fat percentage and a lower lean mass compared with matched controls, despite similar BMI. A redistribution of adipose tissue in JDM patients was demonstrated, as VAT was three times higher in patients compared with controls. Both systolic and diastolic cardiac dysfunction were associated with higher VAT in patients, but not in controls. This suggests that the increased visceral adipose may contribute to subclinical heart disease in JDM.

Session Title: Pediatric Rheumatology – Clinical and Therapeutic Aspects III: Autoinflammatory Diseases and Juvenile Dermatomyositis

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: Periodic fever syndromes (PFS) are rare auto-inflammatory conditions that include, among others, cryopyrin-associated periodic syndromes (CAPS), familial Mediterranean fever (FMF), hyper-IgD syndrome/mevalonate kinase deficiency (HIDS/MKD), and TNF receptor-associated periodic syndrome (TRAPS).[1] Canakinumab (CAN), a fully human, highly specific anti-IL-1β neutralizing monoclonal antibody, is effective in CAPS.[2] IL-1β has been shown to be involved in the pathogenesis of FMF, HIDS/MKD and TRAPS, for which no or limited treatment options exist.[1] Open-label studies have suggested the efficacy of CAN in colchicine-resistant/intolerant FMF (crFMF), HIDS/MKD, and TRAPS.[3-5] We report the efficacy and safety of CAN from the randomized treatment epoch of the Phase 3 pivotal study in patients (pts) with crFMF, HIDS/MKD or TRAPS.

Methods: The study (NCT02059291) consists of 3 disease cohorts (crFMF, HIDS/MKD and TRAPS) and 4 study epochs: a screening epoch (E1) of up to 12 wks, a randomized treatment epoch (E2) of 16 wks, a randomized withdrawal epoch (E3) of 24 wks and an open-label treatment epoch (E4) of 72 wks. Pts (aged ≥2 years) with a flare during E1 were randomized (1:1) in E2 to receive CAN or placebo (PBO). Primary objective was to demonstrate that CAN 150 mg (or 2 mg/kg for pts ≤40 kg) sc q4w is superior to PBO in achieving a clinically meaningful response, defined as resolution of the index flare at Day 15 and no new disease flares over 16 weeks (wks) of treatment. Safety assessments included adverse events (AEs) and serious AEs(SAEs).

Results: Of 181 pts (crFMF, n=63; HIDS/MKD, n=72; TRAPS, n=46) randomized in E2, 6 discontinued the study (5 PBO; 1 CAN). In all 3 disease cohorts, the proportion of responders for the primary outcome at Wk 16 was significantly higher with CAN vs PBO (Table). At Wk 16, a significantly higher proportion of pts achieved a PGA score <2, CRP ≤10 mg/L and SAA ≤10 mg/L in the CAN group vs PBO in all 3 cohorts. The most frequently affected system organ class across 3 cohorts was infections and infestations typically involving the upper respiratory tract. The incidence of SAEs was 8.6%, 4.7% and 11.8% in crFMF, TRAPS and HIDS/MKD cohorts,respectively.

Table. Proportion of responders at Week 16 by cohort

Cohort	CAN (150 mg q4w), n/m (%)	Placebo n/m (%)	p value
crFMF	19/31 (61.3)	2/32 (6.3)	<0.001*
HIDS/MKD	13/37 (35.1)	2/35 (5.7)	0.0020*
TRAPS	10/22 (45.5)	2/24 (8.3)	0.0050*

*Statistical significance (1-sided) at the 0.025 level based on Fisher exact test/logistic regression model. n=number of pts who responded; m=number of pts evaluated for response

Conclusion: These results demonstrated superior efficacy of canakinumab after a 16-week treatment period compared with placebo. The overall safety profile was not distinct from those reported in previous controlled studies. References: 1. Savic S and Wood P. *Clin Med.*2011;11(4):396–401. 2. Session Title: Pediatric Rheumatology – Clinical and Therapeutic Aspects III: Autoinflammatory Diseases and Juvenile Dermatomyositis

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: Canakinumab (CAN) has been shown not to impair antibody production following vaccination in children in an open-label phase 3 study (NCT01302860).[1] Here we present the results from the extension of this study. The objective of this study was to evaluate the presence of protective antibody levels following immunization with inactivated vaccines in CAPS patients during extension study.

Methods: Patients who completed the core study were allowed to continue into the extension study on the standard dosing regimen of 2 mg/kg subcutaneous CAN every 8 weeks or on last dose/dosing regimen received in the core study. Vaccination response was evaluated using post-vaccination antibody titers at 4 and 8 weeks after immunization. Patients were considered assessable for an antibody response to a specific vaccination if they had a measurement of antibody titer 0-14 days post-vaccination (pre-vaccination assessment) and at least 1 subsequent measurement of antibody titer at 4 weeks and/or 8 weeks post-vaccination. However, for patients with adequate pre-dose antibody titers and maintained during the trial, the specific patient vaccination was deemed non-assessable.

Results: During the extension phase, of 17 patients (≤6 years), 4 received 8 types of vaccinations against *Corynebacterium diphtheria*, *Bordetella pertussis*, *Neisseria meningitidis*, *Clostridium tetani*, influenza type A and type B, *Haemophilus influenza* B, *Streptococcus pneumoniae*, or hepatitis B. Of 20 unique patient-vaccination cases, 17 were assessable for a vaccination response, whereas for the remaining 3, pre-dose antibody titer was not available. For 16 (94.1%) assessable cases, post-vaccination antibody titers increased above protective levels. For one patient who received Tetravec formulation (diphtheria, tetanus and acellular pertussis combination), the response observed for 1 (vaccination against *Clostridium tetani*) of the 3 vaccines included in Tetravac represented optical density rather than antibody concentrations and hence considered non-evaluable. For 19/20 patient-vaccinations, including those without pre-dose antibody titers, protective levels were observed during the study, which were maintained throughout the extension.

Conclusion: Canakinumab appeared to have no effect on post-vaccination antibody production following the administration of non-live vaccines in CAPS patients. **References**: 1.Brogan P, et al. *Arthritis Rheumatol*. 2015;67:(S10).

Session Title: Pediatric Rheumatology – Clinical and Therapeutic Aspects III: Autoinflammatory Diseases and Juvenile Dermatomyositis

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: The deficiency of adenosine deaminase type 2 (DADA2) is an autosomal recessive disease resulting from biallelic mutations in *CECR1*. Patients commonly present with vascular and inflammatory manifestations including livedo racemosa, fevers, ischemic strokes, anemia and polyarteritis nodosa (PAN). Neurologic events can occur even when acute phase reactants are normal. Therapeutic options have included anti-thrombotic agents as well as anti-inflammatory agents without adequate disease suppression. Hematopoietic stem cell transplant has been reported to be a successful therapeutic option but has associated risks. Previous reports have demonstrated perivascular tumor necrosis factor (TNF) in DADA2, and suggest that TNF inhibitors ameliorate DADA2-associated PAN. We therefore aimed to assess whether anti-TNF agents would reduce the number of strokes in DADA2.

Methods: Patients with DADA2 and a history of ischemic stroke seen at the NIH between June 2013 and May 2016 were included in this cohort. Patients were initiated on anti-TNF therapy with etanercept, adalimumab or golimumab, and were monitored by follow-up visits to the NIH every six to twelve months. The primary outcome was the number of strokes after initiation of an anti-TNF agent compared to the number of strokes before anti-TNF treatment. Secondary outcomes included progression of other DADA2 related clinical manifestations, change in acute phase reactants, and hematologic markers.

Results: Out of 22 DADA2 patients followed at the NIH, 15 had a history of ischemic stroke. Before anti-TNF initiation, the 15 patients in the stroke cohort had 55 strokes over 1173 patient months (model based recurrence rate 0.043) compared to 0 strokes over 373 patient months occurring post-initiation of anti-TNF (recurrence rate 0). The P value for testing equal recurrence rate is 1.68×10^{-8}. A matched follow up time analysis using 328 patient months both prospectively and retrospectively has an estimated probability of 1 (15/15) for the strokes occurring before anti-TNF treatment as opposed to after, with a 95% Blyth-Still-Casella exact confidence interval of (0.7873, 1) ($P = 5.1 \times 10^{-5}$). This refutes the null hypothesis that anti-TNF therapy will not have an effect on stroke frequency and that the probability of stroke pre-anti-TNF initiation is 0.5. Laboratory studies showed statistically significant improvements in ESR, CRP, hematocrit, hemoglobin, platelets, leukocytes and serum iron.

Conclusion: These results show that anti-TNF treatment is highly effective in reducing the risk of stroke and improving laboratory parameters in DADA2. Although not directly addressed here, it may be advisable to initiate anti-TNF at the time of diagnosis of DADA2 even in the face of normal acute phase reactants.

Session Date: Wednesday, November 16, 2016

Session Title: Pediatric Rheumatology – Clinical and Therapeutic Aspects III: Autoinflammatory Diseases and Juvenile Dermatomyositis

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: Chronically elevated serum IP-10 (CXCL10) levels, and a prominent "interferon (IFN)-response gene signature" in patients with chronic neutrophilic dermatosis with lipodystrophy and elevated temperatures (CANDLE), CANDLE-like diseases or with gain-of-function mutations in *TMEM173/STING* with STING-associated vasculopathy with onset in infancy (SAVI), suggested modulation of IFN signaling might be a therapeutic option for patients with some autoinflammatory interferonopathies. The compassionate use program was developed to provide baricitinib (JAK1/JAK2 inhibitor) to CANDLE, CANDLE-like and SAVI patients who have no other comparable or satisfactory treatment options. Potential efficacy of treatment was assessed by a reduction in mean Autoinflammatory Diary Scores (ADS) to < 0.5 (CANDLE and CANDLE-like pt.) and to <1.0 (SAVI pt.) and reduction of steroid doses to <0.15mg/kg/day or by at least 50% reduction from baseline.

Methods: Paired t-tests were used to compare mean ADS and prednisone doses at the last clinic visit to baseline data

Results: Between October 2011 and March 4th, 2016, 18 patients (pt.) have been treated (mean duration 2.3 years, SD±1). 9 of 11 CANDLE pt. and 3 of 4 SAVI pt. achieved an ADS of < 0.5 and < 1.0 at the time of their last visit, respectively. None of 3 CANDLE-like pt. achieved an ADS of < 0.5 (mean ADS for all cohorts decreased from 1.5 ± 0.8 to 0.5 ± 0.5) ($p< 0.005$), 8 of 10 CANDLE pt. and 2 of 3 CANDLE-like pt. achieved a reduction in steroid doses > than 50% from baseline. 4 of 10 CANDLE pt. discontinued oral steroids completely and continued to have an ADS of <0.5. The only SAVI pt. on steroids at baseline continues at the same dose. Mean total prednisone dose decreased in patients receiving steroids at baseline from 0.7 mg/kg/day (0.2-1.8) to 0.2 mg/kg/day (0-0.8) ($p< 0.005$). The mean baricitinib dose at last patient visit was 6.9 ± 3.3 mg/day (0.2 mg/kg/day). 13 pt. reported at least 1 serious adverse event (SAE), infection being the most common. 2 CANDLE pt. have been discontinued due to SAEs (avascular necrosis; BK viremia and azotemia). Both pt. subsequently died: the first patient due to underlying liver and kidney disease 18 months after discontinuation of baricitinib, the second patient due to worsening interstitial lung disease with development of respiratory failure 4 months after discontinuation of baricitinib and initiation of another JAK inhibitor. 1 pt. required temporary interruption of baricitinib due to neutropenia, and 4 other pt. had their dose electively reduced after testing positive for BK viremia; patients were asymptomatic. The most common adverse events were upper respiratory infections, cough, and BK viruria (baseline BK virus screening was not performed).

Conclusion: Preliminary efficacy and safety data in 18 patients with autoinflammatory type I Interferonopathies treated with baricitinib are encouraging and suggest that targeting IFN signaling with a JAK1/JAK2 inhibitor may be a successful therapeutic strategy. Monitoring BK viral titers in blood and urine, in addition to other measures of safety and efficacy, may be important in dose selection and the benefit-risk assessment of baricitinib for these patients.

Session Title: Rheumatoid Arthritis – Clinical Aspects VII: The Impact of Treating to Target

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

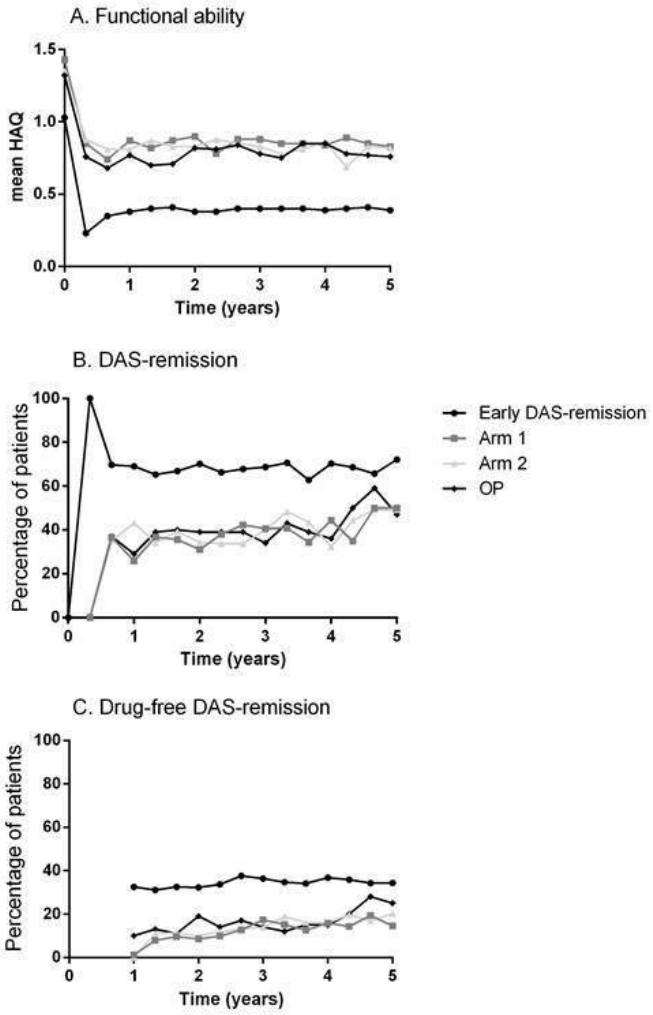
Background/Purpose: To assess clinical and radiological outcomes of induction therapy followed by 5 years disease activity score (DAS)-remission steered treatment in early arthritis patients.

Methods: The IMPROVED study enrolled 610 early rheumatoid arthritis (RA, 2010) or undifferentiated arthritis (UA) patients. All started induction therapy methotrexate (MTX) and tapered high dose of prednisone. If DAS-remission (<1.6) was achieved at 4 months prednisone was stopped (early DAS-remission (ER)) and if remission persisted at 8 months MTX was also stopped. Patients not in ER were randomized to MTX+sulfasalazine+hydroxychloroquine+low dose prednisone (arm 1) or MTX+adalimumab (arm 2), 50 patients were not randomized and were treated 'outside of protocol' (OP). Every 4 months treatment adjustments aimed at DAS<1.6: DAS<1.6 taper/stop medication and DAS≥1.6 restart/intensify. (Drug-free) DAS-remission percentages were compared between the different diagnosis and treatment strategies. Radiologic damage progression (Sharp-vanderHeijde Score, SHS) from baseline to 5 years was scored by 2 independent readers in chronologic order.

Results: Patients in the ER group had better functional ability over time, compared to arms 1 and 2 and the OP group, who between them had similar HAQ scores over time (figure). 295/610 (48%) patients achieved DAS-remission at 5 years: 220/387 (57%) in the ER group, 31/83 (37%) in arm 1, 29/78 (37%) in arm 2 (p=0.768 arm 1 vs arm 2) and 15/50 (30%) in OP (figure). 134/610 (22%) patients achieved DFR (drug-free DAS-remission): 105/387 (27%) in the ER group, 9/83 (11%) in arm 1, 12/78 (15%) in arm 2 (p=0.374 arm 1 vs arm 2) and 8/50 (16%) in OP (figure). DAS-remission percentages were similar in RA and UA patients and autoantibody positive (+) vs negative (–) patients. More UA patients achieved DFR (33% UA vs 19% RA, p<0.001), and more patients negative for anti-citrullinated protein antibodies (ACPA) (31% ACPAneg vs 15% ACPApos, p<0.001) or rheumatoid factor (RF) (28% RFneg vs 17% RFpos, p<0.001) achieved DFR. Median (IQR) SHS progression was 0.5 (0-3) in 306 completers in the ER group, 0 (0-1) in arm 1 (62 completers), 0 (0-1) in arm 2 (59 completers) (p=0.818 arm 1 vs arm 2) and 0 (0-3) in 31 OP completers. SHS progression ≥5 points had occurred in 40/306 (13%) in the ER group, 9/62 (15%) in arm 1, 7/59 (12%) in arm 2 (p=0.710 arm 1 vs arm 2) and 2/31 (6%).

Conclusion: Induction therapy followed by 5 years DAS-remission steered treatment resulted in 48% DAS-remission and 22% DFR in early RA and UA patients. More UA patients and more autoantibody negative patients achieved DFR. Radiologic damage progression was well suppressed in the majority of patients.

Figure: Outcomes over 5 years: A. functional ability, B. DAS-remission, C. Drug-free DAS-remission.



HAQ: health assessment questionnaire; DAS: disease activity score; OP: outside of protocol.

Session Title: Rheumatoid Arthritis – Clinical Aspects VII: The Impact of Treating to Target

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: Few RCTs have investigated long-term (10+ years) outcomes of goal-directed synovitis suppression in early rheumatoid arthritis (RA). The CIMESTRA trial was a 2-year double-blinded Danish multicenter study on aggressive treatment with csDMARDS (methotrexate (MTX) versus MTX and cyclosporine) in combination with intra-articular glucocorticoids (1+2). Disease control after 2 years (yrs) was excellent with ≈50% in remission and halted radiographic progression in both groups. We here present 10+ year follow-up data. The aims were to 1) investigate the clinical and radiographic status and 2) identify baseline predictors of functional status and erosive progression.

Methods: Of 160 patients (pts) included, 93 pts also had MRI of the wrist performed at baseline. 13 pts had died since baseline. All living pts were contacted and 120 signed informed consent to participate in a 10+ yrs' follow-up visit assessing e.g. treatment, disease activity (DAS28, CRP, 4 variables), physical function (HAQ), X-ray of hands and feet. Baseline MRI was scored by OMERACT rheumatoid arthritis MRI scoring (RAMRIS) system, X-rays by Sharp-van der Heijde total Sharp Score (TSS). Descriptive statistics (medians (IQR) or percentages) were appliedMultivariable linear regression analyses of a panel of baseline variables (see foot note in table) with backward selection were performed with HAQ at 10+ yrs (HAQ_{10+}) and radiographic progression since baseline ($\Delta TSS_{0\text{-}10+}$) as dependent variables.

Results: 120 of 160 pts (75%) completed the 10+ yrs visit. 74 pts with available baseline MRI and X-rays of both time points were included in the prediction models. Withdrawal analysis comparing the 160 pts with the 120 and 74 pts showed similar baseline characteristics for all comparisons of demographic and disease-related variables,all $p > 0.20$. Follow-up was after 11.5 yrs (10.7-12.2). Pts were 63 yrs (55-72) and 70% females. 20% received biologics (+/- csDMARD), 53% csDMARD alone. 27% were in drug free remission. DAS28 was 2.0 (1.5-2.6); pain score: 1 cm (0.3-3); pt. global: 1.1 cm (0.2-2.9); swollen joint count (28SJC): 0 (0-0); tender joint count (28TJC): 0(0-1). 76% of pts were in DAS28 remission; HAQ-score was 0.25 (0-0.75); $\Delta TSS_{0\text{-}10+}$(median (IQR)):5(0-14); $\Delta TSS_{0\text{-}10+}$(mean±SD): 11.2±17.1). The annual progression rate since baseline was median (IQR):0.4 (0-1.2); mean±SD:0.99±1.53. Multivariable linear regression analyses are shown in Table.

Conclusion: 10+ years after diagnosis 75% were in DAS28 remission. HAQ-score was low, and mean radiographic progression was <1 TSS unit/year. High DAS28 and positive anti-CCP at baseline were independent predictors of poorer functional status. Baseline MRI bone marrow edema and anti-CCP positivity were independent predictors of radiographic progression . References: 1. Arthritis Rheum 2006; 54: 1401-9. 2. Ann Rheum Dis 2008; 67: 815-22. **Table.**Predictors of functional status and radiographic progression, final models.

Session Date: Wednesday, November 16, 2016

Session Title: Rheumatoid Arthritis – Clinical Aspects VII: The Impact of Treating to Target

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: Implementation of treat-to-target (T2T) in Rheumatoid Arthritis (RA) leads to limited radiological damage during follow-up of 3 years. Questions are whether these results are maintained over time and whether patients with progressive radiological damage can be recognized early. This study describes the 6 years radiological outcomes of patients with early RA following the implementation of T2T in daily clinical practice.

Methods: In the Dutch Rheumatoid Arthritis Monitoring tight control cohort I, patients with early RA were treated according to a

T2T step-up strategy starting with methotrexate monotherapy. Radiographs of hands and feet were obtained at baseline, after 6 and 12 months, and every 3 years thereafter. Primary outcome was the change in median Sharp/vanderHeijde score (SHS) of the total cohort using Friedman's repeated-measures analysis of variance on ranks with signed-rank post hoc Wilcoxon tests. Secondary outcomes were 1) median individual change in SHS scores at different time intervals, 2) percentages of patients with at least minimal clinical important difference in SHS (MCID; increase ≥ 5 SHS points) between consecutive time moments and baseline. Mann-Whitney U test was used to test the difference in radiological progression between patients with and without MCID between 6 months and baseline.

Results: Data of 221 patients were used (78% fulfilling the ACR 1987 criteria). Within the first year of treatment 77% reached remission or low-disease activity (Disease Activity Score in 28 joints ≤ 3.2) and this percentage remained stable during 6 years of follow-up. Median (IQR) total SHS score increased from 2.0 (0.0–7.0) at baseline to 12.0 (6.0–22.0) at 6 years of follow-up (P<0.001) (Figure 1). The median (IQR) of the individual SHS progression rates per time interval were as follows: 2.0 (1.0–4.0) between 1 year and baseline, 2.0 (0.0–4.0) between 3 years and 1 year, 3.0 (1.0–5.0) between 6 years and 3 years (P<0.001). Percentages of patients with at least MCID in SHS scores after 6 months, 1 year, 3 years and 6 years were 12.8%, 22.3%, 44.9% and 76.0% respectively. Patients with MCID between 6 months and baseline had significantly more radiological progression during further follow-up than patients without (Figure 2).

Conclusion: Maintaining strict treat-to-target in early RA in daily clinical practice results in only minor radiological progression in long-term follow-up. Most joint damage occurs in the first year of treatment. Patients with early important clinical radiological progression had significantly more joint damage during further follow-up.

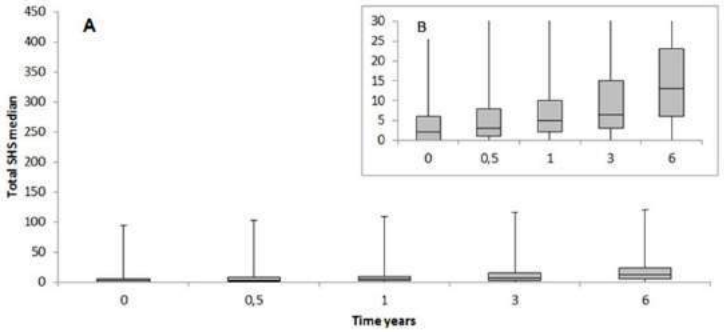

Figure 1. Box plots of the Sharp / van der Heijde score (SHS) over 6 years of follow-up. **A** shown on the full range of the score (0-448), and **B** zoomed into the range of the observed scores

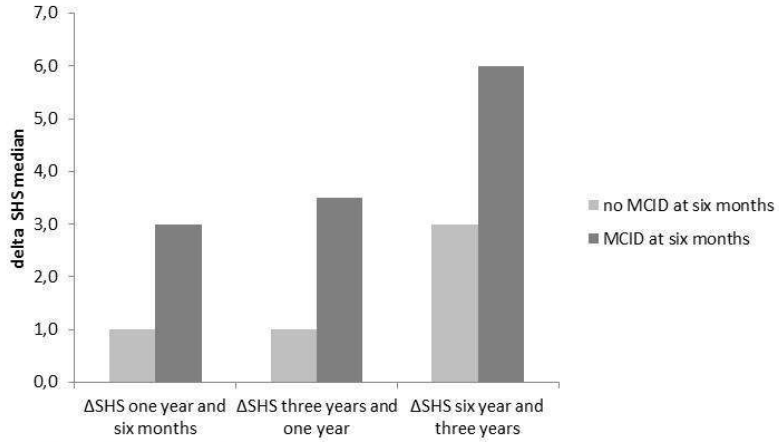

Figure 2. Median SHS progression at consecutive time intervals stratified between patients with and without MCID at six months. ΔSHS = difference in Sharp / van der Heijde score; MCID = minimal clinical important difference (increase in total SHS score ≥ 5).

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016

Session Title: Rheumatoid Arthritis – Clinical Aspects VII: The Impact of Treating to Target

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: The management of rheumatoid arthritis (RA) has evolved considerably during the last couple of decades, with current recommended practice being a treat-to-target approach, involving early intervention and tight monitoring of treatment effect. When starting a new therapy, the recommended target is remission (REM) or alternatively low disease activity (LDA). Limited data exist on the impacts of reaching REM rather than LDA on long-term outcomes. The objective of this study was to compare RA-patients who achieved Simplified Disease Activity Index (SDAI) REM versus LDA 6 months after initiating disease-modifying anti-rheumatic drug (DMARD) therapy, with regard to physical function, Health Related Quality of Life (HRQoL) and disease activity during 5-year follow-up in a real-life clinical setting.

Methods: Data were provided by the Norwegian DMARD study (NOR-DMARD), a multicentre longitudinal observational study. We selected DMARD-naive patients with RA who were consecutively enrolled from December 2000 to April 2009 (n=1617), starting treatment with methotrexate (n=1197), other conventional synthetic DMARDs (n=380) or a biological DMARD (n=33). Data on each patient were collected at baseline, after 3, 6 and 12 months, and yearly thereafter, including the modified Health Assessment Questionnaire (MHAQ), the Medical Outcomes Study 36-item Short-Form Health Survey (SF-36) with Physical and Mental Components Summary scores (PCS and MCS, respectively) and assessments that allowed the calculation of the composite disease activity scores SDAI, Clinical Disease Activity Index (CDAI) and the Disease Activity Score based on 28 joint counts with ESR (DAS28). Multivariate linear mixed models were used to explore the effect of SDAI status at 6 months on physical function (MHAQ), HRQoL (SF-36 PCS and MCS) and disease activity (SDAI, CDAI, DAS28) during 1-5 year follow-up. The statistical models were adjusted for potential baseline confounders such as age, sex, disease duration and disease activity.

Results: Of the 1617 eligible patients at baseline, 1301 (80.5%) had a registered visit at 6 months. 602 patients were in either SDAI REM (n=143, 11.0%) or LDA (n=459, 35.3%) at 6 months and were included in the main analyses. The achievement of SDAI REM rather than SDAI LDA at 6 months was associated with significantly better physical function (MHAQ) and HRQoL (SF-36 PCS) and with lower disease activity (SDAI, CDAI, DAS28) at all yearly follow-up visits between 1 and 5 years (table).

Conclusion: The achievement of SDAI REM rather than LDA 6 months after initiating DMARD-therapy, lead to better long term functional outcomes during 5-year follow-up in a real-life clinical setting. The results support the use of a stringent treatment target, such as SDAI REM, when initiating DMARD-therapy in RA-patients.

Session Title: Rheumatoid Arthritis – Clinical Aspects VII: The Impact of Treating to Target

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: It remains to be determined if setting remission or low disease activity as treatment target affects significant outcomes in early active rheumatoid arthritis (RA) patients. We compared 2 patient groups who were treated for 5 years aiming at DAS<1.6 or DAS≤2.4.

Methods: Five years outcomes were compared in 133 patients from the BeSt study (inclusion criteria: early (≤2 years symptom duration) active (≥6 of 66 swollen joints, ≥6 of 68 tender joints, and either erythrocyte sedimentation rate ≥28 mm/hour or a visual analogue scale global health score ≥20mm) RA (1987)), randomized to initial therapy with methotrexate, sulfasalazine and tapered high dose of prednisone (arm 3), targeted at DAS≤2.4 ('LDA target group'), and 175 early RA patients from the IMPROVED-study who would have fulfilled the inclusion criteria of the BeSt-study, who started with methotrexate and tapered high dose of prednisone, targeted at DAS<1.6 ('remission target group'). To correct for baseline differences, the associations of treatment target with achieving DAS<1.6, Boolean remission at year 1 and drug-free DAS-remission (DFR) at year 5 were analysed by logistic regression analysis.

Results: At baseline, patients in the remission target group had earlier and less active disease than the LDA target group (mean DAS±SD 4.1±0.7 vs 4.4±0.9, p=0.012) (table), and they had better outcomes at the first evaluation point (after 4 months of treatment and 3 months in the LDA target group). The DAS target was achieved by 56% (LDA target group) and 53% (remission target group) (table). At year 1, the DAS target was achieved by 67% (DAS≤2.4) and 51% (DAS<1.6). Similar percentages in both groups had a DAS≤2.4 (67% (DAS≤2.4) and 73% (DAS<1.6), p=0.333), but DAS<1.6 was achieved more often in the remission targeted group (51% (DAS<1.6) vs 30% (DAS≤2.4), p<0.001). DFR was by protocol not possible at year 1 in the LDA targeted group. 15% of the remission target group were in DFR. There was less radiological damage progression in the remission target group (median (IQR)/mean±SD 0 (0-0)/0±0.2 (DAS<1.6) vs 0 (0-1)/0.9±2.3 (DAS≤2.4), p<0.001). At year 5, the target was achieved in 43% (remission target group) and 61% (LDA target group). DAS≤2.4 was achieved in similar percentages (61% vs 61%, p=0.092). More patients in the remission targeted group had DAS<1.6 and DFR (43% vs 32%, p=0.003, and 18% vs 8%, p=0.003, respectively).

DAS<1.6 as treatment target was associated with more DAS<1.6 (OR 3.04 (95% CI 1.64-5.62)) and Boolean remission (3.03 (1.45-6.33)) at year 1 and more DFR at year 5 (3.77 (1.51-9.43)) corrected for gender, symptom duration, baseline DAS, baseline SHS, and time on anti-TNF.

Conclusion: Early active RA patients had better outcomes after DAS<1.6 than DAS≤2.4 steered treatment. DAS-remission targeted treatment was an independent predictor for achieving DAS<1.6 and Boolean remission at year 1 and DFR at year 5.

Table: Clinical characteristics at baseline and follow up in BeSt and IMPROVED patients

Session Title: Rheumatoid Arthritis – Clinical Aspects VII: The Impact of Treating to Target

Session Type: ACR Concurrent Abstract Session

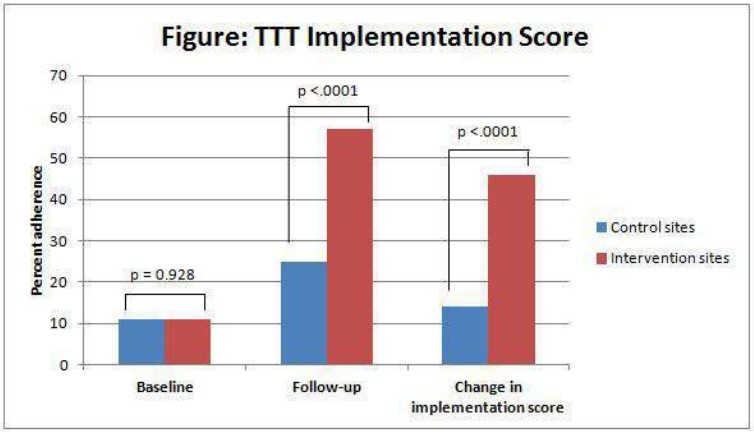
Session Time: 11:00AM-12:30PM

Background/Purpose: Treat to target (TTT) is a recommended strategy in the management of rheumatoid arthritis (RA), but various studies suggest that its uptake in routine US care is sub-optimal. We carried out a randomized controlled trial of a Learning Collaborative to facilitate implementation of TTT.

Methods: We recruited 11 rheumatology sites from the US and randomized them into 2 groups: 5 sites received the Learning Collaborative intervention over 9 months and the other 6 sites formed a wait-list control group. The Learning Collaborative used a description of the problem with strategies for improvement (Model for Improvement with Change Package) and action phases. The intervention included: 1 face to face meeting and 8 learning sessions via webinar; use of a web-based tool for sharing results of plan-do-study-act cycles; and collection by sites of their monthly improvement measures assessing progress. The primary outcome was the between group difference in the change in TTT implementation, as measured in medical records by study staff at baseline and follow-up. TTT implementation was scored using 4 items: shared-decision making, choice of a target, use of a disease activity measure (DAM), and changing treatments based on the target and DAM. The TTT implementation was scored on a 0-100% scale based on the presence/absence of the 4 items. The between group difference was measured at the patient-level, accounting for the clustering in a linear mixed model.

Results: 23 providers participated at the five intervention sites and 23 at the six control sites. The chart review included 320 RA patients from intervention and 321 from control. The patient groups were well matched, with a mean age of 60 years, 78% were female, 64% were seropositive, and treatments were similar at the start of follow-up. At baseline, mean TTT implementation score was 11% in both groups ($p = 0.93$) (see Figure). At follow-up, TTT implementation score in the intervention arm was 46% (SD 36%) compared with 14% (SD 28%) in the control arm ($p < 0.0001$) (see Figure). Improvements were observed for all four items in the implementation score (see Table). No negative consequences from the intervention were observed, with similar use of laboratory testing and x-rays, as well as similar rates of adverse events in the intervention and control arms.

Conclusion: A Learning Collaborative was an effective intervention to improve implementation of TTT for RA. Future steps will focus on analyzing the sustainability of change.



Note: Implementation score included 4 items in TTT, each scored as present or absent.

Table: Results for 4 Items Included in Implementation Score

	Wait List Control	Intervention	p-value
Visits, n	321	320	
Baseline visits with TTT items present			
Shared decision-making	24.5%	51.3%	<0.001

Session Title: Rheumatoid Arthritis – Human Etiology and Pathogenesis II

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: RA fibroblast-like synoviocytes (FLS) possess a unique aggressive phenotype characterized by increased cell growth, cytokine production and invasion. Previous unsuccessful attempts to target the downstream kinases in the mitogen-activated protein kinase (MAPK) pathway in RA have led to increased interest in the MAPK upstream kinases. These interconnected signal transduction pathways can involve the highest level of the MAPKs, namely the MAP3Ks. One of these MAP3Ks, apoptosis signal regulating kinase-1 (ASK1), is upstream of p38 and JNK and could potentially overcome the pro-inflammatory effects of selective p38 inhibitors. To address this question, we examined the expression, regulation and function of ASK1 in RA FLS.

Methods: FLS were obtained from RA and osteoarthritis (OA) synovial tissues at arthroplasty. ASK1 expression was determined by immunohistochemistry (IHC), confocal microscopy and qPCR. ASK1 promoter activity was measured using a minimal promoter luciferase reporter construct (pGL4.23-luciferase) that included a 994 kb region subcloned from the ASK1 promoter. ASK1 was blocked with the selective inhibitor ASKI-1 (IC50=4.7 nM; used at 0.02-2 uM). Migration was assessed using a scratch-wound assay, cell growth using an MTT assay and invasion using a Martigel matrix invasion assay.

Results: IHC demonstrated ASK1 expression in RA synovium, particularly in the synovial intimal lining. Because FLS reside in this region, we then studied its expression in these cells. ASK1 is constitutively expressed in FLS with similar levels in RA and OA as determined by qPCR ($p>0.1$, $n= 6$ each). Unexpectedly, IL-1β (2 ng/ml) or TNF (5 ng/ml) for 1 – 48 hours increased ASK1 mRNA levels. Levels peaked at 6 hours, with 9±4-fold ($p<0.05$, $n=3$) and 9±2-fold ($p<0.05$, $n=3$) increases, respectively. Dose

responses for IL-1β and TNF showed a maximal effect with 0.02 ng/ml for IL-1β and 0.5 ng/ml for TNF. Confocal microscopy showed that ASK1 protein localizes to the nucleus and cytosol before and after treatment with IL-1β (2 ng/ml for 6 or 24 hr) with a 68±16% increase in protein levels compared to medium ($p<0.01$ at 24 hr, n=3). To explore the mechanism of increased gene expression, we used a luciferase reporter construct with the a portion of the ASK1 promoter. After 1 hr of IL-1β stimulation, luciferase expression increased 2±0.5-fold ($p<0.03$, n=3) confirming that ASK1 is induced at the transcriptional level. We then evaluated the effect of a selective inhibitor on FLS functions relevant to RA. ASK1 inhibition in RA FLS reduced invasion into Matrigel by 34±8% (24 hr, $p<0.05$, n=3), migration by 29±9% (24 hr, $p<0.04$, n =3) and cell growth by 29±8% (48 hr, $p<0.03$, n=3).

Conclusion: ASK1 gene transcription is induced by inflammatory cytokines implicated in RA FLS. Because it is perhaps the only inducible MAPK family member, inhibition could have a degree of site and event selectivity for inflamed tissues. ASK1 inhibition also significantly reduced FLS functions related to joint damage. Therefore, targeting ASK1 is a novel therapeutic strategy for FLS-mediated damage in RA.

Session Title: Rheumatoid Arthritis – Human Etiology and Pathogenesis II
Session Type: ACR Concurrent Abstract Session
Session Time: 11:00AM-12:30PM

Background/Purpose: Determining the pathologic functions of T cells that infiltrate target tissues remains a central challenge in autoimmune diseases. In rheumatoid arthritis (RA), the formation of T cell-B cell aggregates and differentiation of plasma cells within synovium suggest a pathologic role for synovial T cells with B cell-helper function. The prevailing view considers CD4+ T follicular helper (Tfh) cells, identified as PD-1^{+} CXCR5^{+}, as the principal T cell population capable of promoting B cell differentiation. However, Tfh cell migration is largely restricted to secondary lymphoid organs. It is thus difficult to reconcile the lymphoid-homing migratory patterns of Tfh cells with the development of T cell-B cell aggregates in inflamed synovium.

Methods: We used mass cytometry and multidimensional flow cytometry to interrogate T cells that express markers of activation, including PD-1, MHC II, CD69, CD25, and CD38, in synovial tissue, synovial fluid, and blood from patients with seropositive RA and other inflammatory arthritides. Sorted PD-1^{hi} T cells from blood and synovial samples were analyzed by RNAseq, RT-PCR, intracellular flow cytometry, and *in vitro* B cell helper assays. Synovial tissue was also evaluated by immunofluorescence microscopy.

Results: Mass cytometric analysis of seropositive RA synovial tissue cells revealed a strikingly expanded population of PD-1^{hi} CXCR5^{-} CD4^{+} T cells, which constituted ~25% of synovial CD4^{+} T cells and outnumbered Tfh cells by 8-fold. PD-1^{hi} CXCR5^{-} cells were similarly enriched in synovial fluid from patients with seropositive RA, but not seronegative inflammatory arthritides. PD-1^{hi} CXCR5^{-} cells, but not Tfh cells, were also expanded in the circulation of seropositive, but not seronegative, RA patients and decreased with DMARD therapy. Surprisingly, these cells were not exhausted, but instead highly expressed factors that enable B cell help, including IL-21, CXCL13, ICOS, SAP, and MAF. Like Tfh cells, PD-1^{hi} CXCR5^{-} cells from synovial tissue, synovial fluid, and blood induced plasma cell differentiation *in vitro*, which was blocked by neutralization of IL-21 or SLAMF5. However, RNAseq transcriptomics robustly separated circulating PD-1^{hi} CXCR5^{-} cells from Tfh cells. Compared to Tfh cells, PD-1^{hi} CXCR5^{-} cells expressed high levels of chemokine receptors that direct migration to inflamed sites, such as CCR2, CX3CR1, and CCR5, and a decreased Bcl6/Blimp1 ratio. Flow cytometry confirmed CCR2 expression on ~50% of synovial PD-1^{hi} CXCR5^{-} T cells. By microscopy, PD-1^{hi} CXCR5^{-} T cells were frequently found adjacent to B cells in RA synovium.

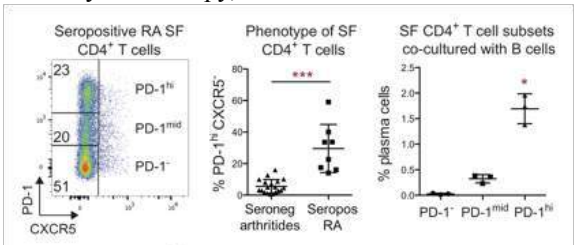

Figure 1. Frequency of PD-1^{hi} CXCR5^{-} CD4^{+} T cells in seropositive RA synovial fluid (left, middle), and ability of PD-1^{hi} CXCR5^{-} T cells to induce plasma cell differentiation *in vitro* (right).

Conclusion: We suggest that PD-1^{hi} CXCR5^{-} T cells represent a T peripheral helper (Tph) cell population, analogous to T follicular helper (Tfh) cells, that supports B cell responses in non-lymphoid tissues. Given their marked expansion in seropositive RA, these cells may be important in driving pathologic B cell responses and autoantibody production.

Session Title: Rheumatoid Arthritis – Human Etiology and Pathogenesis II

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: The establishment of longitudinal pre-clinical RA cohorts is beginning to provide important insights into the mechanisms that precede the onset of clinically detectable disease. In an attempt to identify candidate biomarkers that may suggest the activation of specific biological pathways associated with RA onset, we used aptamer based proteomic technologies to mine the serum proteome of a cohort of individuals who were followed longitudinally into disease onset.

Methods: We have prospectively followed a large cohort of first-degree relatives of North American Native RA patients, a subset of whom developed clinically detectable synovitis after an extended period of follow up. Representative serum samples were selected from 10 such individuals and analyzed using the SOMAmer (slow off-rate modified aptamer) platform (SOMAlogic Inc., Boulder, Co) to generate simultaneous quantitative levels on 1132 serum proteins. For each individual, a sample was obtained as close as possible to the RA onset date, while a matched sample had been obtained a minimum of 2 years prior to the onset. Fold changes for each individual protein at the two time points were derived from the data. The significance of the fold change was calculated by paired analysis using Stanford Analysis of Microarrays (SAM) software set at a false discovery rate <1%. For selected proteins, levels were confirmed using ELISA at multiple time points.

Results: Of the 10 patients who converted from pre-RA to clinical RA, 6 were female and all were active smokers. The average age at conversion was 34.8 (+/- 13.6) years, while the average number of months to conversion was 51.8 (+/- 30.6). Anti-CCP antibodies were detectable in the pre-RA sample in 4 patients. All 10 patients were anti-CCP positive at the time of clinical disease onset. Quantification using SOMAlogic platform indicated that 18 proteins had a mean fold increase of 3.2 (range=1.2-12.8), while 28 proteins had a mean fold decrease of 0.7 (range=0.3-0.8). Ingenuity pathway analysis revealed activation of angiogenesis, and both mucosal and cellular immunity. Of note, there was a consistent proteomic signature suggesting activation of the intrinsic coagulation cascade at the time of RA onset: Factor X increased by a mean fold increase=1.6, Factor IX increased by a mean fold increase=3.4, and Factor V increased by a mean fold increase=1.3, compared to the pre-RA sample. This pattern was detectable in 9 of 10 patients studied.

Conclusion: Based on broad-based quantitative analysis of more than 1000 serum proteins in longitudinally followed individuals who ultimately developed RA, we present evidence indicating activation of the intrinsic coagulation cascade at the time of clinical development of synovitis. Aligning with a growing body of evidence, we hypothesize that these hemostatic cofactors contribute to the pathophysiology of RA, possibly through cytokine signalling as well as synovial fibrin deposition. Our approach also demonstrates the utility of a novel assay for biomarker discovery, one that provided a rich dataset that will help shape the direction of future studies.

Session Title: Rheumatoid Arthritis – Human Etiology and Pathogenesis II

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: Mast cells (MCs) are immune cells present in the synovial membrane and implicated in the pathogenesis of Rheumatoid Arthritis, although their exact contribution to disease development and progression is still unclear. In particular, their presence in synovia has never been evaluated in correlation with longitudinal disease parameters. Aim of this study was to analyse mast cells in the synovia of early RA patients and their correlation with disease outcomes.

Methods: 99 DMARD-naive patients with early (<12 months) RA (n=99) fulfilling the 2010 ACR/EULAR classification criteria were recruited as part of the Pathobiology of Early Arthritis Cohort at Barts Health NHS Trust. Sections of paraffin embedded synovial tissue obtained by ultrasound-guided synovial biopsy were stained for CD117+ by immunohistochemistry to calculate the density of CD117+ MCs. Patients were stratified according to MC numbers and clinical parameters at baseline and 12 months follow-up were evaluated.

Results: At baseline, high synovial MC counts significantly associated with ACPA and RF positivity (p=0.029 and 0.013, respectively) and higher disease activity (DAS28 p=0.003). Accordingly, the density of synovial MCs at baseline correlated with DAS-28 (rS=0.308, p=0.002), ESR (rS=0.273, p=0.007), CRP (rS=0.217, p=0.033), and swollen joint count (rS=0.308, p=0.002). At 12 months follow-up, patients with high baseline MC counts showed a higher prevalence of radiographic progression (9/26 vs 3/26 vs 1/27 in high, medium and low MC counts, p=0.007, n=79), with no differences in terms of treatment and response to therapy. Among baseline characteristics, only age and MC counts showed a statistically significant difference in progressors Vs non-progressors (Table 1).

Conclusion: We show a significant association between synovial mast cells and a severe clinical phenotype and seropositivity for ACPA and RF in a DMARD-naive early RA cohort. Furthermore, patients with high mast cell counts were significantly more likely to develop radiographic damage at 12 months. Interestingly, several baseline parameters, potentially associated with a higher risk of radiographic progression (e.g. antibody positivity, disease activity), were not different in progressors Vs non-progressors, except for age, while mast cell numbers were significantly higher in progressors. Although additional studies are warranted to confirm the association and, possibly, the direct contribution of mast cells to radiographic progression, our work suggests that the analysis of synovial mast cell could be used as a prognostic biomarker for patient stratification in RA. **Table 1.** Baseline characteristics in radiographic progressors Vs non-progressors

Session Title: Rheumatoid Arthritis – Human Etiology and Pathogenesis II
Session Type: ACR Concurrent Abstract Session
Session Time: 11:00AM-12:30PM

Background/Purpose: MicroRNAs (miRNA) have recently emerged as a new class of modulators of gene expression, regulating inflammation, degradation of extracellular matrix and invasive behavior of the resident cells in rheumatoid arthritis (RA). **Objectives**: 1) To investigate the miRNA expression profile in synovial and blood neutrophils in RA and its role in the pathogenesis of this disorder. 2) To study the effects of biological therapies on the miRNA profile in neutrophils.

Methods: Neutrophils were isolated from peripheral blood of 20 healthy donors and 20 RA patients. Synovial neutrophils were isolated from paired synovial fluid of 10 RA patients. nCounter microRNA Assay was used to detect simultaneously 800 human microRNAs in each sample. Altered miRNAs were analyzed for potential mRNA targets using Ingenuity pathways analysis (IPA) software. Several mRNA targets of these miRNAs were analyzed by RT-PCR. Healthy neutrophils were treated in vitro with anti-CCPs isolated from RA patients. mRNA expression of DICER, Ago1, Ago2, exportin was evaluated through RT-PCR. DICER protein expression was analyzed by western blot. Synovial and peripheral blood RA neutrophils were treated in vitro with tocilizumab and infliximab.

Results: Among 800 miRNAs analyzed, 121 were detected in neutrophils from peripheral blood or synovial fluid. Using a 2 fold change cut off, 97 miRNAs were altered in peripheral blood neutrophils from RA patients compared to healthy donors. Most of them were downregulated (94 downregulated and 3 upregulated). Accordingly, RA neutrophils showed a downregulation of the proteins participating in miRNA biogenesis, including DICER, Ago1, Ago2, exportin 5. In addition, treatment of healthy neutrophils with IgGs anti-CCPs isolated from RA patients decreased the expression of these proteins, thus pointing at these autoantibodies as main modulators of microRNA neutrophil expression. Functional IPA analysis showed that altered miRNAs regulated cellular functions such as development, growth, proliferation and movement and were mainly involved in immunological disease. Among the miRNAs found deregulated blood, 34 miRNAs were found even more significantly reduced in synovial neutrophils compared to paired blood neutrophils from RA patients. These miRNAs were mainly involved in inflammatory response, suggesting the abnormal activation of this cell subtype in the joint. In vitro treatment of RA neutrophils with infliximab or tocilizumab reversed the expression of miRNAs and genes involved in their biogenesis.

Conclusion:

1) RA neutrophils exhibit a defect in the miRNAs processing, showed by a decrease in most of the detected miRNAs and the concomitant downregulation of proteins involved in their biogenesis. This defect seems to be modulated, at least partially, by anti-CCPs antibodies. 2) miRNA downregulation is even more pronounced in synovial resident neutrophils, which may contribute to the high inflammatory profile of these cells in the joint. 3) Tocilizumab and infliximab reverse the altered miRNA profile and the defect in the biogenesis machinery, reducing the proinflammatory pattern in these cells. Session Title: Rheumatoid Arthritis – Human Etiology and Pathogenesis II

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: In rheumatoid arthritis (RA), initiating effective treatment as soon as possible within the so-called therapeutic “window of opportunity” is the strategy, and remission is a primary goal. Recent work from our group demonstrated that pre-treatment serum type I IFN- β/α ratio >1.3 can predict non-response to anti-TNF-alpha therapy in RA patients. The cellular mechanisms that underlie the IFN-β/α ratio that predicts response are not known. Effects of IFN on single cells and immune cell subtypes may be masked in whole blood or mixed cell populations.

Methods: To better understand the underpinnings of the pre-treatment IFN-β/α ratio, we used single cell expression analysis to investigate whether monocyte gene expression differs significantly between RA patients according to their pre-TNF-α inhibitor serum IFN-β/α ratio. Single classical (CL) and single non-classical (NC) blood-derived monocytes were isolated from 15 seropositive RA subjects prior to biologic therapy. Subjects were grouped by pre-TNF-α inhibitor serum IFN-β/α ratio into two groups, IFN-β/α >1.3 (n=6) and IFN-β/α <1.3 (n=9). We performed unsupervised hierarchical clustering of 87 target genes, and compared groups by Mann-Whitney and Fisher's. Genes that differed in categorical analysis were tested in logistic regression models.

Results: *JAK1* and *IL1A* were strong differentiators between patients with IFN-β/α < 1.3 and IFN-β/α > 1.3, the groups which correspond to response/non-response to anti-TNF agents. In categorical analyses, in NC cells alone, expression (OR, p) of *STAT2* (19.2, <0.0001), *ILT7* (10.4, 0.02)), *PKR* (8.9, 0.03), *TLR7* (3.1, 0.03), and *IRAK1* (3.4, 0.04) was more likely in the non-response group. In CL monocytes alone, expression of *IFIT2* (8.9, 0.04) and *CD36* (9.7, 0.04) was more likely. In multivariate logistic regression, *IL1A*, *CD32a*, *IL-8*, *TYK2*, and *IRAK1* expression in monocytes (CL+NC) aligned with treatment response groups. Each was also strongly statistically significant in regression models of monocyte subsets. In comparison to the mixed monocyte model, *IL-8* and *IRAK1* in NC and *CXCR3* in CL cells demonstrated even stronger alignment with response groups. STAT2 was strongly predictive of response group in NC cells alone. CXCL9 was strongly predictive of response group in CL cells alone. Models from monocyte subsets provided higher area under the curve in ROC analysis in comparison to the mixed monocyte model.

Conclusion: Within-cell co-expression patterns demonstrate biological differences in monocyte subsets of RA patients with an IFN-β/α > 1.3, the ratio of type I IFNs which predicts non-response to anti-TNF therapy. Differentiation by gene expression was strongest among the response/non-response patient groups when monocyte subsets were analyzed separately, and distinct expression

signatures were identified, suggesting that further study of monocyte subsets will likely illuminate molecular differences that determine treatment response to TNF-α inhibition in RA. This work will help to develop a more individualized approach to therapy in RA based upon the underlying biology of disease in a given patient.

Session Title: Rheumatoid Arthritis – Small Molecules, Biologics and Gene Therapy V: New Biologics and Remission Induction

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: Sarilumab is a human mAb that blocks IL-6 from binding to both membrane-bound and soluble IL-6Rα. Efficacy and safety of sarilumab + non-biologic DMARDs have been demonstrated.[1,2] However, 30% of patients with RA use biologics as monotherapy because of intolerance or contraindications to combination therapy.[3] In this phase 3 trial, safety and efficacy of sarilumab monotherapy were compared with adalimumab monotherapy in adult patients with active RA (NCT02332590).

Methods: Adults (N=369) intolerant of, inappropriate for, or inadequate responders to MTX received subcutaneous sarilumab (200 mg every 2 weeks [q2w]) or adalimumab (40 mg q2w) monotherapy for 24 weeks in this double-blind, double-dummy superiority study. Starting at week 16, patients with inadequate response could increase to weekly adalimumab (or matching placebo). The primary endpoint, change from baseline in DAS28-ESR at week 24, was assessed using a mixed model for repeated measures analysis. Secondary endpoints, including clinical disease activity index (CDAI), were also assessed (Table).

Results: Baseline demographics and disease characteristics were generally comparable between treatment groups. At week 24, significantly greater decrease in DAS28-ESR scores, greater incidence of DAS28-ESR remission and ACR20/50/70 responses, and improvement in HAQ–Disability Index were observed with sarilumab vs adalimumab (Table); results included patients switching to weekly adalimumab. Patients in the sarilumab group were twice as likely to achieve CDAI remission at week 24 vs adalimumab (nominal $P<0.05$). Incidences of adverse events (AEs) (64%) and serious AEs (sarilumab, 5%; adalimumab, 7%) were similar between groups. Neutropenia and injection site reactions were more common with sarilumab; headache and worsening of RA were more common with adalimumab. Incidences of infections (sarilumab, 29%; adalimumab, 28%) and serious infections (1%) were similar between groups. Neutropenia was not associated with an increased incidence of infections. Most injection site reactions were mild; only 2 cases led to treatment discontinuation in the sarilumab group. There was 1 death in the sarilumab group, 35 days after initiating treatment, due to acute cardiac failure.

Conclusion: Sarilumab monotherapy demonstrated superiority to adalimumab monotherapy in reduction of disease activity and improvement in signs and symptoms and physical function in patients with active RA who were inappropriate candidates for continued treatment with MTX due to intolerance or inadequate response. The overall incidences of AEs and serious AEs were

similar between groups, as was the rate of infections and serious infections. **References:** 1. Genovese et al. *Arthritis Rheumatol*. 2015;67:1424-1437. 2. Fleischmann et al. Presented at: ACR; November 7-11, 2015; San Francisco, CA. 3. Emery et al. *Ann Rheum Dis*. 2013;72:1897-1904.

Session Date: Wednesday, November 16, 2016

Session Title: Rheumatoid Arthritis – Small Molecules, Biologics and Gene Therapy V: New Biologics and Remission Induction

Session Type: ACR Concurrent Abstract Session
Session Time: 11:00AM-12:30PM

Background/Purpose: Sirukumab, a human monoclonal antibody that selectively binds to the cytokine IL-6 with high affinity, is under development for rheumatoid arthritis (RA) and other diseases. The objective of this study was to compare the efficacy and safety of sirukumab monotherapy and adalimumab monotherapy in biologic-naive patients (pts) with active RA.

Methods: In this Phase 3 global study (SIRROUND-H), 559 biologic-naive pts with active RA who were intolerant to methotrexate (MTX), considered inappropriate for MTX treatment for safety reasons, or were inadequate responders to MTX were randomized (1:1:1) to sirukumab SC 50mg q4w, sirukumab SC 100mg q2w, or adalimumab SC 40mg q2w, stratified by the reason for MTX failure. Pts with <20% improvement in swollen and tender joint counts at Wk 16 qualified for early escape (adalimumab to q1w dosing; sirukumab 50mg q4w to 100mg q2w). Co-primary endpoints were change from baseline in DAS28 (ESR) at Wk 24 and proportion of pts achieving ACR50 at Wk 24. The treatment comparison of interest for the primary hypotheses was sirukumab 100mg q2w vs adalimumab 40mg q2w. If the first or both of the primary hypotheses were met, the study would be considered positive.

Results: A significantly greater improvement in DAS28 (ESR) at Wk 24 was demonstrated with sirukumab 100mg q2w (P <0.001) and sirukumab 50mg q4w (P = 0.013) vs adalimumab 40mg q2w (**Table**). All 3 treatment groups showed clinically relevant improvements in ACR50 response at Wk 24, but differences between sirukumab and adalimumab were not statistically significant (ie, hypotheses for the second co-primary endpoint were not met). A clinically relevant proportion of pts attained the major secondary endpoints of DAS28 (ESR) remission and ACR20 response at Wk 24 in all 3 treatment groups. Numerical differences were observed in efficacy endpoints depending on the reason pts failed MTX (**Table**). Changes from baseline in CDAI, SDAI, HAQ-DI, SF-36 and FACIT-Fatigue were clinically important for all 3 treatment groups at Wk 24. Efficacy was observed with both sirukumab doses as monotherapy from as early as Wk 2 for most endpoints and sustained through Wk 24. A greater proportion of pts had ≥1 AE through Wk 24 with sirukumab 100mg q2w (63.6%) vs sirukumab 50mg q4w (57.0%) and adalimumab 40mg q2w (55.4%), and rates of serious AEs were 2.7%, 7.0%, and 4.3%, respectively; no deaths were reported through Wk 24.

Conclusion: In biologic-naive pts with active RA who were intolerant to, considered inappropriate for treatment with, or inadequate responders to MTX, sirukumab monotherapy SC 50mg q4w and 100mg q2w reduced signs/symptoms of RA. Significantly greater improvements in DAS28 (ESR) at Wk 24 were demonstrated with both doses of sirukumab monotherapy vs adalimumab monotherapy, while ACR responses were similar. The safety profile of sirukumab was similar to the known safety profile of anti-IL-6 receptor biologics.

Table 1. Key Endpoints for Full Analysis Set and by Reason for MTX Failure at Baseline

Endpoint	Adalimumab 40mg q2w (n = 186)	Sirukumab 50mg q4w (n = 186)	Sirukumab 100mg q2w (n = 187)

Session Title: Rheumatoid Arthritis – Small Molecules, Biologics and Gene Therapy V: New Biologics and Remission Induction

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: Sirukumab is a human monoclonal antibody that selectively binds to the IL-6 cytokine with high affinity and is under development for rheumatoid arthritis (RA) and other diseases. This Phase 3 global study (SIRROUND-T) evaluated the efficacy and safety of sirukumab in patients (pts) with active RA who were refractory or intolerant to anti- TNF agents.

Methods: Eligible pts were ≥18 years, had moderate to severe active RA, and had documented lack of benefit to ≥1 anti-TNF agent or intolerance to ≥2 anti-TNF agents. Pts were randomized 1:1:1 to sirukumab SC 50mg q4w, sirukumab SC 100mg q2w, or placebo SC q2w. Pts randomized to placebo at Wk 0 who had <20% improvement in tender/swollen joints at Wk 18 and pts who remained on placebo at Wk 24 were re-randomized to sirukumab through Wk 52. The primary endpoint was the proportion of pts achieving ACR20 response at Wk 16; major secondary endpoints were change from baseline in HAQ-DI score, proportion of pts achieving ACR50 response, and proportion of pts achieving DAS28 (CRP) remission at Wk 24.

Results: 878 pts (placebo, n=294; sirukumab, n=292 per dose group) were randomized and evaluated for efficacy/safety. All pts had taken ≥1 prior anti-TNF, and 39.4% had taken ≥2 prior anti-TNFs. ~39% of pts had previously received biologics other than anti-TNFs. 74.6% of pts were currently taking methotrexate. A significantly higher proportion of pts achieved ACR20 at Wk 16 with sirukumab (50 mg q4w, 40.1%; 100 mg q2w, 45.2%) vs placebo (24.1%); all major secondary endpoints were met for both sirukumab doses (**Table**; all $P<0.001$). ACR responses, DAS28 (CRP) remission rates, and HAQ-DI score improvements on sirukumab were maintained through Wk 52. In pts with ≥2 prior biologics (including anti-TNFs; n = 523), both sirukumab 50 mg q4w (42.5%) and 100 mg q2w (42.4%) had greater proportions of ACR20 responders vs placebo (20.9%). Significantly greater improvements were also observed in the physical and mental component summary scores of the SF-36 Health Survey with both sirukumab doses vs placebo at Wk 24 (all $P<0.001$) and were maintained through Wk 52. For the placebo-controlled phase (up to Wk 24), the incidence of AEs was numerically higher in the sirukumab 100 mg group (68.2%) than in the placebo (61.9%) or sirukumab 50 mg (61.5%) groups. With placebo, sirukumab 50 mg, and sirukumab 100 mg, respectively, the incidence of SAEs was 5.1%, 8.3%, and 7.6%. Up to Wk 52 with sirukumab 50 mg q4w and 100 mgq2w, respectively, incidences of AEs were 79.6% and 81.3% and SAEs were 14.2% and 13.2%.

Conclusion: In this difficult to treat population that was intolerant/refractory to anti-TNFs and other biologics, sirukumab SC 50mg q4w and 100mg q2w reduced RA signs/symptoms, even in pts who had failed ≥2 prior biologics, and improved physical function and patient reported outcomes. The safety profile of sirukumab was similar to the known safety profile of anti–IL-6 receptor treatment.

Table. Key Endpoints

Endpoints	Placebo (n=294)	Sirukumab 50mg q4w (n=292)	Sirukumab 100mg q2w (n=292)
Primary endpoint			
ACR20 at Week 16, n (%)	71 (24.1)	117 (40.1)[a]	132 (45.2)[a]
Difference (95% CI), %		15.9 (8.5-23.2)	21.0 (13.6-28.5)
Major secondary endpoints			
HAQ-DI mean (SD) change from baseline at Week 24	−0.12 (0.49)	−0.31 (0.54)[a]	−0.33 (0.53)[a]
ACR50 at Week 24, n (%)	26 (8.8)	61 (20.9)[a]	63 (21.6)[a]
DAS28 (CRP) remission at Week 24, n (%)	24 (8.2)	56 (19.2)[a]	63 (21.6)[a]

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016

Session Title: Rheumatoid Arthritis – Small Molecules, Biologics and Gene Therapy V: New Biologics and Remission Induction

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: A global, phase 3 study (SIRROUND-T) evaluating the efficacy and safety of sirukumab, a selective, high-affinity human monoclonal antibody to IL-6, has recently been conducted in patients (pts) with active rheumatoid arthritis (RA) despite anti-TNF therapy. This post hoc analysis sought to compare the efficacy of sirukumab in subgroups of pts with active RA refractory to anti-TNF treatment who previously also received non-anti-TNF biologic therapy (TNFs + other biologics) and who did not previously receive other biologic therapy, other than anti-TNF biologic therapy (TNF only).

Methods: Pts were randomized in a 1:1:1 ratio to sirukumab subcutaneous (SC) 50 mg q4w, sirukumab SC 100 mg q2w, or placebo SC q2w. Pts on placebo with insufficient (<20%) improvement at Wk 18 or still on placebo at Wk 24 were re-randomized to 1 of the 2 sirukumab doses. The primary efficacy endpoint was ACR20 response at Wk 16, and major secondary endpoints included change from baseline (BL) in HAQ-DI score at Wk 24, ACR50 response at Wk 24, and DAS28 (CRP) remission at Wk

24. This post-hoc analysis compared efficacy for TNF only and TNF + biologics pts for sirukumab versus placebo, and across categories within sirukumab dose groups.

Results: In the placebo, sirukumab 50 mg q4w, and sirukumab 100 mg q2w groups, respectively, 104, 119, and 118 pts had previously received non-anti-TNF biologic therapy, in addition to prior TNF therapy. Improvements were observed in all outcomes for sirukumab versus placebo, regardless of prior biologic use (**Table 1**). Significantly more pts achieved ACR20 at Wk 16 with sirukumab 50 mg q4w and 100 mg q2w compared with placebo (all *P* £0.003). Both doses of sirukumab led to significantly greater improvements in HAQ-DI change from BL at Wk 24 than placebo (all *P* £0.012). Significantly more pts (TNF only at both sirukumab doses and TNF + biologics taking sirukumab 100 mg q2w) achieved ACR50 and DAS28 (CRP) remission at Wk 24 with sirukumab treatment compared with placebo; TNF + biologics pts on sirukumab 50 mg q4w had only numerically higher rates of ACR50 and DAS28 (CRP) remission at Wk 24 compared with placebo.

Conclusion: In general, comparable efficacy was observed with both sirukumab doses between pts with active RA despite anti-TNF therapy who had received TNFs only and TNFs + other biologics.

Table 1. Key Endpoints by Prior Biologic Use

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016

Session Title: Rheumatoid Arthritis – Small Molecules, Biologics and Gene Therapy V: New Biologics and Remission Induction

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: ABT-122 is a dual variable domain immunoglobulin (DVD-Ig™) that targets human tumor necrosis factor-α (TNF-α) and interleukin-17A (IL-17A). The object was to investigate the long-term safety and maintenance of efficacy of dual cytokine inhibition with ABT-122 for 24 weeks following the completion of a 12-week double-blind study.

Methods: The 24-week open-label extension (OLE) enrolled 158 patients (pts) receiving background methotrexate (MTX). All received ABT-122 120 mg subcutaneously every other week (eow) with options for 1 extra 120-mg dose (for inadequate efficacy) or downtitration to 60 mg eow (for safety reasons). Safety assessments included adverse events (AEs) and laboratory parameters. Maintenance of efficacy at week 24 of the OLE was evaluated with ACR 20/50/70 responses and low disease activity and clinical remission defined by 28-joint Disease Activity Score using high-sensitivity C-reactive protein (DAS28[hsCRP]) or Clinical Disease Activity Index (CDAI). Analyses using nonresponder imputation (NRI) for missing data are presented.

Results: The AE frequency appeared to be unchanged from the double-blind study and in line with that seen with the adalimumab (ADA) control arm in the 12-week study. Most AEs were mild or moderate **(Table 1)**. Serious AEs were reported for 6 pts and included menorrhagia/anemia, myocardial ischemia, humerus fracture, joint dislocation, enterocolitis, and inflammation of the wound/skin ulcer; all events were unrelated to treatment as assessed by investigator and reported in a single term. Upper respiratory tract infection (n=14) and nasopharyngitis (n=4) were the most frequently reported infections. There were 1 nonserious report of basal cell carcinoma and 2 nonserious reports of liver events. There were no opportunistic infections, systemic hypersensitivity reactions, severe injection site reactions, cardiac failures, hematologic AEs, demyelinating disorders, or clinically concerning laboratory abnormalities. ABT-122 demonstrated consistent efficacy over 36 weeks across endpoints **(Table 2)**, including pts who switched from ADA to ABT-122. Two pts had a downtitration to ABT-122 60 mg eow starting at week 2 or 4. An extra 120-mg dose of ABT-122 was given in 5 pts. Overall ACR20/50/70 responses were 72.2%/48.7%/31.0% at week 24 of the OLE.

Conclusion: Dual cytokine inhibition of TNF-α and IL-17A with ABT-122 demonstrated good tolerability and maintenance of effect in the OLE when dosed up to 36 weeks in pts with rheumatoid arthritis receiving background MTX, including those switching from ADA to ABT-122.

Table 1. Safety in ABT-122 Phase 2 Study and following OLE

	Phase 2 Study (12 wk)				OLE (24 wk)
TEAE, n (%)*	ADA 40 mg eow (n=56)	ABT-122 60 mg eow (n=55)	ABT-122 120 mg eow (n=56)	ABT-122 120 mg ew (n=55)	ABT-122 120 mg eow (N=158)

Session Title: Rheumatoid Arthritis – Small Molecules, Biologics and Gene Therapy V: New Biologics and Remission Induction

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: The efficacy and safety of certolizumab pegol (CZP) treatment in combination with dose-optimized MTX in Japanese MTX-naïve early RA patients (pts) with poor prognostic factors have previously been reported.[1] Here, we report the factors at Week (Wk) 52 associated with the maintenance of clinical remission and radiographic non-progression after discontinuation of CZP treatment to Wk 104.

Methods: MTX-naïve early RA pts entered C-OPERA (NCT01451203)[1] and were randomized to CZP+MTX (n=159) or placebo (PBO)+MTX (n=157); oral MTX was escalated to 16 mg/wk by Wk 8, if tolerated (optimized MTX). After completing the 52-wk double-blind period, CZP or PBO was discontinued and MTX therapy continued up to Wk 104 (post-treatment [PT] period; CZP+MTX→MTX). All pts (n=108) who were initially randomized to CZP+MTX and entered the PT period were included in these analyses. Clinical disease activity, remission (SDAI, DAS28[ESR], Boolean, at Wks 52 and 104), and radiographic non-progression rates (change from baseline [BL] or Wk 52 ≤0.5 in van der Heijde modified Total Sharp Score [mTSS], joint erosion score, and joint space narrowing score) were calculated. Missing values used last observation carried forward (LOCF) for remission and linear extrapolation for radiographic outcomes. Post-hoc logistic regression analyses were used to investigate the Wk 52 factors (DAS28[ESR], HAQ-DI, mTSS, rheumatoid factor [RF], anti-CCP antibody, and MMP-3) associated with remission and radiographic non-progression. Factors with $p<0.1$ in univariate analyses were included in multivariate analyses.

Results: At Wk 52, 77.8%, 79.6%, and 61.1% pts were in DAS28(ESR), SDAI, and Boolean remission, respectively. Remission rates decreased from Wk 52 to Wk 104 after stopping CZP, although most pts maintained remission (Figure A). Over 90% pts who entered the PT period achieved radiographic non-progression during CZP+MTX treatment; the non-progression rate was maintained after stopping CZP from Wks 52–104 (Figure B). In sensitivity analyses, DAS28(ESR) at Wk 52 was associated with DAS28(ESR), SDAI, and Boolean remission at Wk 104 (odds ratio: 0.23, 0.29, 0.36); Wk 52 RF was associated with SDAI and

Boolean remission at Wk 104 (odds ratio: 0.67 and 0.69) (Table).

Conclusion: Clinical remission can be maintained up to an additional 52 wks after CZP discontinuation in early RA pts with poor prognostic factors. Both low disease activity and low RF at CZP discontinuation (Wk 52) were associated with the maintenance of clinical remission. Radiographic non-progression was observed even after CZP discontinuation at Wk 52. **References:** 1. Atsumi T. Ann Rheum Dis 2016;75(1):75–83

Figure A: Clinical remission rates by criteria in the post-treatment population from the CZP+MTX→MTX group (n=108) (LOCF)

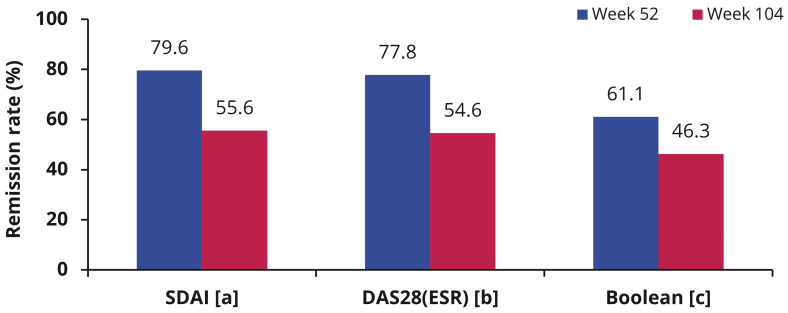

Figure B: Radiographic non-progression [d] rates in the post-treatment population from the CZP+MTX→MTX group (n=108) (linear extrapolation)

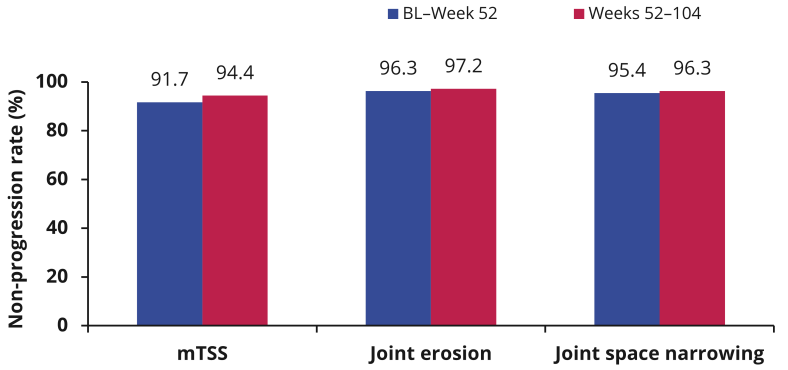

[a] SDAI ≤3.3; [b] DAS28(ESR) <2.6; [c] ≤1 on all of the following criteria: number of tender and swollen joint count (in 28 joints), CRP (mg/dL), and patient's global assessments of disease activity (0–100 mm visual analog scale converted to cm); [d] radiographic non-progression was defined as change from BL or Week 52 ≤0.5 in mTSS, joint erosion, or joint space narrowing score.

Table: Week 52 factors associated with disease activity and remission at Week 104 in the C-OPERA study

Session Title: Sjögren's Syndrome II: Basic Insights

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: Primary Sjögren's Syndrome (pSS) is characterized by lymphocytic infiltration of salivary glands. Unclear interactions between infiltrating cells and salivary gland ductal cells cause reduced gland function (hyposalivation), and significant decrease in patient quality of life. We recently isolated salivary gland stem cells from healthy human salivary gland biopsies, and characterized their self-renewal and differentiation capabilities. These stem cells are ductal cells and are therefore likely to be complicit in pSS manifestation. We sought to elucidate differences in salivary gland stem cells from pSS patients, compared to healthy controls.

Methods: Salivary gland stem cells were isolated as published from parotid gland biopsies of healthy control and pSS patients [1]. After 4 days, stem cells, grown as balls of cells termed 'salispheres', were dispersed into single cells and new salispheres generated. This passaging was repeated to ascertain the proliferative potential. Every week, culture medium samples were taken for mass spectrometry analysis. Immunohistochemistry stainings and electron microscopy were performed as standard.

Results: Yield of salivary gland stem cells from pSS biopsies was significantly lower than from healthy control tissues. The self-renewal capability of stem cells from pSS biopsies was markedly reduced compared to healthy control samples (Fig. 1). Secretome analysis via mass spectrometry revealed an abundance of keratins in culture medium, suggesting expulsion/secretion/mislocalization of keratins by ductal cells in pSS (Fig. 2). In preliminary data, ductal cells cytoplasm from pSS biopsies contained less keratins. Keratin fibers were observed extracellularly basally to pSS ductal cells by electron microscopy.

Conclusion: Our data demonstrates that there is an innate difference in regenerative potential and secretome of salivary gland stem cells from pSS biopsies compared to healthy controls. This deficit suggests an innate defect in stem cell ability to regenerate damaged glandular tissue in pSS, and may hereby contribute to the hyposalivation. We suggest for the first time that expulsion, secretion or mislocalization of keratins may underpin salivary gland stem cell defects in pSS and provide a novel insight into how salivary gland malfunction is manifested in pSS. Further characterization of stem cells from pSS biopsies, including organoid generation (mini salivary glands-in-a-dish), will further reveal mechanisms underpinning ductal cell involvement in pSS, and generate new therapeutic options.

Figure 1

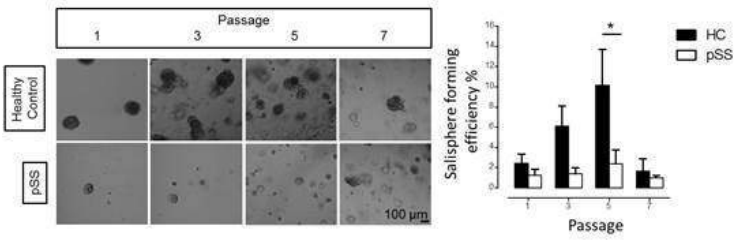

Figure 1. pSS-SGSCs display reduced regenerative potential.
A) Representative phase contrast microscopy of self-renewal cultures of SGSCs from healthy control (top row) and pSS biopsies (bottom row) with increasing passage number (week number). B) Quantification of salisphere formation efficiency in self-renewal cultures from healthy control and pSS biopsies. Error bars = S.E.M. $n = 9$ separate patient biopsies for healthy control, 8 for pSS cultures. [1] Pringle et al, 2016. Human salivary gland stem cells functionally restore radiation damaged salivary glands. Stem Cells34(4): 640-652.

Figure 2

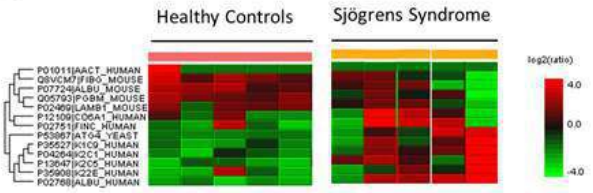

Figure 2. pSS-SGSCs secrete more keratins than HC-SGSCs.
Mass spectrometry was performed on conditioned medium collected from early passage SGSCs from healthy control (HC) and pSS cultures. Heatmap shows Log2 ratio of proteins detected, at a statistically different intensity (≥ 2.0 fold difference) and normalized for protein content. Blue box denotes human keratin proteins detected.

Session Title: Sjögren's Syndrome II: Basic Insights

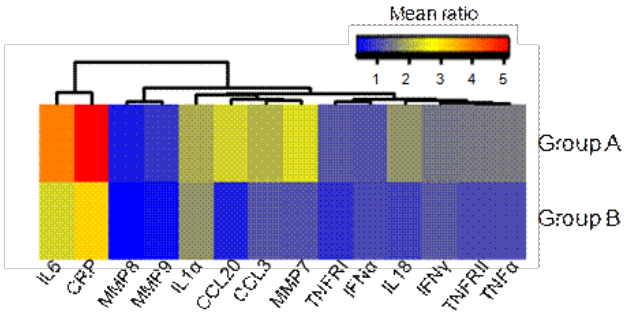
Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose : The goal of the IMI PRECISESADS project is to reclassify individuals affected by systemic autoimmune diseases (SADs) into clusters of molecular, instead of clinical entities. In this project, we investigated 40 individuals with primary Sjögren's syndrome (pSS), as diagnosed by the revised American-European classification criteria (3 men and 37 women, mean age: 56.3±12.3 years). and 53 healthy controls (HCs) (11 men and 42 women, mean age: 44.1±12.1 years) to determine whether a fine flow cytometry analysis of T and B cell distribution in whole blood could cluster individuals according to disease activity.

Methods: Two flow cytometry panels were designed. The first panel was dedicated to T cells and combined FITC-CD57, PE-CD45RA, PC7-CD62L, PC5.5-CD27, APC-CD38, AAF750-CD3, PB-CD4,KO-CD8 mAbs. The second panel was dedicated to B cells and combined FITC-IgD, PE-TACI, KO-CD5, PC7-CD24, PC5.5-CD27, PB-CD38, APC-CD19, AAF750-CD11b mAbs. Disease activity was determined according to ESSDAI. A Luminex-based system was used to analyze up to 88 cytokines, chemokines and soluble factors in serum of pSS patients and HCs.

Results: A combined analysis of T and B cell distribution highlighted two groups of individuals with a strong cluster of pSS patients in one of them. Indeed, the first cluster (group A) gathers together 24 pSS patients and 5 HCs while group B consists in 16 pSS patients and 49 HCs. Group A was characterized by the association of an increase of activated naïve B cells (IgD^+ $CD24^+$ $CD38^+$ $CD27^-$), a decrease of memory B cells (IgD^- $CD38^-$ $CD27^+$), an increase of central memory $CD4^+$ T cells ($CD45RA^-$ $CD62L^+$ $CD27^+$), an increase of effector memory $CD8^+$ T cells ($CD45RA^-$ $CD62L^-$ $CD27^-$) and a decrease of central memory $CD8^+$ T cells ($CD45RA^-$ $CD62L^+$ $CD27^+$) compared to group B and 91% of HCs. Interestingly, group A patients have a higher disease activity score when compared to group B (Mean ESSDAI score 5.0±1.9 versus 3.2±0.9 respectively). Finally, serum pro-inflammatory molecules (interleukin (IL)-6, C-reactive protein (CRP), Chemokine (C-C motif) ligand 20 (CCL20), CCL3, matrix metalloproteinase-7 (MMP-7), IL-18) were markedly up-regulated in group A patients compared to HCs and group B patients (See heat-map below).



Heat-map shows mean-ratio of pro-inflammatory molecule concentrations relative to HCs in each group of pSS patients.

Conclusion: A fine flow cytometry analysis of T and B cell subsets characterizes pSS patients with a higher disease activity score and a pro-inflammatory signature. Similar approaches are ongoing in the context of the PRECISESADS project for other SADs.

This work has received support from the EU/EFPIA Innovative Medicines Initiative Joint Undertaking PRECISESADS grant n° 115565.www.precisesads.eu

Session Date: Wednesday, November 16, 2016
Session Title: Sjögren's Syndrome II: Basic Insights
Session Type: ACR Concurrent Abstract Session
Session Time: 11:00AM-12:30PM

Background/Purpose: Bone morphogenetic protein 6 (BMP6) plays a critical mechanistic role in decreasing salivary gland dysfunction in primary Sjögren's syndrome (pSS) patients. Elevated BMP6 expression is associated with a loss of membrane water permeability and loss of gland function that is independent of inflammatory cell infiltration within the gland. The downstream signals activated by BMP6, which ultimately result in decreased salivary flow, are still unknown. BMP6 signals through type 1 receptors, which results in phosphorylation of SMAD1/5/8 transcription factors that ultimately alter gene expression within the nucleus. Two inhibitors,LDN-212854 and LDN-193189, have been developed to selectively target the ALK2 and ALK3 BMP type 1 receptors. This study examined the ability of these inhibitors to block BMP6 signaling, and their effect on expression of key proteins involved in salivary gland function and inflammation. We also investigated the ability of these inhibitors to restore salivary gland function in vivo.

Methods: BMP6 expression was detected in minor salivary glands (MSG) from N=80 pSS female patients (49.6 years old, range (21-74)) by immunofluorescent staining and quantified using Velocity software. Immunofluorescent staining was also used to confirm the presence of type I BMP6 receptors in human salivary glands. Water permeability was tested by regulated volume decrease (RVD) assay in BMP6 treated HSG cells with or without LDNs treatment, followed by observation of change of phospho-SMAD (pSMAD) expression as detected by Western blotting and immunofluorescent staining. In vivo activity of the ALK inhibitors was tested in C57BL/6.NOD-Aec1Aec2 mice, which have been shown to have decreased salivary gland function, by daily IP injection for 24 days and subsequent assessment of salivary gland flow rates. At the end of the study, local and systemic immune response was investigated by flow cytometric assay. In addition, the levels of pSMAD and aquaporin-5 (AQP-5) expression in submandibular glands from LDN treated mice were measured.

Results: Elevated BMP6 was found in 63/80 (78.8%) of pSS patients examined in this study. In humans, ALK2 and ALK3 receptors were found on both ductal and acinar cells. In vitro treatment of HSG cells with ALK2/3 inhibitors resulted in decreased BMP6 signaling and SMAD 1/5/8 phosphorylation and led to a recovery of fluid movement. Furthermore, daily treatment, with either inhibitor, of C57BL/6.NOD-Aec1Aec2 mice with established decreased salivary gland function, restored salivary flow rate. Associated with this increase in salivary flow was an increased expression of AQP5, a protein critical for membrane water permeability in salivary glands. LDN treatment also decreased infiltrating IFN-gamma producing CD4+ T cells in submandibular glands from C57BL/6.NOD-Aec1Aec2 mice.

Conclusion: BMP6 expression is increased in a majority of pSS patients. Treatment with BMP6 inhibitors can reverse the loss of function within the salivary gland as well as decrease inflammation. These findings suggest that inhibition of BMP6 is a promising approach to the treatment of primary Sjögren's syndrome.

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016
Session Title: Sjögren's Syndrome II: Basic Insights
Session Type: ACR Concurrent Abstract Session
Session Time: 11:00AM-12:30PM

Background/Purpose: Sjögren's syndrome (SS) is a complex autoimmune disease with both environmental and genetic factors contributing to pathophysiology. The goal of this genome-wide association study (GWAS) was to identify SS risk loci that exceed the genome-wide significance (GWS) threshold of 5x10E-8 in European-derived cohort.

Methods: We studied >20,000 subjects that were genotyped on OMNIexpress, OMNI1-Quad, or OMNI2.5 Illumina arrays. Following application of strict standard quality control measures, a total of 2,809 independent SS cases and 17,102 population controls remained. Analysis was performed using logistic regression and accounted for ancestry (first 4 principal components) and gender.

Results were combined using a weighted Z-score method to determine meta P-values. Results: In total, 3101 variants exceeded the GWS threshold and were supported by more than one dataset. The majority of these variants were located within previously established SS risk loci such as *HLA, IRF5, STAT4*, and *TNIP1*. In addition, 3 novel loci were identified that exceeded GWS. The first effect was located within the 5' untranslated region of the gene *NAB1* (NGFI-A binding protein 1) peaking at rs2293765 (P_{meta}=3x10E-11; odds ratio (OR)=1.23). Bioinformatics data in this region denote epigenetic marks that are indicative of enhancer activity in T cells, B cells, monocytes, and neutrophils. Moreover, variation at rs2293765 has also been shown to alter expression in monocytes of neighboring genes including *GLS* (interferon (IFN) stimulation), *TMEM194B* (LPS stimulation), and MFSD6 (naïve). NAB1 has been shown by others to form a complex with EGR3 leading to transcriptional downregulation of the IFNGR1 locus upon IFN stimulation. The second novel effect is a missense allele, rs2304256 (V>F; P_{meta}=1.22x10E-9; OR=0.81), located within *TYK2* (tyrosine kinase 2) and predicted to be damaging in 5 transcripts resulting from this locus by SIFT. Additionally, this variant is predicted to influence the expression in monocytes of multiple genes in the region under various conditions: IFN stimulation (*ICAM1, TMED1*), LPS stimulation (DNMT1), and naïve (*ICAM3, TYK2*). TYK2 is a Janus kinase family member that is responsive to both type I and III IFN signaling. The third novel effect maps to the intergenic space between PTTG1 (pituitary tumor-transforming 1) and mir-146a, peaking at rs2431697 (P_{meta}=3.38x10E-9; OR=0.82). Epigenetic marks in this region indicate enhancer element function in T cells, neutrophils, and monocytes as well as expression changes of *PTTG1* in whole blood. To date, the role of PTTG1 in the immune system remains elusive, but this locus is a risk factor for various forms of cancer. In addition, several loci showed suggestive association with SS (P_{meta}<1x10E-5) including *XKR6*, *PDHX-CD44*, and *ELMO1*.

Conclusion: We have established three novel genetic associations with SS involved in pathways important in the disease pathology. Further replication, imputation, fine mapping, and functional studies are needed to elicit the precise causal variants and the impact on SS etiology.

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016
Session Title: Sjögren's Syndrome II: Basic Insights
Session Type: ACR Concurrent Abstract Session
Session Time: 11:00AM-12:30PM

Background/Purpose: The miRNAs of the miR-200 family are critical regulators of oncogene and tumor suppressor genes. A preliminary study of several miRNAs in the MSGs of SS patients, including 4 patients with MALT lymphoma, suggested that the expression of miR200b-5p may be down-regulated in lymphoma (*Gourzi et al., Clin Exp Immunol. 2015*). The aim of our study is to validate the down-regulation of miR200b-5p in MSGs of patients with SS-related lymphoma and to investigate whether its expression is deregulated before lymphoma development.

Methods: miR200b-5p expression was analyzed by quantitative real-time PCR in total RNA from MSG tissues obtained from 74 SS patients and 9 patients with non-SS sialadenitis associated with sarcoidosis, HCV infection (4 each) or HBV (1 that was also diagnosed with MALT lymphoma). The SS patients group included 28 patients that did not develop lymphoma during follow up (without lymphoma; median follow up time since biopsy performance, range: 6yrs, 1-12.75yrs), 17 patients that developed lymphoma in the future (prelymphoma; median follow up time till lymphoma diagnosis, range: 3.67yrs, 0.42-8.5yrs, 13 MALT, 2 NMZL, 1 DLCBL and 1 SLL) and 30 patients with SS-associated lymphoma at the time of biopsy (lymphoma; 23 MALT, 2 NMZL, 2 DLCBL,1 BALT, 1 LP and 1 SLL). Prelymphoma and lymphoma MSG samples were obtained from the same SS patients in 13 cases (10 MALT, 2 NMZL and 1 DLCBL). Differences in miR200b-5p expression levels among the studied groups was analyzed by Tukey's multiple comparison test, whereas repeated measures analysis was employed to evaluate whether miR200b-5p expression changes over lymphoma development (in the prelymphoma and lymphoma MSGs from the 13 patients).

Results: miR200b-5p was significantly down-regulated in MSG tissues of prelymphoma and lymphoma SS patients (mean relative expression±SE: 0.38±0.10 and 0.27±0.06, respectively) compared to SS patients without lymphoma (0.77±0.12; $p \leq 0.05$ and $p \leq 0.001$ for pre- and lymphoma, respectively) or non-SS sialadenitis (0.82±0.25, $p \leq 0.05$ and $p \leq 0.01$, respectively). The expression of miR200b-5p was not found to differ between patients with SS without lymphoma and non-SS sialadenitis, or pre-lymphoma and lymphoma SS patients. Interestingly, low expression of miR200b-5p (0.17) was detected in the MSG tissue obtained from the HBV-infected patient that had MALT lymphoma. Finally, the expression levels of miR200b-5p were not found to differ in prelymphoma and lymphoma tissues of the 13 patients that had both samples.

Conclusion: The significantly lower expression of miR200b-5p in SS associated MALT lymphoma implicates it in lymphomagenesis, whereas its significant down-regulation in prelymphoma MSGs suggests that miR200b-5p can serve as a prognostic marker for future lymphoma development. The cell types that express miR200b-5p and the molecular pathways that regulates are under investigation.

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016
Session Title: Sjögren's Syndrome II: Basic Insights
Session Type: ACR Concurrent Abstract Session
Session Time: 11:00AM-12:30PM

Background/Purpose: Primary Sjögren's syndrome (pSS) is a systemic autoimmune disease characterized by lymphocytic infiltration of the exocrine glands and dryness of mouth and eyes. Type-1 classical dendritic cells (cDCs) are very potent antigen presenting cells known to induce strong T-cell proliferation and cytokine production. Despite the fact that especially cDC1s are candidate key players in the activation of local T and B-cells in pSS, they have rarely been studied in pSS. Considering the critical role of micro-RNAs (miRNAs) in regulation of gene expression, we investigated miRNA expression in isolated cDC1s of patients with pSS.

Methods: Two independent cohorts (discovery and validation) were established, consisting of 29 pSS patients who were classified according to the 2002 criteria. 17 healthy controls (HC) were included as control group. cD1c+ CD19- cells were isolated from peripheral blood using MACS and we performed miRNA profiling of 758 miRNA targets using the OpenArray platform in the donors included in the discovery cohort. A selection of 15 miRNAs found to be differentially expressed in the pSS group versus the control group (at $p<0.05$, with at least a difference between the groups of log2) was measured in the independent validation cohort using a custom made array. We performed pathway enrichment with the experimentally supported targets of the validated miRNAs to assess their function in these cells.

Results: A total of 24 miRNAs were downregulated in pSS patients versus HC in the discovery cohort. Of these, 16 targets were selected for validation. Pathway enrichment showed that the experimentally supported targets of these miRNAs are mainly involved in growth-factor signalling and vesicle trafficking ($p<0.05$, FDR corrected). We are currently performing functional experiments in primary cells to dissect the effects of the dysregulated miRNA expression in these cells.

Conclusion: miR-130a and miR708 are significantly downregulated in cDC1s of patients with pSS, which indicates dysregulation in a range of pathways that are involved in DC function. These are the first data from primary cells to indicate dysregulation of type-1 cDCs in this group of patients, urging for further assessment of these cells in future studies.

Session Date: Wednesday, November 16, 2016
Session Title: Systemic Lupus Erythematosus – Clinical Aspects and Treatment VI: Quality of Life
Session Type: ACR Concurrent Abstract Session
Session Time: 11:00AM-12:30PM

Background/Purpose: Poor SLE outcomes have been associated with certain clinical and socio-demographic characteristics, but the determinants of patient reported outcomes (PROs) in SLE are unknown. PROMIS, recently validated in SLE, offers dynamic computer adaptive tests (CATs) that precisely and efficiently measure PROs in physical, mental, and social health domains. The

aims of this study were to identify clinical and demographic characteristics independently associated with worse health status in SLE patients as measured by PROMIS CATs.

Methods: Adults meeting ACR SLE classification criteria were recruited from an SLE Center of Excellence. Subjects completed 4 PROMIS CATs: physical function, fatigue, pain interference, ability to participate in social roles. SLE disease activity, flare, and damage were evaluated with the SELENA-SLEDAI and SLICC-ACR damage index. Multivariable generalized linear models were used to assess the cross-sectional association between PROMIS CAT scores and clinical and demographic traits. All variables with $p < 0.2$ in univariate analyses were included in the multivariable analyses. 2-Way interaction terms were considered and significant interaction terms ($p < 0.05$) were included in the final models if doing so provided models of better quality (indicated by lower Akaike and Bayesian Information Criterion values).

Results: A diverse group of 204 SLE patients completed PROMIS CATs (table 1). Black race, Hispanic ethnicity, disability, Medicaid, active arthritis, SELENA-SLEDAI flare, history of cognitive impairment/psychosis, deforming/erosive arthritis, and avascular necrosis were associated with statistically and clinically significantly worse PROMIS scores in univariate analyses. In the final multivariable model only disability and active arthritis were independently associated with worse physical function, fatigue, and social participation, while arthritis and cognitive impairment/psychosis were independently associated with worse pain interference.

Conclusion: Surprisingly, neither flare status nor socio-demographic characteristics were independently associated with these four important PROs, whereas active arthritis, disability, and a history of cognitive impairment/psychosis were. These data suggest that: 1) pain and physical and mental dysfunction drive patient well-being regardless of race, ethnicity, and insurance type; and 2) the physician-derived SELENA-SLEDAI flare measure poorly captures the impact of disease activity on SLE patients.

SESSION INFORMATION
Session Date: Wednesday, November 16, 2016
Session Title: Systemic Lupus Erythematosus – Clinical Aspects and Treatment VI: Quality of Life
Session Type: ACR Concurrent Abstract Session
Session Time: 11:00AM-12:30PM

Background/Purpose: To systematically review the literature on the: 1) prevalence of depression and anxiety in SLE patients and 2) metrics of depression and anxiety.

Methods : This review was conducted based on the recommendation of Preferred Reporting Items for Systematic Reviews and Meta-Analysis-Protocols statement. A literature search (1954-2016) was performed in Ovid Medline, Embase, Psyc INFO and CINAHL for articles on the prevalence of depression and/or anxiety in adult SLE patients or on the metrics of depression/anxiety. Included studies were critically appraised and analyzed. The prevalence of depression and anxiety was studied for all instruments and whenever possible Pooled Prevalence (PP) was determined in the commonly used instruments [Centre for Epidemiological Studies - Depression (CES-D), Beck Depression/Anxiety Inventory (BDI/BAI), Hospital Anxiety/Depression Scales (HADS-D/A), Hamilton Rating Scales for Depression/Anxiety (HAM-D/A)].

Results: A total of 4394 references were identified, 278 were selected for detailed review and 121 were included in the final analysis**.** *Depression:* PP of Depression was 35.2% (95% CI: 30.1, 40.5%) (Figure 1A) based on data from 70 studies in 23399 patients. *Anxiety:* PP of Anxiety was 24.2% (95% CI: 17.9, 31.2%) (Figure 1B) based on data from 39 studies in 4495 patients. *CES-D:* was utilized in 13 studies in 1856 patients. Depression PP was 41.5% (95% CI: 35.1, 48.1%). *BDI/BAI:* was utilized in 14 studies in 1355 patients and 3 studies in 489 patients respectively. Depression PP was 39.9% (95% CI: 31.1, 49.1%) and Anxiety PP was 38.4% (95% CI: 34.2, 42.8%). *HADS-D/A:* was utilized in 14 studies in 1238 patients and 12 studies in 1099 patients respectively. Depression PP was 24.4% (95% CI: 19.1, 30.1%) and Anxiety PP was 38.3% (95% CI: 29.1, -47.9%). *HAM-D/A:* was utilized in 5 studies in 323 patients and 5 studies in 269 patients respectively. Depression PP was 43% (95% CI: 27.9, 58.7%) and Anxiety PP was 37.3% (95% CI: 31.7, 43.2%). We found high variability in the prevalence of depression and anxiety, and high statistical heterogeneity (I^2> 75%) which is attributed to the: 1) lack of standardization in the metrics and definitions of depression and anxiety in SLE, and 2) variability in other demographics such as patients age, education levels and other factors that associate/predict depression and/or anxiety.

Conclusion: The prevalence of depression/anxiety is high in patients with SLE, ranging from 5.7% to 78.6% and 1.1% to 71.4%, respectively. The CES-D, BDI, HAM-D yielded a similar prevalence of depression, ranging between 27.9% and 49.1%, whereas the prevalence of depression with the HADS-D was lower.(24.4%). All metrics (BAI, HADS-A, HAM-A) of anxiety yielded a similar prevalence of anxiety prevalence ranging between 29.1% and 47.9%.

Session Date: Wednesday, November 16, 2016

Session Title: Systemic Lupus Erythematosus – Clinical Aspects and Treatment VI: Quality of Life

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: Systemic lupus erythematosus (SLE) is a chronic autoimmune disorder that causes long-term organ damage over time and impairment in health-related quality of life (HRQoL). We examined the long-term administration of belimumab plus

standard of care (SoC) on HRQoL and fatigue in patients with autoantibody-positive SLE.

Methods: This multicenter continuation study (GSK study 112233, NCT00724867; Aug 2008–Mar 2015) enrolled patients who completed the BLISS-76 randomized controlled trial (RCT) in the US. Patients on belimumab in the RCT continued to receive the same dose (1 or 10 mg/kg IV, every 28 days; all 10 mg/kg post-Mar 2011) plus SoC (belimumab/belimumab group). Those who previously received SoC alone (the RCT placebo [PBO] group) received belimumab 10 mg/kg IV (PBO/belimumab group). Primary outcome measures included long-term safety and efficacy of belimumab, including HRQoL and fatigue, every 48 weeks including HRQoL and fatigue by Short Form-36 v2 (SF-36) Medical Outcomes Survey and Functional Assessment of Chronic Illness Therapy (FACIT)-Fatigue scale, respectively. As the primary endpoint was safety, the baseline (BL) for this analysis was at start of belimumab administration.

Results: The modified intent-to-treat population comprised 268 patients; 140 completed the continuation study, and 128 withdrew (patient request: n=31; adverse events: n=25). At BL, patients in the PBO/belimumab group reported higher SF-36 Physical (PCS) and Mental (MCS) Component, and FACIT scores than the belimumab/belimumab group (**Table**). Patients receiving long-term belimumab reported continued HRQoL and fatigue benefits, with improvements in SF-36 PCS, MCS and FACIT scores up to Year 6 Week 48 (**Table**). Mean changes from BL in the belimumab/belimumab group also exceeded minimum clinically important differences (MCID) at each yearly assessment to Year 6 (SF-36 PCS [range; 4.90–8.31], SF-36 MCS [range; 3.85–4.90], FACIT [range; 5.75–6.85]). At Year 6 Week 48, mean changes from BL in SF-36 domain scores exceeded MCID in 6 of 8 domains: bodily pain, general health, physical functioning, role physical, social functioning, and vitality.

Table: HRQoL scores from BL to Year 6 Week 48 (SF-36v2 health survey and FACIT-Fatigue)

	PBO/belimumab			Belimumab/belimumab			Total		
Mean (SD)	BL[1] (N=91)	Year 6 Week 48 (N=58)	Change from BL to Year 6 Week 48 (N=58)	BL (N=177)	Year 6 Week 48 (N=127)	Change from BL to Year 6 Week 48 (N=127)	BL (N=268)	Year 6 Week 48 (N=184)	Change from BL to Year 6 Week 48 (N=184)
SF-36v2 PCS	42.00 (9.839)	43.31 (10.225)	0.88 (7.790)	34.47 (8.975)	40.90 (9.837)	6.57 (9.566)	37.04 (9.927)	41.65 (9.995)	4.79 (9.406)
SF-36v2 MCS	47.90 (10.307)	48.76 (10.826)	-0.58 (9.287)	42.44 (11.425)	46.16 (11.812)	4.21 (11.805)	44.30 (11.338)	46.98 (11.546)	2.71 (11.274)
FACIT-Fatigue score	31.22 (13.284)	31.75 (13.995)	-0.37 (9.541)	24.06 (11.237)	29.54 (13.258)	5.58 (12.274)	26.50 (12.423)	30.24 (13.495)	3.70 (11.787)

[1]Baseline was set to the start of belimumab treatment. As such, the baseline values for the group assigned to PBO in the RCT study have higher HRQoL and fatigue scores (i.e. less disability and fatigue) and lower disease scores compared with the group commencing belimumab *de novo* in the RCT.

Conclusion: Largest improvements in HRQoL and fatigue were reported in Year 1 of treatment, and maintained during long-term exposure to belimumab. Although reported improvements in the belimumab/belimumab group were greater than those in the PBO/belimumab group, these changes may have been confounded by differences in BL SF-36 scores, as well as SoC treatment with optimized medical care during the RCT. These data suggest that long-term control of disease activity with belimumab plus SoC translates into meaningful benefits in patient fatigue and HRQoL. **Disclosure:** Study funded by GSK and Human Genome Sciences, Inc. Session Title: Systemic Lupus Erythematosus – Clinical Aspects and Treatment VI: Quality of Life

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose:

To describe demographic, socio-economic and lupus-related factors associated with health-related quality of life (HRQOL) in systemic lupus erythematosus (SLE), as measured by 2 generic (Medical Outcome Study Short Form 36 [SF-36] and World Health Organisation Quality of life [WHOQOL] and 2 disease-specific (LupusQoL and SLEQOL) questionnaires recorded simultaneously.

Methods:

We conducted a prospective study involving SLE patients in 10 French tertiary hospitals. Disease activity was recorded by SELENA-SLEDAI (SS) and SS Flare Index Revised [SFI-R] alongside HRQoL and sociodemographic variables. Social precariousness was recorded using the validated "EPICES" questionnaire. Factors influencing HRQOL scores were studied using multivariate linear regression. All scores were transformed to a 0-100 scale (100 corresponding to the best QoL)

Results:

We included 336 patients, of whom 90% were women, mean age (SD) was 41(11.9), 51% were caucasian. Median (IQR) SLEDAI was 4 (0-8), and 39% of patients had at least a moderate flare. Social precariousness was recorded in 38% of patients, 62% had an education level greater than General Education Diploma and 31% were unemployed.

In multivariate analysis (figure 1), we found no effect of ethnicity on HRQOL. Social precariousness was strongly associated with the QoL score in all domains of generic and specific questionnaires, with mean estimated decreases ranging from -6.5 (SF-36 "Physical Functioning, p=0.02) to -17.84 (SLEQOL "Mood", p<0.0001). The occurrence of an articular flare was also associated with a decrease in HRQOL in all domains (e.g. -19.6 in SF-36 "Role Physical" [p<0.0001] and -10 in SLEQOL "mood", [p=0.01]), except for "psychological" and "environment" domains of the WHOQOL. Neuropsychiatric signs had a higher impact on specific questionnaires (figure 1). Obesity was associated with a significant decrease in HRQOL in SF-36 physical-related domains (-12.9, p=0.02 in "physical function" domain), but not in disease-specific questionnaires, except for the LupusQoL "Body Image" Domain (-8.57, p=0.02). Similarly, smoking was associated with a poorer HRQOL in some of the physical domains of generic questionnaires (-5.57 in WHOQOL "physical heath", p=0.03), but not with disease-specific ones.

Conclusion: The social environment is highly associated with HRQOL in SLE patients, regardless of the instrument or domain. Disease-specific questionnaires may be more strongly correlated with some aspects of the disease and may be useful to distinguish the SLE-specific burden from other conditions such as obesity or smoking-related disease.

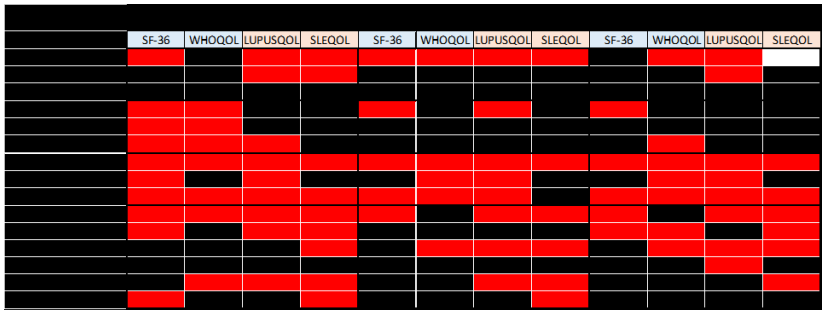

Figure 1: Summary of multivariate analysis. A red square indicates a significant independent association in multivariate linear regression ($p<0.05$) between a variable and at least one QoL domain score

Session Date: Wednesday, November 16, 2016

Session Title: Systemic Lupus Erythematosus – Clinical Aspects and Treatment VI: Quality of Life

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: SF-36 and LupusQoL are Health-Related Quality-of-Life (HRQoL) questionnaires used in SLE. We determined: (1) concurrent construct validity of SF-36 and LupusQoL against disease activity in patients with moderate-to-severely active lupus and (2) intra-individual responsiveness and its magnitude for both questionnaires' domains.

Methods: 99 active SLE patients [SLEDAI-2K ≥6] were recruited from a single centre. Patients completed both questionnaires at baseline and follow-up visits. Questionnaires' domains scores were correlated with SLEDAI-2K and evaluated for floor/ceiling effects. Anchors for responsiveness were defined by: 1-Minimal Clinically Important Difference (MCID) definitions of SF-36, 2-MCID of LupusQoL and 3- SLEDAI-2K. Each of these anchors grouped patients as improved, same, or worsened. The magnitude of change was measured with Standardized Response Means (SRMs).

Results: In the 99 patients, SLEDAI-2K was 7.7±5.2 at baseline and 6.5±4.8 on follow-up at 4.7±3.1 months. SLEDAI-2K did not correlate with questionnaires' domains confirming that HRQoL is an independent domain not associated with disease activity. Correlations among "comparable" domains of both questionnaires ranged from 0.70-0.79. Floor effect was present in 2 SF-36 domains (Role Emot, Role Phys). Ceiling effect was present in 4 SF-36 domains (Bod Pain, Role Emot, Role Phys, Social Funct) and 3 LupusQoL domains (Pain, Planning, Intimate Relat). The number of patients with worsening/improvement in the domains of SF-36 and LupusQoL is represented in table 1. The magnitude of change (SRM) for all domains were small when SLEDAI-2K was an anchor and large when MCID of SF-36 or LupusQoL were anchors (Figure 1 and 2). Responsiveness of SF-36 and LupusQoL using SLEDAI-2K as an anchor (47% patients improved and 16% worsened) was small (SRMs ranged -0.3–+0.3).

Conclusion: In active lupus patients, both SF-36 and LupusQoL are responsive to change with large SRMs in improving and worsening patients. Lupus-specific domains in LupusQoL (planning, burden to others, body image and intimate relationships) showed large SRMs. SF-36 and LupusQoL are acceptable questionnaires for monitoring HRQoL in patients with SLE.

Table 1. Number of patients with worsening, same and improvement in SF-36 and LupusQoL domains in 99 patients

	SF-36 N=99 patients									
	Comparable domains of SF-36 and Lupus QoL				Non-Comparable domains of SF-36 and Lupus QoL

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016

Session Title: Systemic Lupus Erythematosus – Clinical Aspects and Treatment VI: Quality of Life
Session Type: ACR Concurrent Abstract Session
Session Time: 11:00AM-12:30PM

Background/Purpose: Depression is commonly seen in lupus, but widely varying prevalence rates have been reported. This may be due to different demographics and characteristics or varying detection methods across studies. Furthermore, few studies have looked at depression prevalence in lupus patient cohorts inclusive of both children and adults. Better describing the frequency of symptoms of depression in a lupus population at high risk for depression may help identify target populations for screening, treatment, and possible prevention.

Methods: Lupus patients at three affiliated hospitals, regardless of age, who met ACR criteria were enrolled in the Einstein Lupus Cohort. Patients enrolled in the cohort who agreed to depression screening, were given the Patient Health Questionnaire-9 (PHQ9), and extensive clinical and epidemiological data was recorded. Differences in prevalence rates were investigated across age groups using a chi-square analysis. Differences between pediatric and adult patients were examined in relation to depression symptoms and clinical and demographic characteristics by chi-square and Mann-Whitney U tests. Logistic regression was used to identify potential predictors for depression in the cohort.

Results: The median age was 28.4 (IQR 19.5, 45.3) for 175 screened patients; 47.7% were black, 45.5% Hispanic, and 6.9% other; 82% were Medicaid-enrolled; 31.4% had positive PHQ9 screens. Pediatric patients were similar to adult patients in most demographics and clinical characteristics, but had lower rate of comorbid chronic pain syndromes and previously diagnosed psychiatric disease. There was no linear correlation between age and depression, but a peak in prevalence of 50% was seen among patients 22-29 years old compared to a relatively low rate of 16.7% among 18-21 year olds (Fig. 1). Pediatric patients reported statistically significant lower rates of guilt and psychomotor changes, while rates of other endorsed depression symptoms were similar (Fig. 2). There were no significant predictors found for depression in the cohort, including steroid dose and disease activity measured by SLEDAI.

Conclusion: Younger patients with lupus have different depression symptoms than adults. A very high rate of depression was seen in young adult patients from our cohort, especially compared to patients immediately preceding them in age. Our observations have important implications for transitioning processes for teenage lupus patients, and may indicate the need to target adolescence for preventative measures to help minimize the substantial disease burden of depression that may occur in subsequent years.

Session Date: Wednesday, November 16, 2016

Session Title: Systemic Lupus Erythematosus – Human Etiology and Pathogenesis II

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: Ro/SSA autoantibodies and an IFN signature are commonly present in women with Sjögren's syndrome and SLE. During pregnancy, the autoantibodies are transported across the placenta and are associated with a risk of neonatal lupus erythematosus (NLE) including a congenital heart block (CHB) in the baby. Hydroxychloroquine, which inhibits toll like receptor signaling and decreases activity in the type 1 IFN system has been suggested to decrease the risk of NLE. Whether activation of the interferon system occurs in the baby is however not known. In the present study we therefore investigated whether the type 1 IFN system is activated in Ro/SSA autoantibody exposed newborns.

Methods: Seven Ro/SSA autoantibody positive mothers receiving no medication and 3 mothers treated with hydroxychloroquine and/or azathioprine and their newborn babies were included in the study together with 8 healthy mother-baby pairs. Blood was drawn from the mother and cord at birth, with immediate separation into plasma and peripheral blood mononuclear cells (PBMCs). Autoantibodies were analyzed by ELISA and IFN-α by DELFIA. Cell surface expression of molecules was investigated by flow

cytometry, and mRNA expression by microarrays. mRNA expression data was used for calculating an IFN score.

Results: Ro/SSA antibody positive women without treatment and their babies had higher levels of IFN-α than control mothers and control babies, respectively. Activation of the IFN system with increased expression of IFN-regulated genes was observed in both the Ro/SSA antibody positive women and their babies, with a significant correlation between maternal and fetal IFN-scores (R^2=0.53, p=0.005). Further, increased expression of MHC class II was observed on CD14+ monocytes in the Ro/SSA antibody exposed babies, suggesting higher activation of these cells. In babies of mothers receiving immunomodulatory treatment, the IFN score was similar to that of healthy control babies.

Conclusion: Babies exposed to Ro/SSA autoantibodies *in utero* have circulating IFN-α, an IFN-signature in their PBMCs and increased MHC class II expression on the cell surface of monocytes, which is partly reversed by treatment with hydroxychloroquine or other immunomodulatory drugs. This study proposes that fetal activation of the type I IFN system may contribute to the risk of NLE.

Session Title: Systemic Lupus Erythematosus – Human Etiology and Pathogenesis II

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: Cutaneous lupus erythematosus (CLE) lesions are disfiguring, scarring, difficult to treat, and affect up to 70% of patients with systemic lupus erythematosus (SLE). Type I interferons (IFN) are important in the pathogenesis of SLE and CLE, yet we have insufficient data on the source of type I IFNs in the skin and the effects of type I IFNs on cutaneous inflammatory predisposition. In this work, we investigate a novel keratinocyte-produced type I IFN, IFNκ, in promotion of epidermal inflammation and CLE.

Methods: SLE patients for study had biopsy-proven history of CLE and met 4/11 ACR criteria for SLE. Primary keratinocytes were isolated and cultured from the upper thigh of control or SLE patients. SLE keratinocytes were taken from unaffected skin. Keratinocytes from control and SLE patients were cultured and IL-6 production was measured after stimulation with toll-like receptor (TLR) ligands and ultraviolet light (UV). Neutralizing antibodies to the type I interferon (IFN) receptor and IFN kappa were used to define the role of type I IFNs on IL-6 production. IFN kappa production was measured via ELISA. Type I IFN expression in 80 CLE lesions was determined via microarray. IFNκ expression in CLE lesions was confirmed via immunohistochemistry.

Results: Keratinocytes from unaffected skin of lupus patients produced significantly more IL-6 compared with healthy controls following exposure to TLR2 agonist or UVB radiation. This increased IL-6 production was duplicated in control keratinocytes after

pretreatment with type I IFN. Importantly, secretion of keratinocyte-specific IFNκ was significantly increased after TLR2 and UVB treatment in lupus vs. control keratinocytes and neutralization of the type I IFN receptor or IFNκ was sufficient to abrogate the enhanced IL-6 production by lupus keratinocytes. *In vivo* relevance was documented as IFNκ was one of only two significantly increased type I IFNs in both discoid and subacute subtypes of CLE. Immunohistochemistry confirmed epidermal and dermal expression of IFNκ in CLE.

Conclusion: IFNκ is a novel type I IFN that is produced more abundantly by lupus vs. control keratinocytes. Importantly, it is a regulator of the hyperinflammatory response in lupus keratinocytes and is the most significantly regulated type I IFN in CLE lesions. Our data thus support a regulatory loop in which IFNκ is secreted by lupus keratinocytes and primes them for a robust interferon and inflammatory response following stimulation with microbial ligands or UV. IFNκ may thus serve as a novel and organ-specific target for treatment or prevention of CLE.

Session Title: Systemic Lupus Erythematosus – Human Etiology and Pathogenesis II

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: Systemic lupus erythematosus (SLE) disproportionately affects African Americans, and the development of SLE is believed to be triggered by exposure to one or more specific environmental factors in genetically susceptible individuals. Tobacco smoke has been implicated as such a potential agent. In this study, we sought to discover whether smoking and/or secondhand smoke inhalation interacts with certain candidate genes, resulting in elevated risk of SLE in African Americans.

Methods: A case control design was used, and all subjects were African Americans of Gullah ancestry, from the Sea Islands of South Carolina or Georgia. All cases met ACR classification criteria for SLE, and all controls were evaluated by a rheumatologist and determined unaffected by autoimmune disease at the time of enrollment. All subjects completed questionnaires to assess smoking history and exposure to secondhand smoke. Candidate genes included ones previously identified in the literature as interacting with tobacco smoke in rheumatic diseases, and genes in the Comparative Toxicogenomics Database that were relevant to tobacco smoke or in an inference network between tobacco smoke and SLE. Genotypic data was available on subjects genotyped on the Illumina Immunochip genotyping array. After standard GWAS quality control, the following were available for analyses: *NAT2* (4 single nucleotide polymorphisms [SNPs]), *HLA-DRB1* (6 SNPs), *APOE* (2 SNPs), *IL6* (17 SNPs), *CXCL8* (1 SNP), *IRF5* (20 SNPs), *ITGAM* (67 SNPs), and *ITGAX* (31 SNPs). Logic forest, a relatively novel machine learning algorithm we developed, was used to highlight interactions between the environment (i.e. tobacco smoke) and the variants in the candidate genes.

Results: The study population included 204 participants (n=100 cases, n=104 controls), 86% of whom were female. The logic forest model identified secondhand smoke exposure during childhood as the most important predictor of SLE status. Consistent with the literature, the model identified several SNPs in the IRF5, ITGAM, and ITGAX genes as being risk factors for SLE. Although passive smoke exposure during childhood was of high importance and identified as a main effect, the logic forest detected weak to

moderate interactions (odds ratios ranging from 2.3 to 2.5) between it and SNPs in the *ITGAM* gene.

Conclusion: In this case-control study, both genetic and environmental risk factors for SLE were identified, with evidence suggesting potential interactions between exposure to secondhand smoke as a child and genetic variation in the *ITGAM* gene.

Session Title: Systemic Lupus Erythematosus – Human Etiology and Pathogenesis II

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: Systemic lupus erythematosus (SLE) is a chronic autoimmune disease characterized by autoantibody production and dysregulated interferon responses. Genome-wide association studies (GWAS) have identified more than 80 susceptibility or risk genes/loci associated with SLE and other autoimmune diseases, including TNFAIP3 interacting protein 1 (*TNIP1*). *TNIP1* encodes the adaptor protein ABIN1, which functions in the immune system by restricting NF-κB signaling. Previous fine mapping of the *TNIP1* locus demonstrated significant associations with SLE and single nucleotide polymorphisms (SNPs) that are carried on two independent risk haplotypes within *TNIP1*. Both risk haplotypes demonstrated reduced expression of *TNIP1* mRNA and ABIN1 protein. In this work we characterize associated SNPs in *TNIP1* and identify candidate causal SNPs that influence hypomorphic expression of *TNIP1*.

Methods: Eleven *TNIP1* SNPs from both SLE risk haplotypes which have lower binding scores (RegulomeDB) were selected for electrophoretic mobility shift assays (EMSA) to evaluate whether SLE risk alleles affect binding of nuclear protein complexes extracted from different immune cells that were treated with and without PMA/Ionomycin (P/I) in 3 independent EMSA tests. Affinity DNA pull-down assay and Western blotting (WB) was performed to identify proteins bound to rs10036748 probe.

Results: EMSAs using probes containing non-risk and risk alleles of 11 SLE associated SNPs in the *TNIP1* locus identified 3 variants with reduced binding of nuclear proteins to the SLE risk allele from the Jurkat T cell line, EBV transformed B cells and the monocytoid cell line, THP-1. Five of the 11 variants demonstrated P/I stimulation dependency of which 2 variants showed decreased binding to the risk allele and 3 variants showed increased binding to the risk allele. Interestingly, 3 *TNIP1* SNPs showed increased binding of nuclear proteins to the risk-allele under resting conditions; one of these was P/I stimulus dependent. Overall, the SNPs carried on both *TNIP1* SLE risk haplotypes demonstrated complex binding activity with the Jurkat T cell line having the most activity (8 of 11 SNPs showing differential binding). To begin verifying the identity of the nuclear proteins present in the EMSA, we used affinity pull-down followed by WB for the rs10036748 variant which had reduced binding of nuclear proteins to risk-allele in all 3 cell types. Based on ENCODE defined transcription factor binding, we confirm that early growth response 1 and NF-κB subunit, RelA are associated with this variant DNA and reduced with the risk allele of rs10036748.

Conclusion: Functional analyses of SNPs in *TNIP1* SLE risk haplotypes suggested a complex regulation at *TNIP1* locus. The association of transcriptional protein complexes at these SNPs is highly regulated showing cell type specificity, stimulation dependency and allele specific binding. The regulatory insights gained through *in-vitro* assays will better direct us to further separate and characterize individual SLE associated *TNIP1* variants *in-vivo* to decipher molecular mechanisms and cell states by which *TNIP1* risk haplotypes contribute to SLE pathogenesis.

Session Title: Systemic Lupus Erythematosus – Human Etiology and Pathogenesis II

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: SLE is a complex multifactorial systemic autoimmune disease, which has been attributed to poorly understood interactions between genetic and environmental factors. Recent reports have begun to elucidate how imbalances within intestinal communities of commensal bacteria may lead to triggering of inflammatory and autoimmune conditions. Our studies are designed to shed light on the interactions of the immune system and the gut microbiome that may contribute to lupus pathogenesis.

Methods: We have assembled a cohort of 60 female SLE patients and matched 20 healthy controls, and biobanked blood and stool samples. DNA was then extracted from fecal bacterial samples, and from sorted endogenous IgA-coated and non-coated bacterial fractions. 16S bacterial rRNA gene sequencing was then performed by illumina NGS technology. Fecal and serum total Igs and autoantibodies were measured by ELISA and by multiplex-bead autoantigen assays.

Results: Our analyses showed that SLE patients have significantly reduced diversity (i.e., number of different taxa) in their gut microbiomes compared to controls (p=0.038). This dysbiosis was treatment independent, with more marked contractions in patients with high disease activity, based on SLEDAI (p=0.002). The distribution of microbiome taxa was more heterogeneous among SLE patients than healthy individuals (p=0.002). Interestingly, patients with the most active disease commonly displayed expansions of genus and species with putative pathobiont properties, with reciprocal contractions of others associated with protective properties (e.g. *R. gnavus* (p= 0.001) vs. *F. prausnitzii* (p= 0.022) and *B. uniformis* (p=0.016). In immunologic surveys, we found that IgA (the most highly produced Ig isotype in the body), was significantly elevated in SLE patients compared to healthy subjects (p<0.002). Only a limited proportion of bacterial taxa are specifically coated by endogenous intestinal IgA. Yet, SLE patients with high disease activity displayed an increased abundance among IgA-coated taxa of *Prevotella copri (p= 0.018)*, a species which has recently been linked to new-onset RA. In addition, intestinal IgA in SLE patients included high levels of antibodies to lupus autoantigens, with the same IgA autoantibody profiles in the matched sera of individual patients.

Conclusion: Our studies document that SLE is associated with a dysbiosis in the gut microbiome with expansions of specific pathobiont bacteria and reciprocal contractions that may contribute to immune dysregulation. This imbalance was more significant in patients with high disease activity. Certain microbial taxa/species are preferentially recognized by the adaptive immune system of SLE patients and coated in vivo by intestinal IgA, and this correlated with elevated overall levels of fecal and serum IgA. Taken together, these data support the hypothesis that the pathogenesis of SLE may arise from imbalances in the gut microbiome and immune recognition of certain bacterial taxa.

Session Title: Systemic Lupus Erythematosus – Human Etiology and Pathogenesis II

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: Belimumab is a recombinant monoclonal antibody that inhibits soluble B lymphocyte stimulator (BLyS), also known as BAFF or TNFSF13B, and is approved for treating patients with systemic lupus erythematosus (SLE). In this observational prospective cohort study, we sought to identify B cell and T cell alterations in SLE patients during treatment with belimumab.

Methods: Twenty-three SLE patients from the Karolinska University Hospital treated with belimumab were enrolled and followed longitudinally. Peripheral blood mononuclear cells were collected and cryopreserved at inclusion and at regular follow-up visits up to 3 years from treatment initiation. The sample series were assayed by mass cytometry (CyTOF) at the same time point, and analysed in the context of clinical parameters.

Results: Changes in B cell subsets were assessed by analysing the CyTOF data after adjustment for total lymphocyte counts from each visit. As expected, B cells decreased over time. More specifically, transitional and naïve B cells ($CD19^+CD20^+IgD^+IgM^+CD27^-$) showed a rapid reduction already at three months follow-up, and continued to decrease over time ($p<0.0001$). In contrast, the pre-switching ($CD19^+CD20^+IgD^+CD27^+$) and double negative memory B cells ($CD19^+CD20^+IgD^-CD27^-$) showed a more gradual decline ($p=0.01$ and $p=0.0001$, respectively). Moreover, we observed decreases ($p<0.0001$) in age-associated B cells ($CD11c^+CD21^-$), a recently described cell subset implicated in humoral autoimmune responses. However, plasma cells ($CD138^+CD38^+CD27^+CD19^+CD3e^-CD20^-$) and switched memory B cells ($CD19^+CD20^+CD27^+IgD^-$) remained stable ($p=0.7$ and $p=0.3$, respectively). In correlation analyses of individual markers with time from treatment initiation, average CD27 expression among B cells showed the greatest increase during the first 6 months of treatment ($r=0.70$) while expression of IgA ($r=0.46$), CD19 ($r=0.39$), and CD5 ($r=0.34$) also increased (<5% false discovery rate, FDR, for all). In contrast, IgD ($r=-0.75$), IgM ($r=-0.67$), CD22 ($r=-0.64$), Ki-67 ($r=-0.62$), CD20 ($r=-0.58$), CD38 ($r=-0.49$), and CD21 ($r=-0.51$) decreased (<5% FDR for all). During later follow-up times (from 6 months of treatment and during the remaining study period), CD5 ($r=0.53$) and CD38 ($r=0.51$) showed the greatest increases (<5% FDR for both), followed by CD20 ($r=0.36$) and Ki–67 ($r=0.34$) ($p<0.05$ for both), and CD22 continued to decrease ($r=-0.32$, $p<0.05$). In contrast to the clear B cell alterations following belimumab treatment, T cells and monocytes did not change significantly.

Conclusion: In this real-life clinical practice setting, belimumab resulted in an initial rapid reduction of naïve B cells and age-associated B cells, followed by a continuous gradual decrease, which also included pre-switching and double negative B cells. In contrast, memory B cells, plasma cells and T cells were preserved. Our observations of B cell alterations betiding in two distinct phases, a rapid early and a more gradual late phase, may have direct implications in the clinical use of belimumab, as early treatment evaluation and discontinuation might forfeit delayed clinical improvements reflecting the late B cell changes.

Session Date: Wednesday, November 16, 2016
Session Title: Systemic Sclerosis, Fibrosing Syndromes, and Raynaud's – Clinical Aspects and Therapeutics III
Session Type: ACR Concurrent Abstract Session
Session Time: 11:00AM-12:30PM

Background/Purpose: A prior study of patients with systemic sclerosis-related interstitial lung disease (SSc-ILD) demonstrated that serum concentrations of surfactant protein D (SP-D) and Krebs von den Lungen-6 (KL-6), were higher in patients with active alveolitis compared with patients without alveolitis.[1] This present study aimed to further investigate the relationship between KL-6 and SP-D and extent and progression of SSc-ILD in two independent cohorts.

Methods: Patients enrolled in Scleroderma Lung Study (SLS) I and II were included. For SLS I, 158 patients were randomized to oral cyclophosphamide (CYC) versus placebo for 1 year. For SLS II, 142 patients were randomized to receive mycophenolate (MMF) for 2 years or oral CYC for 1 year followed by 1 year of placebo. ELISA kits determined the baseline levels of circulating SP-D and KL-6 in 66 and 136 SLS I and II participants, respectively. Extent of ILD was assessed using pulmonary function tests (FVC, DLCO) and quantitative image analysis (extent of fibrosis [QLF] and ILD [QILD] for the whole lung [WL] and zone of maximum involvement [ZM]). To investigate the relationship between baseline SP-D and KL-6 and progression of ILD, a mixed model was created with the outcome of the course of DLCO over 2 years, and a linear regression model was created with the outcome of QLF/QILD score at 2 years (SLS II cohort). Both models controlled for treatment assignment and baseline ILD severity.

Results: We observed significant correlations between KL-6 and SP-D and extent of ILD. In SLS II, KL-6 was correlated with (r; P-value): DLCO (-0.3; 0.0002), QLF-ZM (0.4; <0.0001), QLF-WL (0.5; <0.0001); QILD-ZM (0.5; <0.0001); QILD-WL (0.5; <0.0001); while SP-D was correlated with: DLCO (-0.3; 0.0005), QLF-WL (0.2; 0.03); QILD-ZM (0.3; 0.003); QILD-WL (0.3; 0.0007). In SLS I, KL-6 was correlated with (r; P-value): DLCO (-0.4; 0.003), QLF-ZM (0.3; 0.01); while SP-D was correlated with: DLCO (-0.3; 0.05), QLF-ZM (0.3; 0.02). However, neither KL-6, nor SP-D was significantly correlated with FVC in both cohorts (P>0.4). There were no significant differences in KL-6 or SP-D levels between patients with diffuse versus limited cutaneous disease or between treatment arms in SLS II. In the mixed model (SLS II data), patients with low KL-6 at baseline had a trend for an improvement in the DLCO over 24 months (P=0.06) (Table 1a). Low KL-6 at baseline was significantly associated with improvement in QILD-WL (P=0.03) (Table 1b).

Conclusion: KL-6 and SP-D each were associated with extent of ILD as measured by quantitative fibrosis and DLCO, but not by FVC, in SLS I and II participants. Patients with lower baseline KL-6 appeared to respond more favorably to immunosuppression with MMF/CYC, suggesting that levels of this glycoprotein may be used in conjunction with clinical factors to predict prognosis in SSc-ILD. **References**: 1. Hant FN, et al. *J Rheumatol* 2009;36:773-80.

Table 1a. Low baseline KL-6 is associated with improved course of DLCO over 24 months in SLS II participants in mixed model

Variable	Estimate	Standard Error	P-Value
Treatment arm*	-3.9	1.4	0.005
Baseline DLCO	0.8	0.06	<0.001
Low KL-6	2.7	1.5	0.06

Table 1b. Low baseline KL-6 is associated with improved QILD-WL at 24 months in SLS II participants in linear regression model

Variable	Estimate	Standard Error	P-Value
Treatment arm*	0.7	1.8	0.7
Baseline QILD-WL	-0.3	0.08	0.0003
Low KL-6	-4.3	2.0	0.03

*Reference group is CYC; MMF participants had improved course of DLCO.

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016

Session Title: Systemic Sclerosis, Fibrosing Syndromes, and Raynaud's – Clinical Aspects and Therapeutics III

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: Pulmonary arterial hypertension (PAH) is a leading cause of death in patients with systemic sclerosis (SSc). Predictors of short-term mortality include male sex, age>60 years, functional class IV, and lung diffusing capacity (DLCO) <39% (1). The purpose of this study was to identify independent predictors of long-term outcomes.

Methods: Pulmonary Hypertension Assessment and Recognition of Outcomes in Scleroderma Registry is a prospective registry of SSc patients at high risk for PAH or with definite PH based on right heart catheterization within six months of enrollment. World

Health Organization Group I PAH patients were included (using the strict criteria of baseline pulmonary artery pressure (PAP) >= 25 mmHg, pulmonary capillary wedge pressure <=15 mmHg, and forced vital capacity >= 65%). Baseline characteristics, time to clinical worsening (TTCW), and cause of death in the short (<1 year), medium (1-4.9 years) and long (>=5 years) term were assessed. TTCW was defined as time to death, PAH-related hospitalization, lung transplantation, parenteral prostacyclin treatment, or worsening symptoms (decrease of >15% in the 6-minute walk distance (6MWD) *and* worsening of functional class *and*addition of PAH-specific medication). Cox proportional hazard models were used to identify the predictors of overall survival and TTCW.

Results: A total of 167 SSc-associated PAH patients were included. The patient population was predominantly Caucasian (80%), female (90%), and had limited cutaneous SSc (72%). The 1, 3, 5, and 8-year cumulative survival rates were 95%, 76%, 64%, and 50%, respectively. The majority of patient deaths in the short and medium term were due to PAH (62% and 60%, respectively), while in the long-term were due to causes unrelated to SSc (75%), including cancer (n=2), infection (n=1), cerebrovascular disease (n=1), sudden death (n=1), and unknown (n=1). Baseline 6MWD >165 m (HR 0.38 95% CI 0.16-0.88) and % predicted DLCO >40 (HR 0.45 95% CI 0.23-0.89) were predictors of long-term survival on multivariate analysis. The median TTCW was 4.15 years (95% CI 3.07-5.94). At 1, 3, 5, and 8 years the percentage of patients meeting criteria for clinical worsening was 23%, 40%, 57%, and 70%, respectively. Mean PAP (mPAP) >34 mmHg (HR 2.09 95% CI 1.16-3.79) and pulmonary vascular resistance (PVR) >4.76 WU (HR 2.04 95% CI 1.14-3.68) were predictive of progression to clinical worsening.

Conclusion: This is the longest-term prospective study to date evaluating outcomes in a US based multi-center cohort of patients with SSc-associated PAH. These data suggest that if PAH is well-controlled in the first several years after diagnosis, SSc patients have favorable outcomes, and typically die of causes unrelated to SSc. PVR and mPAP can predict progression to clinical worsening while 6MWD and % predicted DLCO values at the time of diagnosis predict long-term survival in this population.

Session Title: Systemic Sclerosis, Fibrosing Syndromes, and Raynaud's – Clinical Aspects and Therapeutics III

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: Abnormalities of B cell function are part of the pathogenesis of systemic sclerosis (SSc), and B-lymphocyte stimulator (BLyS) is increased in the serum and skin of patients with SSc. Belimumab, a human monoclonal antibody, is a BLyS-specific inhibitor indicated for the treatment of some patients with systemic lupus erythematosus. It is not known whether there may be a role for the use of belimumab in the treatment of SSc.

Methods: This was an investigator-initiated, industry-sponsored, single-center, randomized, double-blind, placebo-controlled,

pilot study. Adults with diffuse cutaneous (dc)SSc of ≤3 years duration from first non-Raynaud's symptom were randomly assigned 1:1 to belimumab IV (10 mg/kg) or placebo after starting on background mycophenolate mofetil (MMF) 1000 mg po bid. The primary objectives were to assess the safety and tolerability of belimumab in patients with early dcSSc on background MMF as assessed by the number of adverse events (AE) and serious (S)AE and to assess efficacy as measured by change in Modified Rodnan Skin Score (MRSS) after 52 weeks.

Results: Baseline demographic information is shown below and was balanced between groups. After a MMF wash-in period, 20 patients were randomized: 10 to belimumab and 10 to placebo. One patient in each group was withdrawn by the investigators soon after randomization due to disease progression. A modified intent-to-treat analysis was performed including all patients who had at least one MRSS assessment after randomization. All randomized patients were included in the safety analysis. In the belimumab+MMF group, the MRSS decreased from a mean (SD) of 26.7 (5.4) to 19.1 (10.3), p = 0.039. In the placebo+MMF group, the mean MRSS decreased from 26.4 (5.4) to 19.9 (8.8), p= 0.023. The mean change in MRSS at 52 weeks was –8.6 (7.7) in the belimumab group and –6.6 (7.7) in the placebo group, p=0.40. In the belimumab group 7/9 patients achieved an MRSS improvement of ≥ 20% versus 3/9 patients in the placebo group, p=0.08. Patients in the belimumab group had a greater improvement in health assessment questionnaire - disability index (HAQ-DI). There were no significant differences in AE with 56 AE, 16 of which were infections, in the placebo group and 53 AE, 18 of which were infections, in the belimumab group. Three SAEs occurred after randomization, all in the placebo group and not deemed related to study medication.

Conclusion: Patients in both the belimumab+MMF and the placebo+MMF groups experienced clinically and statistically significant improvement in MRSS although the difference in the mean change in MRSS between the groups was not significant in this small pilot study. A higher proportion of patients in the belimumab group achieved an improvement in MRSS ≥ 20% although this missed statistical significance. Adverse events and rates of infection were similar in the groups. Additional study is needed to determine the role of belimumab in the treatment of dcSSc.

Table 1. Baseline Characteristics and Change in MRSS and HAQ-DI

	n	Belimumab + MMF	n	Placebo + MMF	P value
Age at baseline - (years, mean ± SD)	10	53 ± 12.1	10	56.7 ± 10.26	0.406
Disease duration - (months, mean ± SD)	10	9 ± 4.03	10	11.7 ± 7.82	0.567
Sex – n (% female)	10	7 (70)	10	8 (80)	0.999

Efficacy of mycophenolate mofetil and oral cyclophosphamide on skin thickness: post-hoc analyses from the Scleroderma Lung Study I and II.

Background/Purpose: Assess the efficacy of mycophenolate mofetil (MMF) and cyclophosphamide (CYC) on the modified Rodnan skin score (mRSS) in patients enrolled in the Scleroderma Lung Study (SLS)-I and II.

Methods: SLS-I participants received daily oral CYC or matching placebo for one year followed for an additional year off therapy, whereas SLS-II participants received daily MMF for 2 years or daily oral CYC for 1 year followed by placebo for a second year. We assessed the within-treatment impact of MMF and CYC on mRSS in subjects with diffuse cutaneous systemic sclerosis (dcSSc) and limited cutaneous systemic sclerosis (lcSSc) participating in SLS-II over a 24-month period. We also compared the change in mRSS in the patients with dcSSc assigned to CYC and MMF in SLS-II and to the CYC group arm of SLS I with the change in the placebo arm of SLS I over a 24-month period.

Results: In SLS-II, the baseline (mean± SD) mRSS was 14.0±10.6 for CYC and 15.3±10.4 for MMF; 58.5% were classified as dcSSc. Each treatment was associated with a significant improvement in mRSS from baseline over 24 months ($P< 0.05$ at each time point, Figure 1. A and B) but there were no significant differences between the2 groups at any time point in either the dcSSc or lcSSc subset ($p> 0.05$ for all comparisons). In the dcSSc subgroup, the changes in mRSS from baseline to 6-, 12-, 18-, and 24-months were similar in the SLS-II pooled cohort (MMF+ CYC) and the SLS-I CYC cohort and showed statistically significant improvements compared to the SLS-I placebo group at 12, 18, and 24 months (Table 1).

Conclusion: In SLS-II, MMF and CYC each resulted in significant improvement from baseline in mRSS in the subset of patients with dcSSc over a 24-month period. In addition, MMF and CYC each resulted in statistically significant improvements in mRSS over the placebo group in the subjects with dcSSc at 12, 18, and 24 months.

Table 1.	N	SLS II Pooled data(CYC and MMF groups) (Mean±SD)	N	SLS I CYC group (Mean±SD)	N	SLSII and SLS I CYC (Mean±SD)	N	SLS I Placebo group (Mean±SD)
Baseline	83	20.8 (9.4)	49	21.6 (10.3)	132	21.1 (9.7)	46	20.4 (9.4)
6 month	69	-2.4 (6.4)†	45	-2.7 (6.4)†	114	-2.6 (6.4)†	43	-2.6 (5.7)†
12 month	66	-5.5 (5.9)*†	43	-5.3 (7.4)*†	109	-5.4 (6.5)*†	37	-1.7 (6.9)†
18 month	58	-6.4 (7.3)*†	36	-6.9 (7.4)*†	94	-6.6 (7.3)*†	33	-3.4 (6.2)*†
24 month	62	-7.0 (8.6)*†	32	-7.2 (7.3)*†	94	-7.1 (8.1)*†	34	-3.9 (5.9)*†

Table 1. Mean changes in modified Rodnan Skin Score from baseline at 6, 12, 18, and24 months in SLS-I and II in dcSSc. †P< 0.05 for mRSS at follow up vs. baseline within each group. *P< 0.05 for SLS-II pooled and SLS-I CYC groups compared to SLS-1 Placebo group. Negative score denotes improvement of skin score.

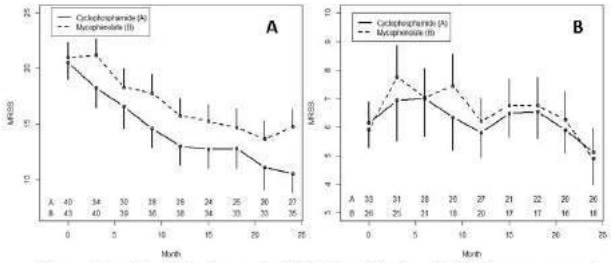

Figure 1 (Panel A and B). Course of modified Rodnan Skin Score (mRSS) in cutaneous systemic sclerosis over 24 month period in participants whom were either treated with cyclophosphamide vs. mycophenolate, **A.** diffuse (dcSSc): P ≤ 0.05 at each time point between CYC and MMF in dcSSc and **B.** limited (lcSSc) P ≥ 0.05 at each time point between CYC and MMF in lcSSC.

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016

Session Title: Systemic Sclerosis, Fibrosing Syndromes, and Raynaud's – Clinical Aspects and Therapeutics III

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: While chronic cough occurs in the majority of patients with systemic sclerosis-related interstitial lung disease (SSc-ILD),[1] its impact on quality of life has not been adequately addressed. Furthermore, minimal literature exists on the relationship between cough and SSc-ILD treatment response. This study uses data from the Scleroderma Lung Study (SLS) II to evaluate the disease burden of cough in SSc-ILD and to determine whether cough changes in response to treatment for SSc-ILD.

Methods: SLS II randomized adult SSc-ILD participants to mycophenolate (MMF) for 2 years (N=69) versus oral cyclophosphamide (CYC) for 1 year followed by 1 year of placebo (N=73). The primary outcome was FVC%-predicted and key secondary outcomes included frequent cough, as assessed by the St. GeorgeÕs Respiratory Questionnaire (SGRQ), along with breathlessness, quantitative extent of ILD (QILD) and fibrosis (QLF) on HRCT imaging and cough-specific quality of life (QOL), as assessed by the Leicester Cough Questionnaire (LCQ).

Results: The majority of participants (61%) reported frequent cough at baseline, of whom 66% also had moderate-severe GERD. Compared with those without cough, participants with frequent cough more often had GERD (p=0.025) and had increased breathing difficulty, lower DLCO and greater QLF in the whole lung (WL) and greater QILD in the WL and the lobe of maximal involvement (LM). LCQ scores were significantly correlated with dyspnea, general QOL measures, severity of GERD and QILD/QLF (all P<0.05). A 42% reduction in the proportion of participants with frequent cough occurred over the 24-month trial with no difference noted between treatment arms or between those with/without GERD at baseline (See Figure 1). However, patients in whom frequent cough persisted at 2 years were more likely to have developed GERD compared with patients who had resolution of frequent cough at 2 years (P=0.03). Logistic regression demonstrated associations between a reduction in cough and improvements in FVC%-predicted (P=0.06), breathlessness (P=0.02), and QILD-WL (P=0.03) at 24 months.

Conclusion: The majority of SLS II participants experienced frequent cough that was significantly associated with the severity of GERD, physiologic and radiographic measures of extent of ILD and non-cough specific QOL. After SSc-ILD treatment, participants experienced a significant reduction in cough, which correlated with improvements in physiologic and radiologic outcomes. These findings suggest that changes in cough may serve as a surrogate measure of treatment response in SSc-ILD. However, the development of GERD may diminish improvement in cough with SSc-ILD therapy. **References**: 1. Theodore, et al. Chest 2012;142:614-21.

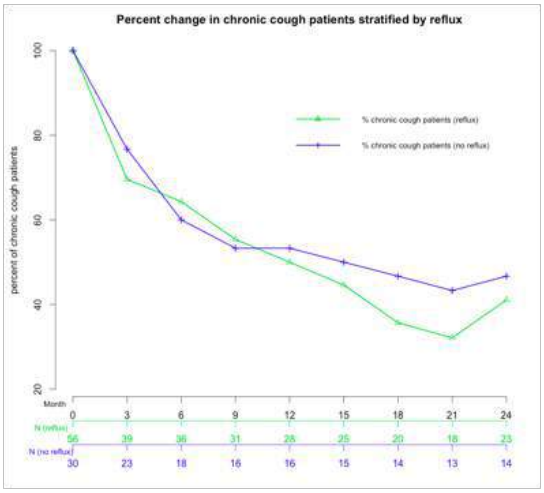

Figure 1. Changes in the proportion of patients with frequent cough for patients with and without reflux at baseline.

Session Date: Wednesday, November 16, 2016

Session Title: Systemic Sclerosis, Fibrosing Syndromes, and Raynaud's – Clinical Aspects and Therapeutics III

Session Type: ACR Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: Currently available clinical biomarkers are not reliable predictors of long-term progression of interstitial lung disease (ILD) in the context of systemic sclerosis (SSc) A previous study of the GENISOS cohort demonstrated that higher plasma MCP-1 (CCL2) predicted a more rapid decline of forced vital capacity (FVC) while IL-10 levels were protective. IL-6 has also been proposed as a cytokine predictive for SSc-ILD progression (De Lauretis et al. J Rheumatol. 2013). Herein, we determined the predictive significance of baseline serum MCP-1, IL-10 and IL-6 levels for progression of ILD and survival in an independent cohort of patients with early SSc.

Methods: Baseline serum samples of SSc patients with disease duration < 5 years enrolled in the Canadian Scleroderma Research Group were investigated. Samples were collected according to a common standard operating procedure. The serum levels of 3 key cytokines MCP-1, IL-10 and IL-6 were determined by highly sensitive Mesoscale assays (Meso Scale Discovery, Rockville, MA). The primary outcome was decline in forced vital capacity (FVC% predicted) over time. The rate of change in a longitudinally obtained FVC % predicted value was investigated by a joint analysis of longitudinal measurements (sequentially obtained FVC% predicted) and Cox regression for survival. This approach allows inclusion of all FVC measurements and accounts for dependency on survival. Cytokines were analyzed as log-transformed continuous variable.

Results: A total of 190 patients with early SSc were investigated. The proportion of female patients was 82% (n=156) and diffuse skin involvement was present in 40% (n=76) patients. The mean disease duration at enrollment was 2.2 years and mean follow-up time was 5.72 years. 19 patients (10%) died during follow-up period. After adjustment for age, gender and ethnicity, there was a trend for an association between higher levels of MCP-1 and faster FVC decline (b=-0.50, 95% CI: -1.54; 0.04, p=0.072) while IL-6 and IL-10 levels were not predictive of differential rate of FVC decline (p=0.109 and p=0.679, respectively). When the model was additionally adjusted for treatment with immunosuppression and disease subtype, the relationship between baseline serum MCP-1 levels and long-term decline in FVC became significant (b=-0.54, 95% CI:-1.08; -0.00, p=0.048). IL-10 and IL-6 also did not show predictive significance in the expanded model (p=0.571 and p=0.116, respectively). Higher serum MCP-1 levels was also associated with poorer survival (HR: 5.31, 95% CI: 1.45; 19.43, p= 0.012).

Conclusion: We confirmed MCP-1 is an important biomarker predictive of ILD progression and poorer survival in SSc. MCP-1 might aid in informing clinical decisions and enrichment strategies for clinical trials. Furthermore, these data supports MCP-1, a

marker of pro-fibrotic macrophages as an important treatment target in SSc-ILD.

Sleep and Physical Activity: A Nationwide Survey Among People with Rheumatic Disease in Ireland

Sean McKenna[1], Alan Donnelly[2], Sandy Fraser[3] and Norelee Kennedy[1], [1]Department of Clinical Therapies, University of Limerick, Ireland, Limerick, Ireland, [2]Department of Physical Education and Sports Sciences, University of Limerick, Ireland, Limerick, Ireland, [3]Department of Rheumatology, University Hospitals Limerick, Ireland, Limerick, Ireland
First publication: September 28, 2016

SESSION INFORMATION
Session Date: Wednesday, November 16, 2016
Session Title: ARHP VI: Rehabilitation Sciences
Session Type: ARHP Concurrent Abstract Session
Session Time: 11:00AM-12:30PM

Background/Purpose: Sleep is an important aspect in maintaining the body's circadian rhythm and plays an important role in maintaining health. Disrupted or lower levels of sleep have been related to serious outcomes such as an increased risk of morbidities. Sleep disturbances and poor sleep quality are prevalent complaints in people with rheumatic disease and may exacerbate pain in this population, potentially leading to reduced levels of activity. The aim of this study was to investigate sleep quality, sleep disturbances and physical activity among Irish people who have Inflammatory Arthritis

Methods: Members from Arthritis Ireland, a national charitable organisation for patients with arthritis, were invited to participate in a cross-sectional survey hosted on SurveyMonkey$^{(R)TM}$. Ethical approval was received. Descriptive statistics, Chi-square tests/Fisher's exact tests were used to analyse the data using Statistical Package for the Social Sciences (SPSS) version 22

Results: Ninety (90) people with Inflammatory Arthritis responded and report an average of 5.7 (SD 1.46) hours sleep per night. Results found the mean number of years with inflammatory arthritis to be 10.09 (SD 9.92). A majority (61%) report their sleep quality as fairly bad/very bad, with 31% having taken medications at least once a week to help their sleep, over the previous month. Ninety three percent (93%) reported arthritis pain in the previous week, while 23% were limited a lot and 62% limited a little with moderate activities. A large majority report 'pain' (95%), 'waking up in the middle of the night or early morning' (97%) and 'cannot get to sleep within 30 minutes' (91%) as disturbances. There was a statistically significant association between longer years with symptoms (p=0.004), taking medication at least once a week (p=0.009) and limited in their activities (p=0.004), when rating their sleep quality as bad. When using the Short Questionnaire to Assess Health-enhancing physical activity (SQUASH), patients' physical activity levels were a low 1,210 minutes per week, compared to other physical activity surveys from their healthy counterparts, even-though 72% believe it is important to measure physical activity. Of those getting less than 1,210 minutes per week of physical activity, 73% report their sleep quality as fairly bad/very bad, while 65% received more than the reported average of 5.7 hours sleep per night

Conclusion: Irish people with Inflammatory Arthritis fall far below the 'sleep needs spectrum' with those having symptoms longer, taking medications regularly and having limitations with their activities, reporting poorer sleep quality. More research is needed with regards to investigating poor sleep quality and disturbances in order to promote health and well-being in people with Inflammatory Arthritis. In addition the effects of physical activity interventions on poor sleep needs to be examined to show if it is a positive non-pharmacological treatment approach for the management of poor sleep in patients with Inflammatory arthritis

SESSION INFORMATION

Session Date: Wednesday, November 16, 2016
Session Title: ARHP VI: Rehabilitation Sciences
Session Type: ARHP Concurrent Abstract Session
Session Time: 11:00AM-12:30PM

Background/Purpose: Work cessation and at-work productivity loss are common and early outcomes of inflammatory arthritis (IA). Ergonomic accommodations contribute to successful management of arthritis symptoms in the workplace. The self-assessment and interview format of the Ergonomic Assessment Tool for Arthritis (EATA) mitigates concerns about disclosing diagnoses to employers. However, evaluation of its utility is needed, including whether or not it adequately captures ergonomic issues and leads to appropriate recommendations. The purpose of the present study is to descriptively analyze the kinds of ergonomic issues experienced by working adults with IA and the potential solutions proposed by the occupational therapist (OT) as identified with the EATA.

Methods: This descriptive study is nested within a randomized controlled trial of the Making it Work program to prevent work loss secondary to IA. One element of the intervention is a 1:1 ergonomic consultation with an OT performed outside of the workplace. OTs were provided training in the EATA protocol. We extracted data from OT's written assessments and the solutions form of EATA for 67 consecutive participants at one provincial site of the trial. Content analysis of ergonomic issues and recommended solutions was conducted by two authors and verified by co-authors.

Results: Participants ranged from 23-60 years of age (mean=47); 81% were women; and all were currently employed 3-62 hours per week. The majority (62%) had rheumatoid arthritis. Issues identified during the consultation were predominantly related to work station design and symptom management in the workplace, especially fatigue. Recommended solutions to issues in the workplace, while predominantly ergonomic in nature, also included non-ergonomic suggestions to reinforce medical, therapeutic, and health lifestyle recommendations that participants identified as problematic. Ergonomic solutions tended to fit one of two primary categories: (1) strategies such as pacing (72%) or modifying work tasks (57%), and (2) equipment recommendations, such as adjusting current work stations (51%) to support improved work postures or recommending equipment like an adjustable chair or assistive device to improve biomechanics for task performance. A review of EATA data with the occupational therapists involved also showed that issues of greatest concern to participants were frequently outside the realm of this very specific work-based consultation, indicating the complexity of living with IA and need for ready access to a broad range of resources and/or interdisciplinary team.

Conclusion: A structured, interviewed-based assessment is feasible for identifying ergonomic issues faced by employed adults with IA, and proposing solutions to support work performance. Follow up research is recommended to assess the usefulness of the proposed solutions in achieving the goal of preventing work loss.

Session Time: 11:00AM-12:30PM

Title: Minimum Physical Function Needed To Walk 6000 steps/day In People With Knee Osteoarthritis.

Background/Purpose: Adopting a physically active lifestyle provides major health benefits to people with knee osteoarthritis (OA). Yet, most people with knee OA are sedentary. Difficulty with physical function, such as stair climbing and walking, may be one barrier to physical activity participation for people with knee OA. Little is known about what minimum level of physical function is necessary to engage in physical activity. Establishing minimum thresholds will help clinicians prioritize prescribing intervention for physical activity or physical function in knee OA. The purpose of the study was to identify minimum thresholds of performance on clinical tests of physical function required to target a goal of 6000 steps/day, an important benchmark of activity in knee OA.

Methods: We used publically available data from the Osteoarthritis Initiative (OAI). Physical activity was measured with an accelerometer (Actigraph GT1M) worn during waking hours during the 48-month follow-up visit, and quantified as steps/day. Physical function was quantified with three clinical tests: timed 5 repetition sit-to-stand test (STS), timed 400-meter walk, and walking speed (calculated from a 20-meter walk). We calculated Pearson correlation coefficients to examine the association between steps/day and physical function. To identify a minimum threshold for each, we calculated cut-points at 80% to 95% specificity for walking 6,000 steps/day, i.e., the proportion classified with good physical function and ≥ 6000 steps/day divided by all with ≥ 6000 steps/day.

Results: Participants who wore the monitor for ≥ 3 days (n=1790, age [mean (± sd)] 65.0 ± 8.8 years, BMI 28.4 ± 4.9 kg/m^2, 55% female), had 6319 ± 2920 steps/day with 47% walking ≥ 6000 steps/day. The mean STS was 10.2 ± 3.2 seconds, 400-meter walk was 305.3±51.4 seconds, and walking speed was 1.3 ± 0.2 meters/sec. Steps/day had a small negative correlation with STS (r=-0.2, p<0.001) and 400-meter walk (r=-0.4, p<0.001) and a small to moderate positive correlation with walking speed (r=0.4, p<0.001). Thresholds of high specificity (80-95%) of physical performance for walking ≥ 6000 steps/day ranged from 11 to 14 seconds for STS, 315 to 350 seconds for the 400-meter walk, and 1.10 to 1.25 meters/sec for walking speed (Table).

Conclusion: Physical function at or worse than stated thresholds may represent insufficient physical function for attaining an important benchmark of physical activity. Intervention targeting physical function may be more appropriate than directly targeting physical activity for those below these physical function thresholds with knee OA. **Table:** Physical function measures that reflect 80, 85, 90 and 95% specificity*.

	Specificity*			
Physical function measures	**80%**	**85%**	**90%**	**95%**
STS (seconds)	11.0	12.0	12.5	14.0
400-meter walk (seconds)	315	320	330	350
Walking speed (meters/sec)	1.25	1.22	1.18	1.10
*Specificity is defined as the proportion classified with good physical function and ≥ 6000 steps/day divided by all with ≥ 6000 steps/day.

Session Date: Wednesday, November 16, 2016

Session Title: ARHP VI: Rehabilitation Sciences

Session Type: ARHP Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: Systemic sclerosis is a chronic autoimmune connective tissue disorder that results in skin thickening, vascular insufficiency, and fibrosis of internal organs, such as the heart, lungs, kidneys, gastrointestinal tract, and joints and muscles. People have difficulty participating in daily tasks due to pain, finger ulcers, Raynaud's phenomenon, and internal organ involvement, particularly decreased pulmonary function. Most of the research on scleroderma has focused on performance of basic daily living and work tasks. Little is known about participation in household, leisure, and community activities. The Valued Life Activities Scale (VLA) measures difficulty in self-care, household, leisure and community activities (1). The VLA has been used to track changes over time in persons with different rheumatic diseases and thus, maybe useful for people with scleroderma. However, the 33 items may be too long for clinical use. Purpose: To examine the internal consistency and validity of the 14 item Short-VLA Scale in persons with systemic sclerosis.

Methods: The sample was a convenience sample of 83 people with systemic sclerosis recruited from the Scleroderma Foundation website and annual conference. Participants completed the VLA, a questionnaire with 33 items under three domains: obligatory, committed, and discretionary. Obligatory activities include self-care, committed activities include household tasks, and discretionary activities include leisure and community activities. For each item, participants rated difficulty with performance from 0 (no difficulty) to 3 (unable to do). A Short-VLA score is calculated as the mean from 14 of the items as described by Katz et al.(2). Participants also completed a demographics questionnaire, questions regarding the presence and severity of disease symptoms, the Health Assessment Questionnaire (HAQ), and Center for Epidemiologic Studies Depression Scale (CES-D) and the Adelaide Activities Profile (AAP), a measure of *frequency* of participation in household and community tasks.

Results: The majority of the participants were Caucasian (94%), female (90%), and married; 98% had Raynaud's phenomenon, 93% reported gastrointestinal problems and 50% reported lung involvement. Our participants had a mean age of 53 years and mean disease duration of 9 years. About half of the participants had limited SSc and half had diffuse SSc. The mean score on the S-VLA was 1.10 indicating mild difficulty. Internal consistency of the S-VLA was excellent (Cronbach's alpha=0.92). The correlation between the S-VLA and the original long form VLA was excellent (r=0.96). A moderate correlation was also found between the S-VLA and the HAQ (r=0.73) and AAP (r = 0.56), however the correlation with the CES-D was only fair (r=0.35).

Conclusion: The S-VLA was found to be a reliable and valid measure in persons with SSc. In addition, the S-VLA may be useful to monitor participation in household, leisure, and community activities as decreasing participation in these types of activities has been correlated with depression and decreased quality of life (1).

SESSION INFORMATION

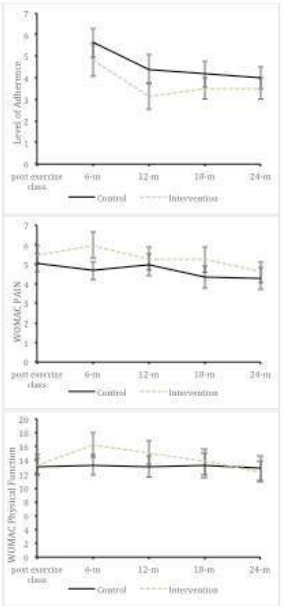
Session Date: Wednesday, November 16, 2016
Session Title: ARHP VI: Rehabilitation Sciences
Session Type: ARHP Concurrent Abstract Session
Session Time: 11:00AM-12:30PM

Background/Purpose: In knee osteoarthritis (OA) strengthening exercise improves pain and physical function, however a marked decline in exercise adherence has limited the long term efficacy of exercise. Adherence drops precipitously when trainer instruction and social support for exercise are withdrawn. We developed an interactive automated telephone calling system, Boston Osteoarthritis Strengthening telephone linked-communication (BOOST TLC), that provides low cost trainer instruction and behavioral counseling to motivate people with knee OA to continue strength exercises after participating in a group class. We tested the effect of BOOST TLC on exercise adherence over 24-m in a randomized trial.

Methods: Participants were recruited from the community and had painful, self-reported doctor-diagnosed knee OA. Participants initially completed a 6-week trainer led strength class using a protocol previously shown to improve pain and function in knee OA. The protocol included exercises for warm-up, posture, functional strength (squats and stair stepping), isolated knee strength with ankle weights (knee flexion and knee extension), hip abduction, core, and stretching. The instruction emphasized proper form and progressive resistance training. After completing the class, participants were randomized to BOOST TLC or control. BOOST TLC is an automated, interactive conversation system that asks questions, comments on responses, and educates and counsels users. TLC stores the question responses in a database to direct current and future TLC conversations and provides alerts and reports to staff. The BOOST TLC group received biweekly calls for 6-m and monthly calls for the subsequent 18-m. The control and BOOST TLC group received an automated monthly phone message encouraging continued strength training. The primary outcome was self-rated adherence to the strength exercises in the previous 3 months (from Ônot at allÕ to Ôcompletely as instructedÕ) on a 10-point scale. Evaluations occurred at 6-m, 12-m, 18-m and 24-m after the strength class. Secondary outcomes included WOMAC pain and physical function. 24-m adherence was analyzed using nonparametric Wilcoxon test and adjusted for baseline WOMAC pain using robust generalized estimating equations regression.

Results: There were 104 trial participants (82% female; 65 ± 8 years old; BMI 31 ± 7). The 24-m treatment difference in adherence was not statistically significant (Boost TLC 3.5 ± 3.3, control 4.0 ± 3.5, p= 0.53), and remained non-significant when adjusted for baseline pain (p=0.46). There was no 24-m treatment difference in WOMAC pain (Boost TLC 4.6 ± 3.7, control 4.3 ± 3.7, p= 0.68) or physical function (Boost TLC 12.3 ± 9.7, control 12.8 ± 11.7, p= 0. 0.82).

Conclusion: BOOST TLC provided no additional benefit for exercise adherence above that provided by an automated, non-



interactive message reminding participants to exercise.

Functional Ability 'to Rise' and Autonomy Support for Physical Activity: Implications for Light Physical Activity Engagement and Psychological Wellbeing in People Living with Rheumatoid Arthritis

Session Title: ARHP VI: Rehabilitation Sciences

Session Type: ARHP Concurrent Abstract Session

Session Time: 11:00AM-12:30PM

Background/Purpose: Epidemiological studies indicate participation in light physical activity (LPA) is positively associated with psychological wellbeing. For patients with Rheumatoid Arthritis (RA), reduced functional ability may result in lower LPA engagement and consequently, compromised mental health. In particular, lower-limb physical dysfunction in RA may result in a reduced ability to transition from a sitting (or sedentary) to a standing posture (i.e., 'sedentary breaks'), contributing towards lower LPA engagement. Since physical dysfunction is symptomatic of RA, it is also important to determine modifiable correlates of LPA. Studies framed by Self-determination Theory demonstrate autonomy supportive social environments to be relevant to levels of physical activity engagement in healthy and patient populations. Thus, the social environment may represent a malleable target for interventions that seek to promote LPA in RA. The primary aim of this study was therefore to test a model examining the

implications of 1) functional disability to 'rise', and 2) autonomy support for physical activity, for levels of objectively assessed LPA and associated psychological wellbeing.

Methods: RA patients (N = 50, Mage = 55.5 ± 12.5 yrs), completed questionnaires assessing; 1) functional disability to 'rise' [e.g., are you able to stand up from an armless straight chair, higher score = lower function], 2) autonomy support for PA [from a patient-specified important other], 3) depressive symptoms, and 4) subjective vitality. Sedentary breaks and LPA engagement were determined from 7-days of accelerometry (i.e., *sedentary breaks*, interruptions in sedentary time with ≥1 min activity ≥100 counts/min, *LPA,* activity 100 - 2019 counts/min).

Results: Path analyses supported a model (χ^2 (5) = 8.83, p =.12, CFI =.95, SRMR = .08, RMSEA =.13), in which functional disability to rise significantly negatively predicted the number of sedentary breaks (per/hour), which in turn, significantly positively predicted LPA engagement (min/hour). A significant positive association between important other autonomy support and LPA was observed, independent of functional disability 'to rise'. LPA then significantly and negatively predicted depressive symptoms. The association between LPA and subjective vitality was positive and approached significance (p =.06, Figure 1).

Conclusion: Functional disability to 'rise' may be adversely related to levels of LPA engagement in RA, via the patient's ability to transition from sitting to standing. However, autonomy support from an important other may represent a modifiable target for interventions seeking to promote LPA, independently of the negative consequence of lower limb functional disability. Subsequently, LPA engagement may hold positive implications for psychological health in RA. Figure 1: Data fit of the hypothesised model *Note:* * p < .05, ** p <.01

The Cardiovascular Safety of Celecoxib Versus Ibuprofen or Naproxen in 24,081 Patients with Osteoarthritis or Rheumatoid Arthritis

M. Elaine Husni[1], Daniel H. Solomon[2], Katherine E Wolski[3], Lisa M Wisniewski[3], Steven E Nissen[4] and on behalf of the PRECISION Trial Investigators, [1]Rheumatology, Cleveland Clinic, Cleveland, OH, [2]Division of Rheumatology, Brigham and Women's Hospital and Harvard Medical School, Boston, MA, [3]Cardiovascular Medicine, Cleveland Clinic, Cleveland, OH, [4]Cardiovascular Medicine, Chair, Cleveland Clinic, Cleveland, OH

Session Date: Tuesday, November 15, 2016
Session Title: ACR Late-breaking Abstract Session
Session Type: ACR Late-breaking Abstract Session
Session Time: 4:30PM-6:00PM

*Both authors (Husni, Solomon) contributed equally and will co present

Background/Purpose: The relative cardiovascular (CV) safety of non-selective NSAIDs and selective COX-2 NSAIDs remains unclear. Given the chronic use of NSAIDs in the osteoarthritis (OA) and rheumatoid arthritis (RA) population along with known concomitant risk for CV disease, the relative safety of these agents is of critical importance for rheumatologists and their patients. The best opportunity to answer this question is to conduct a very large randomized controlled trial (RCT) that directly and prospectively compares the CV safety of these agents, the PRECISION trial.

Methods: PRECISION was a double blind and triple dummy RCT conducted worldwide. Subjects enrolled in PRECISION had to have a known history of CV events (myocardial infarction, stroke, or coronary re-vascularization) or evidence of CV risk based on traditional CV risk factors. Additional criteria included a physician diagnosis of OA or RA, daily need for NSAID therapy, no CV events within the last 90 days and no contraindications to the use of these agents. Subjects were randomized to celecoxib 100-200mg bid, ibuprofen 600-800mg tid, or naproxen 375-500mg bid. All subjects were provided open-label esomeprazole at 20-40mg qd and aspirin was allowed as part of standard of care if applicable. The primary CV outcome was a composite of CV death (including hemorrhagic), non-fatal MI, and non-fatal stroke with at least 18 months of follow-up. The study was designed as a non-inferiority trial with the main hypothesis that CV risk among subjects randomized to celecoxib would have an upper confidence interval (CI) of ≤ 1.33 for the intention to treat (ITT) and a HR ≤ 1.12 with an upper CI of ≤ 1.40 for the on treatment population compared with naproxen or ibuprofen based on a one-sided confidence interval of 97.5%. The trial continued for 10 years until the required 580 CV events for 30 months ITT analysis and 420 events for 42 months on-treatment population analysis were observed. Additional measures of function, global arthritis activity, and VAS pain were recorded.

Results:

The trial enrolled patients from 13 countries, with 923 sites, and 80% of subjects came from the US. A total of 24,081 subjects were enrolled and included in the final analyses, with 90% having OA and 10% RA. The mean age of subjects with OA was 63.5 years and for RA 60.7 years; 63.1% of subjects with OA were female and 73.2% with RA were female. The age and gender distribution did not differ by NSAID treatment assignment. Adherence was 80% over at least 6-months of follow-up, with a median follow-up of 18 months. The comparative CV risk by NSAID treatment arm will be presented separately for subjects with OA and RA. Gastrointestinal (GI) and renal adverse events were also adjudicated and will be presented for subjects with OA and RA by treatment arm.

Conclusion: PRECISION represents the largest CV safety trial of commonly used NSAIDs among patients with OA or RA. The results to be presented will clarify whether these NSAIDs carry the same CV, GI and renal risk across OA and RA patients.

Session Title: ACR Late-breaking Abstract Session

Session Type: ACR Late-breaking Abstract Session

Session Time: 4:30PM-6:00PM

Background/Purpose: Glucocorticoid (GC)-induced osteoporosis (GIOP) remains the most common

secondary cause of osteoporosis. Despite approved therapies, many subjects do not receive GIOP prevention or treatment. There is increased RANKL and decreased osteoprotegerin (OPG) expression in GIOP. Denosumab (DMAb) is a monoclonal antibody to RANKL. This study was designed to assess the safety and efficacy of DMAb compared with risedronate (RIS) in GC-treated individuals, in whom treatment guidelines advocate a GIOP intervention.

Methods: This was a phase 3, randomized, double-blind, active-controlled study to evaluate DMAb vs. RIS in GC-treated individuals for 24 mos. Eligible subjects were women and men ≥18 yrs receiving GC therapy at a dose ≥7.5 mg prednisone daily or its equivalent for ≥3 mos or <3 mos prior to screening (GC-continuing [GC-C] and GC-initiating [GC-I], respectively). All subjects <50 yrs were required to have a history of osteoporotic fracture. GC-C subjects ≥50 yrs were required to have a lumbar spine (LS), total hip (TH), or femoral neck bone mineral density (BMD) T score ≤–2.0; or a T-score ≤–1.0 with a history of fracture. Subjects were randomized 1:1 to SC DMAb 60 mg every 6 mos or oral RIS 5 mg daily for 24 mos. Subjects were to receive daily calcium (≥1000 mg) and vitamin D (≥800 IU) supplementation. The primary objective was to demonstrate in the GC-C and GC-I subpopulations separately that DMAb was not inferior to RIS with respect to percentage change from baseline in LS BMD at 12 mos. Secondary objectives were to assess superiority of DMAb over RIS with respect to percentage change from baseline in LS and TH BMD at 12 mos. The study remains blinded and is ongoing.

Results: A total of 795 subjects (505 GC-C and 290 GC-I) enrolled in the study. Baseline characteristics were balanced between treatment groups (Table). Non-inferiority and superiority with DMAb were demonstrated for both the GC-C and GC-I subpopulations, due to significantly greater gains in BMD compared with RIS at the LS and TH in both subpopulations (Figure). The incidences of adverse events (AEs) and serious AEs, including serious AEs of infection, as well as fracture, were similar between treatment groups and consistent with the known safety profile of DMAb.

Conclusion: DMAb significantly increased BMD more than RIS at the spine and hip at 12 months. The overall safety profile was similar between treatment groups. DMAb has the potential to become another treatment option for patients newly initiating or continuing GC who are at risk for fracture.

Table. Baseline Characteristics

Session Type: ACR Late-breaking Abstract Session

Session Time: 4:30PM-6:00PM

Background/Purpose: Treatment of rheumatoid arthritis (RA) with tocilizumab (TCZ), a humanized monoclonal antibody directed against the IL-6 receptor, is associated with clinical efficacy and marked reduction in systemic inflammatory markers associated with atherogenesis and atherothrombosis, but treatment-associated increases in low-density lipoprotein (LDL-C) have called into question the net cardiovascular risk-benefit ratio of TCZ in RA.

Methods: Seropositive RA patients with active disease (≥8 swollen and ≥8 tender joints and CRP >3 mg/L) and inadequate response to ≥1 nonbiologic DMARD were randomized 1:1 to receive open-label TCZ 8 mg/kg infused monthly or etanercept (ETA) 50 mg injected weekly. Enrollment was restricted to patients ≥50 years of age with ≥1 cardiovascular disease (CVD) risk factor, extra-articular RA manifestations, or history of a CVD event. The primary outcome was the comparison of incident major adverse CVD event (MACE), defined as CVD death, nonfatal myocardial infarction or nonfatal stroke, for TCZ vs ETA. Rates of other CVD events and non-CVD safety outcomes were explored as secondary outcomes. Lipid levels were tracked throughout the trial. CVD events were adjudicated by an independent committee. The study was powered to rule out ≥80% relative hazard of MACE for TCZ vs ETA.

Results: A total of 3080 RA patients were enrolled (TCZ n=1538; ETA n=1542), and 2957 (96%) completed the study with a full assessment of CVD events. Average follow-up time was 3.2 years. Early discontinuation of randomized treatment occurred in 23% of ETA- vs 26% of TCZ-treated patients. Baseline characteristics (mean age 61 years, 22% male, 29% current smokers, 71% with hypertension, 18% with diabetes, mean CRP 19.3 mg/L) were balanced between treatment groups. A total of 161 MACE qualified for inclusion into the primary analysis. In the intention-to-treat analysis, 83 MACE occurred over 4900 PYs in the TCZ arm vs 78 over 4891 PYs in the ETA arm (HR 1.05; 95% CI 0.77, 1.43). HRs for TCZ vs ETA for other secondary CVD outcomes are summarized in the Table. By week 4, total cholesterol, LDL-C, HDL-C, and triglycerides increased significantly in the TCZ arm compared with the ETA arm, with median LDL-C increasing 12% for TCZ vs 1% for ETA. Thereafter, average levels remained consistent to trial conclusion. The overall rate of adverse events, serious infections, and medically confirmed gastrointestinal perforations was numerically higher for TCZ vs ETA.

Conclusion: This comparative study of TCZ with ETA excluded a >43% relative increase in the hazard of MACE (HR 1.05; 95% CI 0.77, 1.43), with an estimated 5% increase in TCZ compared with ETA among RA patients with severe active disease and elevated baseline CVD risk. Average treatment-associated increases in LDL-C were higher for TCZ vs ETA. The CVD safety of TCZ relative to ETA should be interpreted in the context of its non-CVD safety and clinical efficacy.

Table. Hazard Ratios of Major End Points for Tocilizumab vs Etanercept

Session Title: ACR Late-breaking Abstract Session

Session Type: ACR Late-breaking Abstract Session

Session Time: 4:30PM-6:00PM

Background/Purpose: To evaluate the efficacy, safety, and tolerability of guselkumab (GUS), a fully human monoclonal antibody against the p19 subunit of IL-23, in patients (pts) with active psoriatic arthritis (PsA).

Methods: In this double-blind, placebo-controlled, multicenter study, pts with active PsA and ≥3% body surface area (BSA) of plaque psoriasis despite current or previous treatment with standard-of-care therapies, including those previously exposed to anti-TNFα agents, were randomized 2:1 to receive GUS 100 mg subcutaneously (SC) or placebo (PBO) at wks 0, 4, and every 8 wks (q8w) thereafter through wk44. At wk16, pts from either group with <5% improvement from baseline in both swollen and tender joint counts were eligible for early escape to open-label ustekinumab. At wk24, all remaining PBO pts crossed-over to receive GUS 100 mg, and then received GUS at wk28, and q8w thereafter through wk44. The primary endpoint was ACR 20 response at wk24. Major secondary endpoints were PASI 75 and ACR 50 responses, change from baseline in HAQ-DI, and improvement in enthesitis (Leeds enthesitis index) and dactylitis score (by a 0-3 scoring system) at wk24; and ACR 20 response at wk16. Other secondary endpoints included change from baseline in SF-36 and proportion of pts achieving Minimal Disease Activity (MDA). Through wk24, efficacy analyses were performed in a modified Intent-to-Treat (mITT) population. Pts who met treatment failure criteria, early escaped or had missing data at wk24, were considered non-responders for ACR and MDA endpoints at wk24.

Results: 149 pts were randomized to receive study agent (PBO: 49, GUS: 100). Baseline demographics and ACR component measures were generally similar between the two groups. Four [8.2%] pts in PBO and 9 [9.0%] pts in GUS were previously exposed to TNFα agents. The study met its primary and all secondary endpoints. Significantly more GUS pts achieved ACR 20/50/70 responses and PASI 75/90/100 responses at wk24 (Table 1). Significant treatment effect on ACR20 response was observed as early as wk4 (21% vs 0, $p<0.001$), and the effect increased over time reaching the maximum by wk16 (60.0% vs. 16.3%, $p<0.001$) vs. PBO. Results for other secondary efficacy endpoints are summarized in Table 1. Through wk24, proportions of pts with ≥1 AE were comparable between the two groups (PBO: 32.7%; GUS: 36.0%, respectively). Infections were the most common AEs (PBO: 20.4%; GUS: 17.0%, respectively). Two pts had SAEs (knee injury, n=1; myocardial infarction, n=1). There were no serious infections, malignancies, or deaths through wk24.

Conclusion: In pts with active PsA and ≥3% BSA of psoriasis, GUS demonstrated significant improvement on joint symptoms, physical function, psoriasis, enthesitis, dactylitis and quality of life. GUS was well tolerated with no unexpected safety findings in this population.

Table 1 Summary of Efficacy Results at Week 24 in mITT Population			
Efficacy Endpoints	PBO	GUS	p-value
ACR 20	18.4%	58.0%	p<0.001
ACR 50	10.2%	34.0%	P=0.002

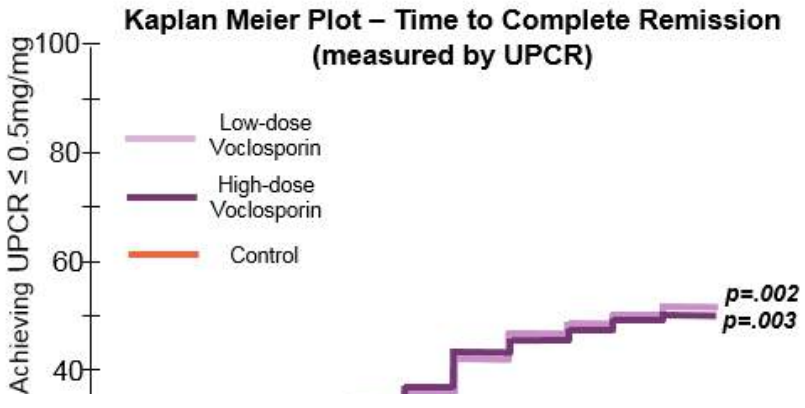
Session Title: ACR Late-breaking Abstract Session

Session Type: ACR Late-breaking Abstract Session

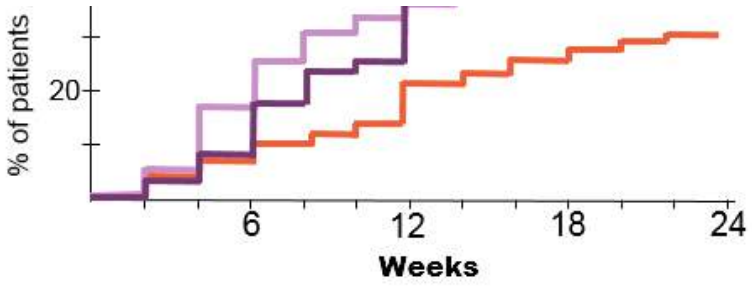
Session Time: 4:30PM-6:00PM

Background/Purpose: Voclosporin (VCS) is a novel CNI intended for use in the treatment of autoimmune diseases such as lupus nephritis. VCS's unique structure allows for less pharmacokinetic–pharmacodynamic variability and a potentially improved safety profile compared with other CNIs. The AURA study enrolled 265 subjects in over 20 countries using low (23.7 mg BID) or high dose VCS (39.5 mg BID) in addition to MMF 2g/day and steroids in active lupus nephritis (LN).

Methods: Entry criteria: renal biopsy within 6 months (Class III/V LN, ISN/RPS); UPCR≥1.5 (III/IV) or ≥2.0 mg/mg (V); serologic evidence of active LN; and eGFR >45ml/min. The steroid protocol was 20-25 mg (Day 1) with taper to 5 mg (Week 8), and 2.5 mg (Week 16-24). 24 week objectives included: Complete Remission (CR) defined as a urine protein/creatinine



ratio (UPCR) of ≤0.5 mg/mg using first morning void with an eGFR ≥ 60 mL/min without a decrease of ≥20%; time to CR, Partial Remission (PR: 50% reduction in proteinuria) and time to PR.



Results: The groups were generally well-balanced for age, gender and race, with a trend to higher proteinuria and lower eGFR data in the low dose VCS arm. The trial met its primary endpoint with superior CR rates in the low dose arm (OR: 2.03, p=0.045). There was a statistically significant improvement in time to CR and time to PR in both treatment arms (P<.01). A mean reduction in serum creatinine was seen in both arms (0.2 mg/dL low, 0.1 high; p<.001). BP did not vary by group. Over 90% of subjects experienced at least one adverse event; the most common being infectious (56.2% low, 63.6% high and 50.0% control), GI disorders (41.6% low, 52.3% high and 36.4% control). More serious adverse events occurred in the voclosporin groups (25.8% low, 25.0% high, 15.8% control), and were consistent with those observed in LN patients. Most deaths occurred in the first 2 months and were: low dose (infection-3, ARDS-2, thrombotic-3, cardiac tamponade, pulmonary hemorrhage), high dose (infection, PE) and control (CVA). All were considered unrelated to drug exposure by the investigators.

Study Demographics

		Control	Voclosporin 23.7 mg BID	Voclosporin 39.5 mg BID
n		88	89	88
Age (yrs)		33 ± 10	31 ± 12	31 ± 10
Race	White	42 (47.7)	30 (33.7)	36 (40.9)
	Black	5 (5.7)	3 (3.4)	6 (6.8)
	Asian	36 (40.9)	52 (58.4)	44 (50.0)
	Other	5 (5.7)	4 (4.5)	2 (2.3)
Biopsy Class (III/IV)		59 (67.0)	56 (62.9)	63 (71.6)
Baseline eGFR		100 ± 27	95 ± 28	105 ± 28)
Baseline UPCR		4.4 ± 3.6	5.2 ± 4.2	4.5 ± 3.0
Death:	Infection	0	3	1
	Thromboembolic	1	3	1
	Other	0	4	0

Conclusion: The AURA study is the first global LN study to meet its primary end point, Response rate was rapid; increasing CR in the VCS arms was seen by week 6. This study demonstrated the positive additive effects of VCS, despite the rigorous steroid taper (mean steroid dose 4 mg at Week 16). Adverse events were higher in the VCS treatment arms, consistent with increased immunosuppression. The overall mortality rate was similar to other recent LN trials (ALMS 3.8%, ALLURE 4.7%, BELONG 3.7%), with a higher mortality rate in the lowdose group. These promising data will be used to plan subsequent studies of voclosporin in LN.

Session Title: ACR Late-breaking Abstract Session

Session Type: ACR Late-breaking Abstract Session

Session Time: 4:30PM-6:00PM

Background/Purpose: Therapeutic options for diffuse cutaneous systemic sclerosis (dcSSc) are limited. The Scleroderma: Cyclophosphamide or Transplantation (SCOT) trial was a multicenter study designed to evaluate the long-term benefit of myeloablative autologous HSCT compared to 12 monthly pulses of CYC.

Methods: Adults (18-69 years) with dcSSc (ACR criteria) and high-risk lung and/or renal involvement were randomized to CYC (750 mg/m^2/mo.) or myeloablation (800 cGy total body irradiation with lung and kidney shielding, 120 mg/kg CYC and 90 mg/kg antithymocyte globulin) followed by CD34+selected autologous HSCT. The primary endpoint was a global rank composite score (GRCS) at 54 months that ordered subjects based on a hierarchy of outcomes: death, event-free survival (EFS), forced vital capacity (FVC), scleroderma health assessment questionnaire, and modified Rodnan skin score (mRSS).

Results: Seventy-five subjects were randomized (39 CYC, 36 HSCT) with mean baseline mRSS=30, mean FVC=74% and mean DLC0=53% of predicted. All but two had lung involvement. In the ITT (randomized) sample, GRCS comparisons favored HSCT and met the predefined primary endpoint at 54 months (p=0.013) and 48 months (p=0.008). In those who were transplanted or received ≥ 9 CYC doses (34 CYC, 33 HSCT), GRCS results (figure 1) were even stronger (p=0.004 and 0.003, respectively). Secondary analyses in treated subjects supported the primary results: at 54 months, EFS was 50% in CYC and 79% in HSCT (p=0.021) and overall survival (OS) was 77% and 91% (p=0.19), respectively. Treatment related mortality at 54 months was 0% CYC and 3% HSCT. Among HSCT recipients, 9% had initiated DMARDs by 54 months compared to 44% of CYC (p=0.001). As shown in figure 2, Kaplan-Meier estimates for EFS and OS differed significantly between groups (p=0.030, 0.019, respectively). The

rate of SAEs was similar in both arms. Grade 3 and above AEs including regimen-related cytopenias were more common in the HSCT arm. Herpes zoster was more frequent in the HSCT arm.

Conclusion: This study demonstrates long-term superiority of myeloablative autologous HSCT over CYC on efficacy endpoints, and shows a significant reduction in use of DMARDS among HSCT recipients. Transplant-related mortality was lower and overall survival was better than projected both during the peri-transplant period and long term. The SCOT trial supports myeloablative HSCT as a significant advance in the care of dcSSc. Funded by NIAID; ClinicalTrials.gov NCT00114530 _ _ _

Overall Reduction in Acute Flares during Treatment with Febuxostat Compared with Placebo over 2 Years in Patients with Early Gout

Nicola Dalbeth[1], Kenneth G. Saag[2], William Palmer[3], Hyon K. Choi[3], Barbara Hunt[4], Patricia MacDonald[4], Ulrich Thienel[5] and Lhanoo Gunawardhana[4], [1]University of Auckland, Auckland, New Zealand, [2]University of Alabama at Birmingham, Birmingham, AL, [3]Massachusetts General Hospital/Harvard Medical School, Boston, MA, [4]Takeda Pharmaceuticals International, Deerfield, IL, [5]RRD International, Rockville, MD

First publication: October 19, 2016

SESSION INFORMATION

Session Date: Sunday, November 13, 2016

Session Title: ACR Late-Breaking Poster Session

Session Type: ACR Late-breaking Abstract Session

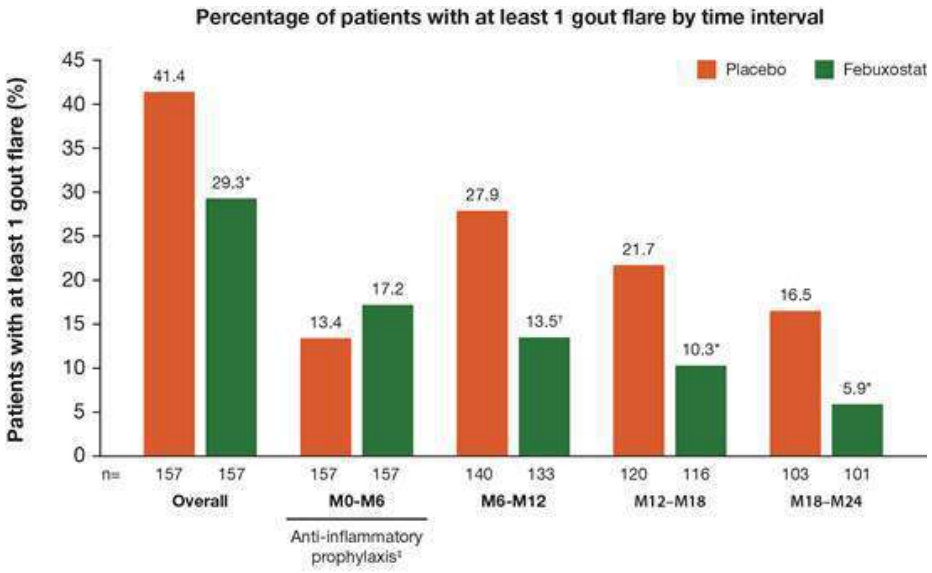
Session Time: 9:00AM-11:00AM

Background/Purpose: No clinical trials have previously investigated the frequency of acute flares in early gout or the benefit of instituting urate-lowering therapy (ULT) earlier in the course of the disease. Currently, the standard of care for a vast majority of patients with early gout who have experienced only a single gout attack is limited to acute flare treatment with no ULT. In this analysis of data from a Phase 2 study, we have evaluated the frequency of acute flares in patients with early gout treated with febuxostat versus placebo during a 2-year period.

Methods: In this randomized, double-blind, placebo-controlled trial, patients with serum urate (sUA) ≥7.0 mg/dL and estimated glomerular filtration rate ≥60 mL/min were randomized to either febuxostat 40/80 mg or placebo for up to 2 years. Febuxostat was titrated from 40 to 80 mg at the Month 1 visit if sUA was ≥6.0 mg/dL at the Day 14 visit. All patients had early gout, defined as having experienced 2 or fewer gout flares in total and only 1 flare during the previous 12 months. Patients in both treatment groups received standard of care for acute gout flares throughout the study at the discretion of the investigator. All patients also received gout flare prophylaxis for the first 6 months of the study; patients who were either nonresponsive or intolerant to prophylaxis could be managed at the discretion of the investigator. The percentage of patients with at least 1 gout flare was summarized by time interval (Months 0–6, 6–12, 12–18, and 18–24) as well as for the overall study. Each percentage was calculated based on the number of

patients who had at least 1 day of drug exposure in the corresponding time interval. Differences between treatment groups were assessed using Fisher's exact test.

Results: A total of 314 patients received treatment with placebo (n=157) or febuxostat (n=157). During the first 6 months, the febuxostat group showed a slightly higher percentage of patients with at least 1 flare, which was not statistically significant (Figure). During the subsequent time intervals (Months 6–12, 12–18, and 18–24), the percentage of patients with at least 1 flare was consistently and significantly lower in the febuxostat group than the placebo group (Figure). Over the entire study duration, the percentage of patients with at least 1 flare was significantly lower in the febuxostat group than the placebo group (29.3% vs 41.4%, p<0.05).



*p<0.05 and †p<0.01 for febuxostat 40/80 mg QD versus placebo;
‡Anti-inflammatory prophylaxis was given during the first 6 months of the study.
M=month; QD=once daily.

Conclusion: Recurrent flares commonly occur in early gout, affecting >40% of patients over a 2-year period. This first clinical trial in patients with early gout demonstrates that treatment with febuxostat, to a target sUA of <6.0 mg/dL, can achieve a significant reduction in gout flares compared with placebo over a 2-year period, with significantly fewer gout flares during Months 6–12, 12–18, and 18–24.

SESSION INFORMATION

Session Date: Sunday, November 13, 2016
Session Title: ACR Late-Breaking Poster Session
Session Type: ACR Late-breaking Abstract Session
Session Time: 9:00AM-11:00AM

Background/Purpose: Bimagrumab (BYM338) is a novel fully human monoclonal antibody that binds competitively to activin type II receptors with greater affinity than natural inhibitory ligands such as activin and myostatin, thereby inducing skeletal muscle hypertrophy. This study examined efficacy and safety of bimagrumab on physical function, muscle strength and muscle mass in patients with sporadic inclusion body myositis (sIBM).

Methods: RESILIENT was a multicenter, randomized, double-blind, placebo-controlled, dose-finding study (clinicaltrials.gov NCT01925209). Eligible participants were randomized (1:1:1:1) to receive i.v. infusions of bimagrumab 10, 3, 1 mg/kg or placebo every 4 weeks for at least 48 weeks. Change from baseline to Week 52 in 6-minute walk distance test (6MWD; primary outcome), quadriceps quantitative muscle testing (QMT), sIBM physical functioning assessment (sIFA) and lean body mass (LBM) were assessed. Safety assessments included recording of adverse events (AEs) and serious AEs.

Results: 251 patients (mean[SD] age: 68.1[8.2] years; 162[64.5%] men; mean time since sIBM diagnosis: 4.6[3.53] years) were randomized and treated. Participants on placebo and 1 mg/kg bimagrumab had a mean 6MWD decrease from baseline to Week 52 of 8.96 and 10.27 m, respectively, vs. an increase of 9.63 m for 3 mg/kg and 8.63 m for 10 mg/kg bimagrumab. Differences between treatment vs. placebo did not reach statistical significance ($p>0.1$). No consistent differences in quadriceps QMT were observed vs. placebo. However, at Week 52, there was less deterioration (mean treatment difference: 5.10; 0-100 scale) in the patient-reported outcome (PRO) instrument, sIFA, in 10 mg/kg bimagrumab vs. placebo ($p=0.03$), resulting in a clinically relevant and statistically significant increase in responders in this group (55% vs. 30%; $p=0.0115$). Bimagrumab showed a dose-dependent increase in LBM vs. placebo (mean treatment ratios: 3 and 10 mg/kg vs. placebo: 1.033 and 1.058, respectively). At Week 52, the difference was statistically significant for the 3 and 10 mg/kg doses ($p\leq0.0001$). The most frequently reported AEs in the bimagrumab groups were diarrhea and muscle spasm. About one-third patients in all groups reported serious AEs, except for bimagrumab 3 mg/kg (17.5%).

Conclusion: Bimagrumab was well-tolerated, increased LBM and showed a potential benefit in PRO, but did not reach the primary endpoint of improving 6MWD or showed an improvement in muscle strength.

Session Title: ACR Late-Breaking Poster Session

Session Type: ACR Late-breaking Abstract Session

Session Time: 9:00AM-11:00AM

Background/Purpose: Evidence points to the role of abnormal IL-1β production in familial Mediterranean fever (FMF), hyper-immunoglobulin D syndrome/mevalonate kinase deficiency (HIDS/MKD) and TNF receptor-associated periodic syndrome (TRAPS). Analysis of the efficacy of canakinumab (CAN), a fully human anti-IL-1β monoclonal antibody, in the double blind randomized epoch 2 of the phase 3 CLUSTER trial in patients (pts) with colchicine-resistant FMF (crFMF), HIDS/MKD or TRAPS has demonstrated highly significant differences vs placebo (PBO) in the primary outcome (resolution of the index flare by Day 15 and no subsequent flares up to week [wk] 16) in the 3 diseases[1]. Here we report the results from the subsequent epoch 3 (up to wk 40) that included a randomized withdrawal phase to evaluate CAN at a prolonged dosing interval (8 wks [q8w]) or complete discontinuation.

Methods: The study comprises 3 disease cohorts (crFMF, HIDS/MKD and TRAPS) and 4 epochs: a 12-wk screening epoch (E1), a 16-wk randomized treatment epoch (E2), a 24-wk randomized withdrawal epoch (E3) and a 72-wk open-label treatment epoch (E4). Pts who were initially randomized to CAN 150 mg every 4 wks (q4w) and did not flare in E2 were re-randomized 1:1 to CAN 150 mg q8w or PBO in E3. The endpoint of E3 was the proportion of pts who maintained control of disease (no flares: PGA ≤2 and CRP ≤30 mg/L) between Wk 16 and Wk 40 after re-randomization to CAN 150 mg q8w vs PBO. Moreover, in order to gain additional information on the maintenance dose in the long-term, pts who escaped to open-label CAN during E2, were dosed to open-label CAN 150mg q8w during E3. Pts with a flare could be escalated up to 300 mg q4w.

Results: 42 pts who were CAN (150 mg q4w) responders in E2 were re-randomized to CAN 150 mg q8w or PBO in E3. At Wk 40, the proportion of responders was numerically higher in the CAN vs PBO group in all 3 disease cohorts (Table). Overall in E3, including pts treated in open-label, 49% of the crFMF pts, 53% of the TRAPS pts and 23% of the HIDS/MKD pts maintained disease control with a prolonged dosing interval (150 mg q8w). Up-titration to 300 mg q4w was needed in few pts with crFMF (10%) or TRAPS (8%) and in 29% of those with HIDS/MKD. No new safety findings were reported in CAN-treated pts through E3, with no toxicity accumulation (Table). No deaths were reported in the 3 disease cohorts.

Conclusion: The results of E3 in this pivotal trial confirm long-term efficacy of CAN in crFMF, HIDS/MKD and TRAPS, and yield information on the long-term dose needed to control disease, with approximately half of the pts with crFMF or TRAPS and approximately 1/3 of the pts with HIDS/MKD showing no flare at a prolonged dose interval administration of 150 mg q8w. The higher dose of 300 mg q4w was needed in few pts with crFMF or TRAPS and in 1/3 of the pts with HIDS/MKD. No new safety issues were reported over 40 wks of CAN treatment; the safety profile was not distinct from previous controlled studies.

Table. Efficacy results up to 40 weeks and summary of safety							
Efficacy

SESSION INFORMATION
Session Date: Sunday, November 13, 2016
Session Title: ACR Late-Breaking Poster Session
Session Type: ACR Late-breaking Abstract Session
Session Time: 9:00AM-11:00AM

Background/Purpose: Tofacitinib is an oral Janus kinase inhibitor under investigation for treatment of PsA. In this first study of tofacitinib in patients (pts) with active PsA and an inadequate response (IR) to TNF inhibitors (TNFi), efficacy and safety vs placebo (PBO) were evaluated.

Methods: Eligible pts in this 6-month, randomized, PBO-controlled, double-blind, multicenter, Phase 3 study had ≥6 months' PsA diagnosis, fulfilled ClASsification criteria for Psoriatic ARthritis, had active arthritis (≥3 tender/painful and ≥3 swollen joints) at screening and baseline, active plaque psoriasis at screening, and IR to ≥1 TNFi (discontinuation for inadequate efficacy or an adverse event [AE]). Pts were randomized 2:2:1:1 to tofacitinib 5 mg twice daily (BID; n=132), tofacitinib 10 mg BID (n=132), PBO→tofacitinib 5 mg BID (n=66), or PBO→tofacitinib 10 mg BID (n=65). Pts randomized to PBO advanced (blinded) to tofacitinib 5 or 10 mg BID at Month (M) 3. Ongoing treatment with 1 conventional synthetic DMARD was required. The primary endpoints were ACR20 response rate and change from baseline in Health Assessment Questionnaire Disability Index (ΔHAQ-DI) at M3.

Results: Pt demographics and baseline disease characteristics were broadly similar across groups (Table 1). Of the 395 randomized pts, 394 were treated, 361 (91.6%) completed M3, and 345 (87.6%) completed M6. There were significantly greater improvements in ACR20 response and HAQ-DI for both tofacitinib doses vs PBO at M3; improvements persisted to M6 (Table 2). Tofacitinib 5 and 10 mg BID demonstrated superior ACR20 response vs PBO as early as Week 2 (26.7% and 28.8% vs 13.0%; $p \leq 0.05$). Effects on secondary efficacy endpoints were generally consistent with the primary findings (Table 2). Serious AEs and discontinuations due to AEs were low in frequency (Table 3). The most common AEs were upper respiratory tract infection (5.3–10.8% of pts across groups), nasopharyngitis (1.5–10.7%), and headache (4.5–9.1%).

Conclusion: In this first study comprising only TNFi-IR pts with PsA, tofacitinib was superior to PBO in ACR20 response and ΔHAQ-DI at M3, with ACR20 superiority vs PBO as early as Week 2 (first assessment). Secondary endpoints were consistent with the primary analyses. No new safety risks were identified vs previous tofacitinib studies in RA and psoriasis.

BMS-986165 Is a Highly Potent and Selective Allosteric Inhibitor of Tyk2, Blocks IL-12, IL-23 and Type I Interferon Signaling and Provides for Robust Efficacy in Preclinical Models of Systemic Lupus Erythematosus and Inflammatory Bowel Disease

Session Title: ACR Late-Breaking Poster Session
Session Type: ACR Late-breaking Abstract Session
Session Time: 9:00AM-11:00AM

Background/Purpose: Tyk2 mediates signaling downstream of the receptors for IL-12, IL-23 and Type I interferons, all key drivers of autoimmune disorders such as SLE. BMS-986165, an investigational agent entering Phase 2 studies for the treatment of multiple immune-mediated disorders, is a highly selective inhibitor of Tyk2-mediated signal transduction that acts by stabilizing the pseudokinase domain of the protein. The current report describes the preclinical pharmacology of BMS-986165, including mouse models of lupus and inflammatory bowel disease.

Methods: The affinity of BMS-986165 for the pseudokinase domain of Tyk2 was evaluated using recombinant protein, and functional assays used both cells isolated from peripheral human blood and whole blood from lupus patients. The efficacy in a mouse model of lupus nephritis employed NZB/W lupus-prone mice in which BMS-986165 was administered PO QD for 16 weeks. Body weight, proteinuria, anti-dsDNA titers, and gene expression (kidneys and blood) were measured, and kidneys were examined histologically for nephritis and immune complex deposition. In a model of inflammatory bowel disease, colitis was induced in SCID mice by an agonistic anti-CD40 Ab, and effect of BMS-986165 (administered PO QD) was evaluated against both the body weight loss and histologically evident colitis.

Results: BMS-986165 potently binds to the Tyk2 pseudokinase domain (Ki = 0.02 nM), and is highly selective against a panel of 265 kinases and pseudokinases. The compound potently inhibited IL-23-, IL-12-, and Type I interferon-driven cellular signaling and transcriptional responses (IC50 range 2-14 nM). BMS-986165 was approximately 200-fold selective against JAK1/3-dependent signaling in IL-2-stimulated T cells and >3,000-fold selective over JAK2-dependent EPO-induced signaling in TF-1 cells. In human whole blood, BMS-986165 inhibited Tyk2-dependent IFNa-induced signaling with an IC50 of 13 nM. Addition of BMS-986165 to whole blood from lupus patients led to reduced expression of Type I IFN response genes, a response identical to that achieved with an anti-IFNAR Ab and superior to an anti-IFNa Ab. BMS-986165 treatment in NZB/W lupus-prone mice rapidly (24 hours) reduced the elevated expression of Type I interferon-dependent genes and dose-dependently protected from nephritis and other disease endpoints with chronic dosing, with efficacy correlating with inhibition of Type I interferon-dependent gene expression. Protection from nephritis at 10 mpk trended to be superior to a blocking anti-Type I IFN receptor antibody (anti-IFNAR). BMS-986165 was also highly efficacious in the anti-CD40-induced colitis model in SCID mice, providing protection against both weight loss (wasting) and histologically evident colitis, and was as effective as an anti-p40 antibody.

Conclusion: In summary, the potent and highly selective suppression by BMS-986165 of the IL-23/TH17 axis, IL-12-mediated TH1 functions, and Type I interferon-driven modulation of immune pathways results in robust efficacy in preclinical models of SLE and IBD. These results provided the rationale for progression into human trials, and the compound is entering Phase 2 studies for the treatment of multiple immune-mediated disorders.

Session Title: ACR Late-Breaking Poster Session

Session Type: ACR Late-breaking Abstract Session

Session Time: 9:00AM-11:00AM

Background/Purpose: Atacicept targets B-cell stimulating factors BLyS and APRIL. In the APRIL-SLE trial, atacicept 150 mg was associated with reduced SLE flares in post-hoc analyses.[1]

Methods: ADDRESS II was a phase IIb, multicenter study (NCT01972568). Patients with active (SLEDAI-2K $\geq$ 6), autoantibody-positive SLE on standard-of-care therapy were randomized (1:1:1) to weekly SC injections of atacicept (75 or 150 mg) or placebo (PBO) for 24 weeks. The primary endpoint

was the % of patients achieving SRI-4 response at week 24.

Results: The ITT population included 306 patients (100 PBO; 102 atacicept 75 mg; 104 atacicept 150 mg). There was a trend towards improved SRI-4 response with atacicept vs PBO at week 24 (p=ns) (primary analysis; screening visit as baseline, BL) (**Table 1**). In a prespecified sensitivity analysis using study day 1 as BL, a significantly larger proportion of patients on atacicept achieved SRI-4 response at week 24: PBO, 41%; atacicept 75 mg, 55.9% (OR 1.88) p=0.029; atacicept 150 mg, 55.8% (OR 1.96) p=0.020. In predefined subpopulations with high disease activity (HDA; SLEDAI-2K ≥10, n=158), serologically active (SA) disease (dsDNA antibody-positive and low complement, n=84), or both (HDA SA, n=69), enhanced improvements in SRI-4 and SRI-6 response rates were seen with atacicept vs PBO (**Table 1**). SRI-6 response rates in HDA patients were significantly greater with atacicept 150 mg vs PBO at weeks 8, 16 and 24 (**Figure 1**). In HDA patients, severe flare was significantly reduced by atacicept 75 mg (BILAG A HR 0.1; p=0.002; SLEDAI flare index [SFI] HR 0.3; p=0.029) and 150 mg (BILAG A HR 0.3; p=0.038; SFI HR 0.2; p=0.004). In the ITT population, BILAG A flare was significantly reduced vs PBO with atacicept 75 mg (p=0.019), and severe SFI flare reduced with 150 mg (p=0.002). Atacicept was associated with increased serum complement C3/C4, and decreased IgG, IgM, IgA, and anti-dsDNA antibodies over time. Rates of AEs were similar between groups. Compared with placebo, the risks of SAEs and serious/severe infections were not increased with atacicept (**Table 2**).

Conclusion: Atacicept showed evidence of efficacy in SLE, particularly in HDA and SA patients; reduction in disease activity and severe flare was observed. Atacicept was associated with a favorable safety profile. 1. Isenberg D, et al. *Ann Rheum Dis*. 2015;74:2006-15.

SESSION INFORMATION

Session Date: Sunday, November 13, 2016
Session Title: ACR Late-Breaking Poster Session
Session Type: ACR Late-breaking Abstract Session
Session Time: 9:00AM-11:00AM

Background/Purpose: Interleukin-2 (IL-2) is crucial for the growth and survival of regulatory T cells (Treg), and thus for the control of autoimmunity. In previous studies we have proven the significance of an acquired IL-2 deficiency and related Treg defects in the pathogenesis of systemic lupus erythematosus (SLE). Accordingly, we showed that compensation of IL-2 deficiency by low dose IL-2 therapy is capable to correct Treg defects in SLE patients.

Here, we conducted a combined phase I/IIa single center clinical trial (PRO-IMMUN; EudraCT-Number: 2013-001599-40; DRKS-ID: DRKS00004858) addressing the safety, tolerability, immunological responses and clinical efficacy of a subcutaneous low-dose IL-2 therapy in patients with refractory and active SLE.

Methods: 10 patients with active and refractory SLE (SLEDAI $\geq$ 6; at least two different immunosuppressive therapies) were enroled into the trial and 2 patients were treated „off-label“ with the same regimen. The therapeutic regimen consisted of four treatment cycles each with daily subcutaneous injections of recombinant human IL-2 (aldesleukin) at single doses of 0.75, 1.5 or 3.0 million IU on five consecutive days separated by washout-periods of 9-16 days and followed by a 9-week follow-up period. Cells from peripheral blood were analysed by flow cytometry at every study visit before the IL-2 injections and one day after the 5th IL-2 injection. The primary objective was to show an increase in the percentage of CD25hi cells among CD3+CD4+Foxp3+CD127lo Treg cells by at least 100% (2-fold) after the 4th treatment cycle compared to baseline. Safety and tolerability were evaluated descriptively. Secondary objectives included the clinical responses assessed by SLEDAI and changes in serological and other immunological parameters.

Results: All 12 patients showed an effective and cycle-dependent increase in the percentage of CD25hi cells among Treg ($p<0.001$). 10 patients showed a reduction in SLEDAI (83.3%, $p<0.05$) and 8 patients achieved a clinical response (66.7%) with a complete disappearance of clinical manifestations such as rash, arthritis, myositis and alopecia. Levels of complement were significantly increased after the treatment compared to baseline ($p<0.05$). However, we could not observe a reduction in levels of anti-dsDNA-Abs. Treatment-related adverse events were generally mild and transient.

Conclusion: Low-dose IL-2 therapy is capable to safely and selectively expand the Treg population and to decrease disease activity in patients with active and refractory SLE. This study provides the basis for

larger and placebo-controlled clincial studies aiming to prove the efficacy of this novel biologic treatment strategy.

Use of Intravenous Epoprostenol As a Treatment for the Digital Vasculopathy Associated with the Scleroderma Spectrum of Diseases

Shing Law[1], Robert W. Simms[2] and Harrison W. Farber[3], [1]Rheumatology, Boston Medical Center, Boston, MA, [2]Rheumatology, Boston University School of Medicine, Boston, MA, [3]Pulmonary Center, Boston University Medical Center, Boston, MA

SESSION INFORMATION

Session Date: Sunday, November 13, 2016

Session Title: ACR Late-Breaking Poster Session

Session Type: ACR Late-breaking Abstract Session

Session Time: 9:00AM-11:00AM

Background/Purpose:

Intravenous prostanoid therapy is recommended for severe systemic sclerosis related digital vasculopathy. Evidence to support this recommendation is limited. Our objective is to evaluate the safety and efficacy of treating scleroderma spectrum digital vasculopathy with intravenous epoprostenol.

Methods:

Patients with systemic sclerosis and received intravenous epoprostenol for scleroderma spectrum digital vasculopathy (defined as digital ischemic ulcers, digital ischemia with or without gangrene, but not uncomplicated Raynaud's) between 10/01/2003 – 09/01/2015 at Boston University Medical Center were identified using ICD-9 code search and their charts were reviewed in this retrospective case series. The epoprostenol infusion protocol used was as follows:

Continuous intravenous epoprostenol begun at 2ng/kg/min and increased every 15min to a maximum dose

of 8ng/kg/min. Epoprostenol was administered via central access (most frequently a PICC line); the final dose was dependent on tolerability, hemodynamic stability and oxygenation. This dose (most frequently 8ng/kg/min) was maintained for five days and then weaned by 2ng/kg/min every 12h unless there was recurrence of the digital ischemia. In that case, the dose was held or increased, depending on the severity of the ischemia, until the ischemic episode resolved. Prior to discontinuing the epoprostenol, another vasodilator (usually a PDE-5i) was added.

Results:

There were 46 epoprostenol infusions in 35 patients with scleroderma spectrum digital vasculopathy. 32 patients were female. Patients' ages ranged from 21 to 85 with a median age of 50. 19 patients had limited cutaneous systemic sclerosis, 5 had diffuse cutaneous systemic sclerosis, 3 had mixed connective tissue disease, 2 had systemic sclerosis sine scleroderma. Scleroderma spectrum subtype was not documented in 6 patients. Epoprostenol was usually titrated to 8ng/kg/min and held at that dose for 5 days.

Out of 46 epoprostenol infusions, 29 had documentation of improvement as indicated by pain relief, increased perfusion of digits as assessed by warmth or color, reduced number and size of digital ulcers. Two epoprostenol infusions resulted in no improvement. In 16 infusions, there was no documentation as to whether the digital vasculopathy improved or not. Although there was no documented clinical deterioration during an infusion, 5 patients ultimately required surgical intervention including amputation or debridement.

Out of 46 infusions, adverse effects occurred in 26. Adverse events were common and included nausea/vomiting, jaw pain, headaches and flushing, but were transient and typically occurred with dose escalation. Serious adverse events were uncommon and included hypotension (4), line infection (1) and line thrombosis (1).

Conclusion:

This is the largest study investigating the use of intravenous epoprostenol infusion in the treatment of scleroderma spectrum digital vasculopathy. We demonstrate that the use of our intravenous epoprostenol infusion protocol vasculopathy is generally safe and effective, and should be considered an important therapeutic option for scleroderma spectrum digital vasculopathy.

Selective Oral ROCK2 Inhibitor Reduces Clinical Scores in Patients with Psoriasis vulgaris and Normalizes Skin Pathology

Via Concurrent Regulation of IL-17 and IL-10 Levels

Alexandra Zanin-Zhorov[1], Jonathan Weiss[1], Alissa Trzeciak[1], Carmen Arencibia[1], Seetharam Polimera[1], Wei Chen[1], Jingya Zhang[1], Melanie Nyuydzefe[1], Judilyn Fuentes-Duculan[2], Kathleen Bonifacio[2], Norma Kunjravia[2], Inna Cueto[2], Mark Berger[1], James Krueger[2], Samuel Waksal[1] and John Ryan[1], [1]Kadmon, New York, NY, [2]Rockefeller University, New York, NY

SESSION INFORMATION
Session Date: Sunday, November 13, 2016
Session Title: ACR Late-Breaking Poster Session
Session Type: ACR Late-breaking Abstract Session
Session Time: 9:00AM-11:00AM

Background/Purpose: Rho-associated kinase 2 (ROCK2) was shown to be implicated in regulation of autoimmunity in mice and humans[1]. Previous findings demonstrated that oral administration of a selective ROCK2 inhibitor (KD025) in healthy subjects decreases IL-17 and IL-21 secretion induced by *ex vivo* stimulation[2]. Moreover, targeted ROCK2 inhibition shifted the balance between Th17/Tfh and Treg subsets via concurrent regulation of STAT3/STAT5 phosphorylation[2-4]. We have hypothesized that targeting of ROCK2 may therefore restore disrupted immune homeostasis and has a role in the treatment of Th17-driven inflammatory disorders.

Methods: We conducted a Phase 2, open-label, dose-finding study to evaluate the safety, tolerability, and activity of KD025 in subjects with psoriasis vulgaris who failed first-line therapy (NCT02317627 at ClinicalTrials.gov). KD025 was orally administrated at three daily dose regimens for 12 weeks. Decreases in Psoriasis Area and Severity Index (PASI) scores were measured and peripheral blood samples were collected on a monthly basis. The levels of cytokines in plasma samples were determined by using the Simoa® Immunoassay. Skin punch biopsies were obtained at baseline and at the end of treatment.

Results: KD025 treatment resulted in PASI score reductions in 85% of patients completing the study, with minimal side effects. In the 400 mg QD and 200 mg BID cohorts, 42% and 71% of patients respectively achieved at least a 50% decrease in PASI score (PASI 50) after 12 weeks of treatment. KD025 reduced levels of both IL-17 and IL-23, but not IL-6 and TNF-a in the peripheral blood of clinical responders, whereas IL-10 levels were increased at the end of the study. The clinical improvement and changes in cytokine levels were associated with decreased epidermal thickness and T-cell infiltration in the skin.

Conclusion: Collectively, our results demonstrate that selective ROCK2 inhibition with KD025 down-regulates Th17-driven autoimmune response and improved clinical symptoms in psoriatic patients via concurrent modulation of cytokines without deleterious impact on the rest of the immune system.

SESSION INFORMATION

Session Date: Sunday, November 13, 2016
Session Title: ACR Late-Breaking Poster Session
Session Type: ACR Late-breaking Abstract Session
Session Time: 9:00AM-11:00AM

Background/Purpose: Remission of ANCA-associated vasculitides (AAVs) can be induced with combined glucocorticoids and cyclophosphamide or rituximab (RTX) with comparable efficacy.[1] RTX superiority to azathioprine was demonstrated for remission maintenance;[2] in that trial, at month 28, major relapses occurred in only 5% of the patients on RTX vs 29% taking azathioprine (AZA). Although, at present, neither ANCA-positivity and/or their titers nor peripheral blood CD19 B-cell detection are considered reliable predictors of AAV relapses, relapses are rare when they are negative.[3] This trial (MAINRITSAN2, registered with ClinicalTrials.gov, no. NCT01731561) was designed to evaluate RTX use, adapted to ANCA-positivity and/or titer and/or reappearance of circulating CD19 B cells, to maintain AAV remission.

Methods: Patients with granulomatosis with polyangiitis (GPA) or microscopic polyangiitis (MPA) in complete remission after induction therapy with glucocorticoids and cyclophosphamide or rituximab or methotrexate were included in an open-label, multicenter, randomized–controlled trial to compare regimens with RTX given according to ANCA status/titer and/or circulating CD19 B-cell reappearance vs systematic RTX infusions (controls). The experimental arm received fixed, 500-mg RTX infusions on day-0 post-randomization, then every 3 months until month 18, when CD19 lymphocytes exceeded 0/mm^3 or ANCA status (reappearance)/titer (higher) differed from the previous determination. Controls received 500 mg of RTX on days 0 and 14 after randomization, and then 6, 12 and 18 months after the first infusion. The primary endpoint was the number of relapses (new or reappearing symptom or worsening disease with BVAS>0) at month 28; it was evaluated by an independent Adjudication Committee blinded to

treatment arms.

Results: The 162 patients included [117 (72.2%) GPA and 45 (27.8%) MPA] were equally allocated to the experimental arm (n=81; 50%) and control (n=81; 50%) groups. Pre-randomization induction therapy was cyclophosphamide for 100 (61.7%) patients, RTX for 61 (37.7%) or methotrexate for 1 (0.6%). Twenty-one (13%) patients suffered 22 relapses: 14 (17.3%) in 13 experimental arm patients and 8 (9.9%) in 8 controls (P=0.20). Median (interquartile range (IQR)) numbers of RTX infusions were 3 (2–4) for the experimental arm and 5 (IQR 5–5) for controls. Four patients died, 1 of an infectious complication.

Conclusion: AAV relapse rates for patients given individually tailored or systematic RTX-infusion schedules did not differ significantly. However, the experimental arm patients received fewer infusions and lower total RTX doses. [1]Stone JH *et al*. N Engl J Med 2010;363:221–32. [2]Guillevin L *et al*. N Engl J Med 2014;371:1771–80. Session Title: ACR Late-Breaking Poster Session

Session Type: ACR Late-breaking Abstract Session

Session Time: 9:00AM-11:00AM

Background/Purpose: Hepatitis C virus (HCV) is the aetiological agent for most cases of cryoglobulinemia vasculitis. Interferon containing regimens are associated with important side effects and may exacerbate the vasculitis. Objective: To evaluate safety and efficacy of an oral interferon free regimen, sofosbuvir plus daclatasvir in HCV cryoglobulinemia vasculitis.

Methods: We enrolled 35 patients (median age of 57 years and 45% of women) with HCV cryoglobulinemia vasculitis. Sofosbuvir (400mg/day) was associated with Daclatasvir (60mg/day) for 12 or 24 weeks. The primary efficacy end point was a complete response of the vasculitis at the end of treatment. Secondary endpoints included (i) immunological response (i.e. clearance of cryoglobulin), (ii) sustained virological response (viral eradication, i.e. prolonged negative viremia), and safety.

Results: HCV genotype was 1 (n=21), 2 (n=2), 3 (n=7), 4 (n=3) and 5 (n=2). Seventeen (48.6%) had cirrhosis. Main features of HCV cryoglobulinemia vasculitis included arthralgia (66%), purpura (54%) peripheral neuropathy (54%), skin ulcers (11%) and glomerulonephritis (11%).Thirty two (91%) were complete clinical response at end of treatment. The mean cryoglobulin and alanine aminotransferase levels decreased from [0.36 ± 0.12 to 0.10 ± 0.08 g/L, ($p=0.019$) and 57.6 ± 7.1 to 20.4 ± 2.0 IU/ml, ($p<0.0001$)], respectively at week 12 post treatment. Fifty percent of patients achieved complete immunological response (i.e. clearance of cryoglobulin). All patients had a sustained virological response at week 12 post treatment and the HCV viral load dropped from 5.6 to 1.18 IU/ml at week 4, ($p<0.0001$). The most common side effects were asthenia (14.3%), nausea (8.6%), and insomnia (3%). No serious adverse event was reported.

Conclusion: S Sofosbuvir plus daclatasvir antiviral combination is highly and quickly active in HCV-cryoglobulinemia vasculitis, with a good tolerance profile.

SESSION INFORMATION

Session Date: Sunday, November 13, 2016
Session Title: ACR Late-Breaking Poster Session
Session Type: ACR Late-breaking Abstract Session
Session Time: 9:00AM-11:00AM

Background/Purpose: Neurosarcoidosis and primary angiitis of central nervous system (PACNS) are inflammatory diseases affecting central nervous system, with overlapping clinical and pathological characteristics. Differentiating between both conditions is crucial for differences in therapeutic options. In this study, we aimed to compare the MRI findings between these two conditions to enhance our diagnostic approach, which can lead to more accurate decisions about appropriate treatment strategy.

Methods: Thirty-four patients with PACNS and forty two patients with neurosarcoidosis were included in the study. Brain and/or spinal cord MRI performed near the time of presentation were blindly evaluated by two neuroradiologists. Data regarding involvement of pachy- and leptomeninges, basal meninges, cranial nerves, cerebral grey and white matter, and spinal cord were recorded for each patient. For each of these sites, presence, pattern (focal vs diffuse), localization (cerebral lobes, brain stem, cerebellum, tentorium, falx cerebri), and laterality of involvement (right, left, bilateral) were recorded. Additionally, ventriculomegaly, mass effect, and parenchymal hemorrhage were recorded. Chi square and Fisher's exact tests were used to compare the groups, as appropriate. All statistical analyses were performed using SAS 9.4 software.

Results: Mean age of patients was 45.6 (range, 5-80) and 44.1 (range, 25-66) in PACNS and neurosarcoidosis groups, respectively. MRI findings are summarized in the Table. Enhancement and abnormal signal in grey and/or white matter were significantly more common in patients with PACNS. However, localization and laterality of grey and/or white matter involvements did not show a difference between groups. In addition, basal ganglia enhancement and parenchymal hemorrhage were significantly associated with PACNS. On the other hand, patients with neurosarcoidosis had more common basal meningeal, spinal cord and cranial nerve involvements. Frequency, pattern, laterality and localization of pachy- and leptomeningeal, pituitary and hypothalamic involvements; frequency of brain mass effect and ventriculomegaly were similar between groups.

Conclusion: Patients with PACNS had higher frequency of cerebral and basal ganglia enhancement, and

parenchymal hemorrhage, while patients with neurosarcoidosis demonstrated more frequent spinal cord, basal meningeal and cranial nerve involvements. These findings suggest that MRI can be an efficient tool in distinguishing PACNS from neurosarcoidosis. **Table.** Frequencies and comparison of MRI findings in patients with PACNS and neurosarcoidosis (NS).

Session Title: ACR Late-Breaking Poster Session

Session Type: ACR Late-breaking Abstract Session

Session Time: 9:00AM-11:00AM

Background/Purpose: TNF-inhibitors (TNFi) have improved treatment of spondyloarthritis (SpA), rheumatoid arthritis (RA), psoriatic arthritis (PsA), Crohn's disease (CD), ulcerative colitis (UC), and chronic plaque psoriasis (Ps). The NOR-SWITCH trial was funded by the Norwegian government. The aim of the NOR-SWITCH trial was to examine switching from originator to biosimilar infliximab regarding efficacy, safety and immunogenicity.

Methods: The study was designed as a 52-week randomized, double-blind, non-inferiority, phase IV trial. Adult patients with a diagnosis of SpA, RA, PsA, CD, UC or Ps on stable treatment with the originator infliximab (Remicade®, INX) for at least 6 months were eligible. Patients with informed consent were randomized 1:1 to either continued INX or switch to CT-P13 treatment (biosimilar infliximab, Remsima®), using unchanged dosing regimen. Data were collected at infusion visits. The primary endpoint was disease worsening during follow-up according to worsening in disease-specific composite measures and/or a consensus between investigator and patient leading to major change in treatment. Exploratory subgroup analyses were performed to examine disease worsening within each of the six diagnoses. The non-inferiority margin was set to 15% and power calculations indicated that 394 patients were required in the primary Per Protocol Set (PPS). The primary endpoint was analysed using logistic regression, adjusted for diagnosis and disease duration at baseline.

Results: Between October 6, 2014 and July 8, 2016, 481 patients (INX 241, CT-P13 240, Full Analysis Set, FAS) at 40 Norwegian study centres were randomized, received treatment and were followed for 52 weeks. The main demographic and baseline characteristics are shown in the table. Disease worsening occurred in 26.2% and 29.6% of patients in the INX and CT-P13 arms, respectively (PPS). The 95% confidence interval of the adjusted treatment difference (-4.4%) was -12.7 – 3.9 which was within the pre-specified non-inferiority margin. The frequency of disease worsening in each specific diagnosis is shown in the table (exploratory analyses). Changes in the generic disease variables and disease specific composite measures were similar in both arms (table). The incidence of anti-drug antibodies detected during the study was 17 (7.1%) and 19 (7.9%) in the INX and CT-P13 patients, respectively (FAS). The trough drug levels and the frequencies of reported adverse events including infusion reactions were also similar (data not shown).

Conclusion: The NOR-SWITCH trial demonstrated that switching from INX to CT-P13 was not inferior to continued treatment with INX.

Table. Demographic and baseline characteristics (FAS), percentage of patients with disease worsening and change in disease measures during 52 weeks follow-up (PPS)			
	INX	**CT-P13**	95% CI of group difference after 52 weeks
Number of patients (FAS)	**241**	**240**
