Figure 1. Urine L-selectin levels and its correlation with clinical indices. (A) Urine L-selectin was significantly elevated exclusively in aLN patients when compared with HC (ng/mg), or aNR, iLN, iNR patients, or even CKD patients. (B) Receiver operating characteristic curve analysis (ROC) showed urine L-selectin significantly discriminated aLN patients from aNR, iLN, iNR, CKD and HC. Values in the plot indicate areas under curve. (C) ROC analysis showed urine L-selectin outperformed C3, C4 or anti-dsDNA antibody in discriminating active lupus nephritis (aLN) from active non-renal SLE (aNR). Values in the plot indicate areas under curve (AUC). (D, E, F) Urine L-selectin was correlated significantly with SLEDAI, rSLEDAI and SLICC RAS. aLN, active lupus nephritis; HC, health control; aNR, active non-renal; iLN, inactive lupus nephritis; iNR, inactive non-renal; CKD, chronic kidney disease; C3, complement 3; C4, complement 4; R, Spearman's correlation coefficient; SLEDAI, Systemic Lupus Erythematosus Disease Activity Index; rSLEDAI, renal SLEDAI; SLICC RAS, SLICC renal activity score; ****P<0.0001.

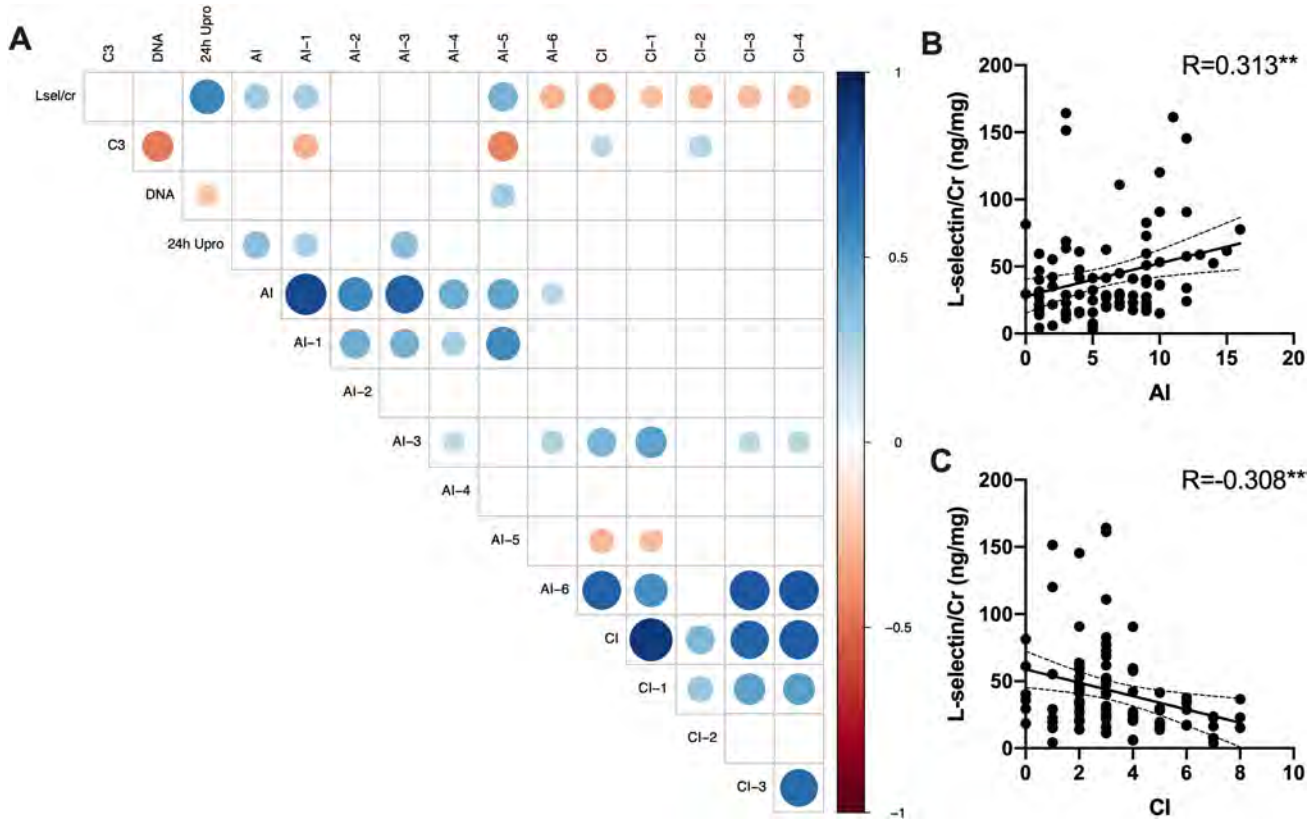

Figure 2. Correlation analysis between urine L-selectin and renal histopathology. (A) Correlation heatmap analysis for comparison of L-selectin and conventional metrics (C3, anti-dsDNA and 24h Upro) in AI, CI and their component attributes. The size and color of circles reflected the corresponding correlation coefficient values (R) of correlation analysis. The larger the circle, the bigger the value. Circles in which the corresponding R values were over 0.05 were removed off the squares. (B, C) Correlation analysis between urine L-selectin and AI, CI in renal histopathology. AI, activity index; CI, chronicity index; DNA, anti-dsDNA antibody; 24h Upro, 24-hour urine protein quantity; AI-1, Endocapillary hypercellularity; AI-2, Glomerular leukocyte infiltration; AI-3, Cellular and/or fibrocellular crescents; AI-4, Fibrinoid necrosis and/or karyorrhexis; AI-5, Wire loop deposits; AI-6, Interstitial inflammation; CI-1, Glomerulosclerosis; CI-2, Fibrous crescents; CI-3, Interstitial fibrosis; CI-4, Tubular atrophy; R, Spearman's correlation coefficient; **P<0.01.

Methods: In a single center Chinese lupus cohort, a total of 197 SLE patients were recruited. 33 chronic kidney disease (CKD) patients and 27 health volunteers were also included as controls. Urine L-selective levels were tested using ELISA. Clinical characteristics and laboratory tests were collected at baseline. Renal histopathology was viewed by an experienced renal pathologist for paired urine-kidney biopsy samples from active LN patients. Furthermore, 18 patients with active LN were followed up for a minimum of 6 months, and we valuated their clinical outcomes and, simultaneously, retested their urine L-selective levels at the end of follow up.

Results: In the cross-sectional cohort, urine L-selectin was significantly increased in active lupus nephritis (aLN) patients (n=89) exclusively compared with active SLE patients without renal involvement (aNR) (n=57) ($p < 0.0001$), inactive LN patients (iLN) (n=25) ($p < 0.0001$), inactive SLE patients without renal involvement (n=26) ($p < 0.0001$), chronic kidney disease (CKD) patients (n=33) ($p < 0.0001$), and health controls (n=27) ($p < 0.0001$) **(Fig.1A)**. ROC analysis further confirmed that urine L-selectin had the better capacity to discriminate aLN patients from other groups, especially from aNR patients **(Fig.1B)**, outperforming conventional indices (C3, C4 and anti-dsDNA) **(Fig.1C)**. Correlation analysis exhibited urine L-selectin correlated well with the SLEDAI score ($r = 0.491$, $p < 0.0001$), renal SLEDAI (rSLEDAI) score ($r = 0.651$, $p < 0.0001$), and SLICC renal activity score (SLICC RAS) ($r = 0.526$, $p < 0.0001$) **(Fig.1D-1F)**. Moreover, urine L-selectin positively correlated with activity index (AI) ($r = 0.313$, $p < 0.01$) and negatively correlated with chronicity index (CI) ($r = -0.308$, $p < 0.01$) of renal pathology. It also strongly correlated with their related pathological attributes (endocapillary hypercellularity, fibrinoid necrosis and/or karyorrhexis, wire loop deposits, interstitial inflammation; glomerulosclerosis, fibrous crescents, interstitial fibrosis and tubular atrophy) (all $p < 0.05$) **(Fig.2A-2C)**. In the follow-up cohort, 12 patients

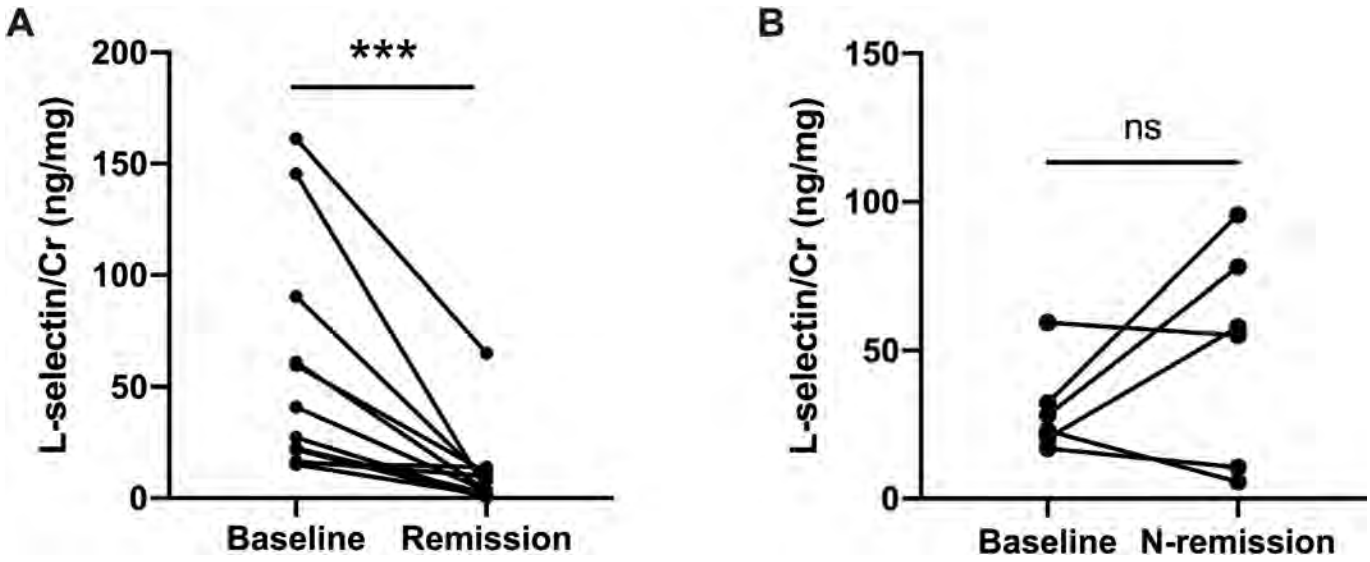

Figure 3. Urine L-selectin may reflect treatment response in clinical situation. The urine L-selectin levels (A) decreased in remission group (CR+PR) (n=12), while (B) remained stable in non-remission group (NR) (n=6). Mann-Whitney U test. N-remission, non-remission. *** P<0.001.

achieved complete remission or partial remission, while 6 patients still maintained no remission. In remission group, urine L-selectin levels at the end of follow up were lower than those at baseline ($p < 0.01$) **(Fig.3A)**. While in non-remission group, urine L-selectin levels showed no differences between the baseline and the end of follow up ($p = 0.44$) **(Fig.3B)**.

Conclusion: Urine L-selectin is a novel biomarker of lupus nephritis disease activity and potential to predict renal histopathology. Besides, it may reflect treatment response of patients in clinical situation.

Abstract Number: 0341

Addition of Narrative Text Abstraction to ICD-Based Abstraction Significantly Improves Identification of Lupus Nephritis in Real-World Data

Meghan Tierney and Chris Rowe, PicnicHealth, San Francisco, CA

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: SLE – Diagnosis, Manifestations, & Outcomes Poster I: Diagnosis (0323–0356)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Lupus nephritis (LN) is often underrecognized and difficult to identify retrospectively, presenting challenges for clinicians and researchers hoping to explore this condition using real-world data (RWD). Common abstraction techniques use ICD codes to pull diagnoses from electronic health records (EHR). However, documentation of LN as a specific diagnosis is an inconsistent practice across providers, leading to underrepresented LN prevalence. Adding abstraction of unstructured narrative text may improve RWD for LN research.

Methods: We retrieved medical records for patients with lupus across the U.S. To be included in the study, patients were required to have a lupus diagnosis documented in their medical record. Natural language processing and

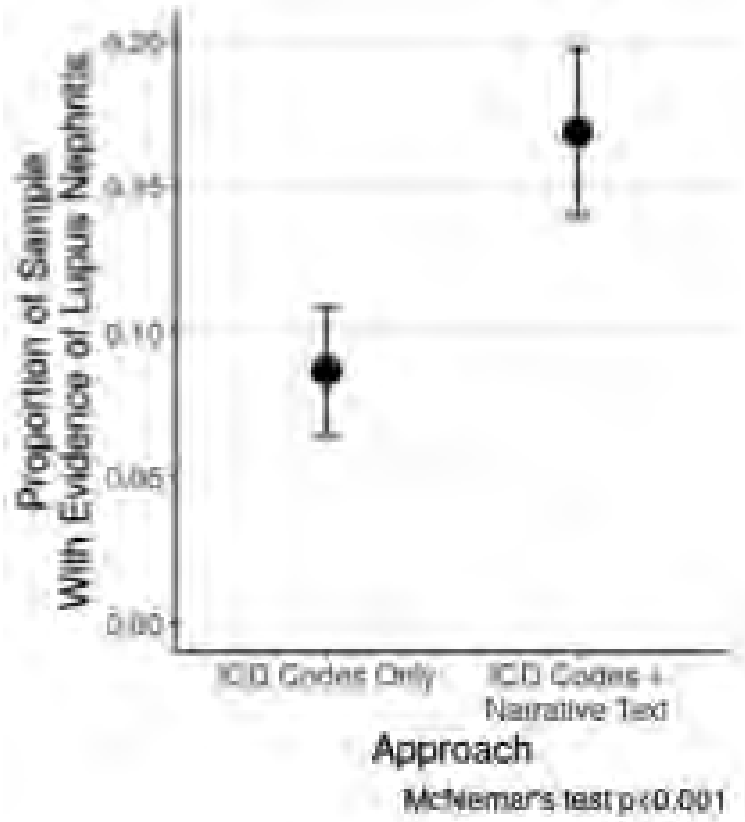

Figure 1. Comparison of the performance of ICD code-only abstraction to ICD code + narrative text abstraction of lupus nephritis from electronic health records.

human-reviewed machine learning were used to abstract and structure the data. We compared 2 approaches to identifying LN in EHR: 1) Query structured sections of the EHR using an ICD-based case definition* (ICD-only); 2) Employ the first approach but also query all unstructured narrative text for LN-related terms (ICD + narrative text). All terms identified using either approach were manually reviewed for validity. For each approach, we calculated the proportion of the sample with evidence of LN (percent, 95% CI) and compared performance using McNemar's test.

Results: Our sample of 635 patients with a diagnosis of lupus in their medical record was 95% female, had a median age of 47 years (IQR=39-56), and resided in 46 U.S. states and Washington D.C. Records spanned a median of 5.4 years (IQR=2.4-10.2), including a median of 6 (IQR=3-13) providers and 3 (IQR=1-5) care sites. The ICD-only approach identified evidence of LN in 55 (8.7%, 95%CI = 6.5-10.8%) patients and the ICD + narrative text approach identified 107 (16.9%, 13.9-19.8%) patients ($p < 0.001$, Figure 1). Leveraging unstructured narrative text identified 95% more patients with LN than only using ICD codes in structured sections of the EHR.

Conclusion: Narrative text abstraction significantly increased capture of LN in this sample of patients with lupus, demonstrating that use of ICD codes alone is not sufficient. An ICD + narrative text has the potential to improve the quality of RWD and better facilitate the generation of RWD for lupus research. Future research should investigate the remaining gap between the rates of LN identified in this manner and the prevalence expected from clinical practice.

*Adapted from Li T. et al, 2021 and Chibnik LB et. al, 2010 (Table 1).

Table 1. Criteria[a] used to identify patients with lupus nephritis (LN) based on ICD codes found in structured sections of electronic health records. Patients were required to have either presence of the specific ICD-10 code for LN (M32.14) *or* presence of ≥2 of the following ICD-9 codes for clinical indicators of nephritis:

ICD-9 Code	Associated Diagnosis
583.81	Nephritis or nephropathy, not specified as acute or chronic, in diseases classified elsewhere
791.0	Proteinuria
581.9	Nephrotic syndrome with unspecified pathological lesion in kidney
580.0	Acute glomerulonephritis with lesion of proliferative glomerulonephritis
582[b]	Chronic glomerulonephritis
583[b]	Nephritis and nephropathy, not specified as acute or chronic
584[b]	Acute kidney failure
585.5	Chronic kidney disease, stage V
585.9	Chronic kidney disease, unspecified
586[b]	Renal failure, unspecified
585.6	End stage renal disease
V56[b]	Renal dialysis encounter

a. Adapted from *Li T. et al, 2021* and *Chibnik LB et. al, 2010*.
b. All ICD-9 codes with this root were included.

RAIL Distinguishes Responder and Non-Responder in Pediatric Lupus Nephritis

Ellen Cody[1], Scott Wenderfer[2], Qing Ma[1], Angela Merritt[1], Prasad Devarajan[1] and Hermine Brunner[1], [1]Cincinnati Children's Hospital Medical Center, Cincinnati, OH, [2]Baylor College of Medicine, Houston, TX

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: SLE – Diagnosis, Manifestations, & Outcomes Poster I: Diagnosis (0323–0356)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Systemic Lupus Erythematosus (SLE) is a diagnostic and therapeutic challenge, particularly lupus nephritis (LN). We described a composite score, the Renal Activity Index for Lupus (RAIL), consisting of neutrophil gelatinase-associated lipocalin (NGAL), kidney injury molecule-1 (KIM-1), monocyte chemotactic protein 1 (MCP-1), adiponectin, hemopexin and ceruloplasmin, where higher scores reflect more active inflammation on biopsy. We hypothesize that when followed longitudinally during induction therapy, a change in RAIL score distinguishes clinical responders from non-responders.

Methods: Pediatric patients (< 18 years) diagnosed with LN were included (IRB #2008-0635), N=15. Diagnosis was made according to ACR criteria for SLE with renal biopsy confirmation of LN. Urine was collected at diagnosis and end of induction. Responders were defined by urine protein to creatinine ratio < 0.2 mg/mg, absence of hematuria, and normal glomerular filtration rate. Response also defined as improved activity index on follow up biopsy. There were 10 responders, 5 non-responders. Analysis by T-test, as well as sensitivity and specificity for no change in RAIL score.

Results: RAIL score in the responder group pre and post therapy was significantly different, p-value 0.015. T-Test between non-responder and responder difference scores showed trend towards significance, p-value 0.081 (Fig 1).

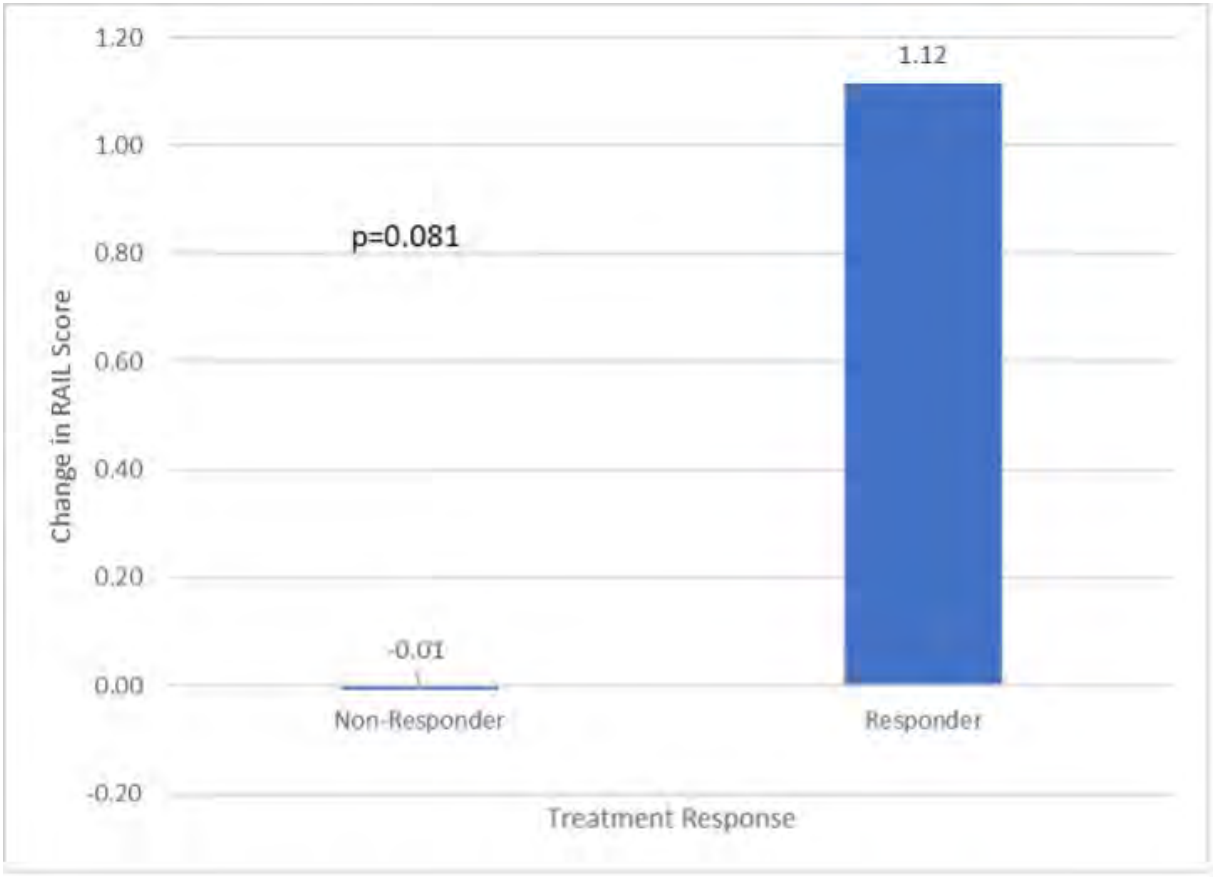

Figure 1. Change in RAIL Score in Clinical Non-Responders vs Responders.

Most responders had a difference of at least 0.5 during induction, whereas most non-responder had no difference or an increase in RAIL score, and a change score >0 identified responders with 90% sensitivity.

Conclusion: A change in RAIL during induction therapy is promising for predicting responders vs non-responders, with average decrease of 1 compared to no change. To further evaluate, more samples are needed, which is on-going.

tients with pediatric-onset rheumatic diseases in North America, Israel and Italy. This study aimed to describe the demographic features, cumulative clinical manifestations, and treatments of the childhood systemic lupus erythematosus (cSLE) cohort within the CARRA Registry.

Methods: Since 2015, the CARRA Registry has enrolled 10,411 patients at 70 centers. Childhood-onset SLE enrollment began in March 2017. We performed a retrospective cohort study of patients with cSLE enrolled in the US between March 2017 to December 2020. Inclusion criteria for participants in the CARRA cSLE Registry include: 1) diagnosis of cSLE at < 18 years based on American College of Rheumatology (ACR) or Systemic Lupus Erythema-

tosus International Collaborating Clinics (SLICC) criteria; 2) enrollment within two years of cSLE diagnosis or at the time of a flare of lupus nephritis; and 3) enrollment prior to 21 years of age. Sociodemographic and clinical data were summarized using descriptive statistics.

Results: The current registry cohort includes 671 participants with cSLE. The majority are female (85%) with mean age at enrollment of 14.3 (SD 2.9) years. The cohort is both ethnically and racially diverse (Table 1). Socioeconomic status varies widely, noting 12.5% having a household income below $25,000/year. The median time from symptom onset to diagnosis was two months (interquartile range (IQR) 25 days to 6 months), from diagnosis to enrollment was 5 (IQR 1-15) months, and from enrollment to end of follow up was 14 (IQR 6 to 23) months. At the end of the follow-up period, more than 60% of participants developed nephritis as defined by ACR or SLICC criteria. 6.1% and 10% had neurological manifestations per ACR and SLICC criteria, respectively (Table 2). Systemic Lupus Erythematosus Disease Activity Index (SLEDAI) at enrollment was a median of 4 (IQR 2-10). Most patients were prescribed hydroxychloroquine. In the first 2-3 years of disease, participants received a variety of immunosuppressive therapies including Mycophenolate Mofetil, Cyclophosphamide, Azathioprine, Rituximab, Belimumab and disease modifying anti-rheumatic drugs such as Leflunomide and Methotrexate. 84% of patients were prescribed either oral or intravenous glucocorticoids during their disease course (Table 3).

Conclusion: The CARRA Registry has enrolled a racially and ethnically diverse cohort of cSLE patients in the early course of their disease. These participants exhibit moderate disease activity and although the use of hydroxychloroquine in this cohort is high, a significant proportion of patients are utilizing glucocorticoids at the last study visit. We anticipate enrolling a minimum of 1000 participants with more than ten years of follow-up. This cohort, which is one of the Centers for Disease Control (CDC) funded SLE registries, provides a unique opportunity to describe the natural history, treatments, and outcomes in patients with cSLE.

Anti-gAChR Antibody as a Novel Biomarker for Lupus Enteritis in Systemic Lupus Erythematosus

Kuniyuki Aso[1], Michihito Kono[1], Keita Ninagawa[1], Nobuya Abe[1], Yuichiro Fujieda[1], Masaru Kato[1], Olga Amengual[1], Kenji Oku[1] and Tatsuya Atsumi[2], [1]Department of Rheumatology, Endocrinology and Nephrology, Faculty of Medicine and Graduate School of Medicine, Hokkaido University, Sapporo, Japan, [2]Hokkaido University, Sapporo, Japan

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: SLE – Diagnosis, Manifestations, & Outcomes Poster I: Diagnosis (0323–0356)

Session Type: Poster Session A

Session Time: 8:30AM–10:30AM

Background/Purpose: Anti-ganglionic nicotinic acetylcholine receptor (gAChR) antibody (Ab) is associated with widespread autonomic dysfunction in autoimmune autonomic ganglionopathy. Although it is also detected in several autoimmune diseases, including systemic lupus erythematosus (SLE), the clinical significance of anti-gAChR Ab remains unclear. The aim of this study was to compare the clinical manifestation of lupus patients with anti-gAChR Ab.

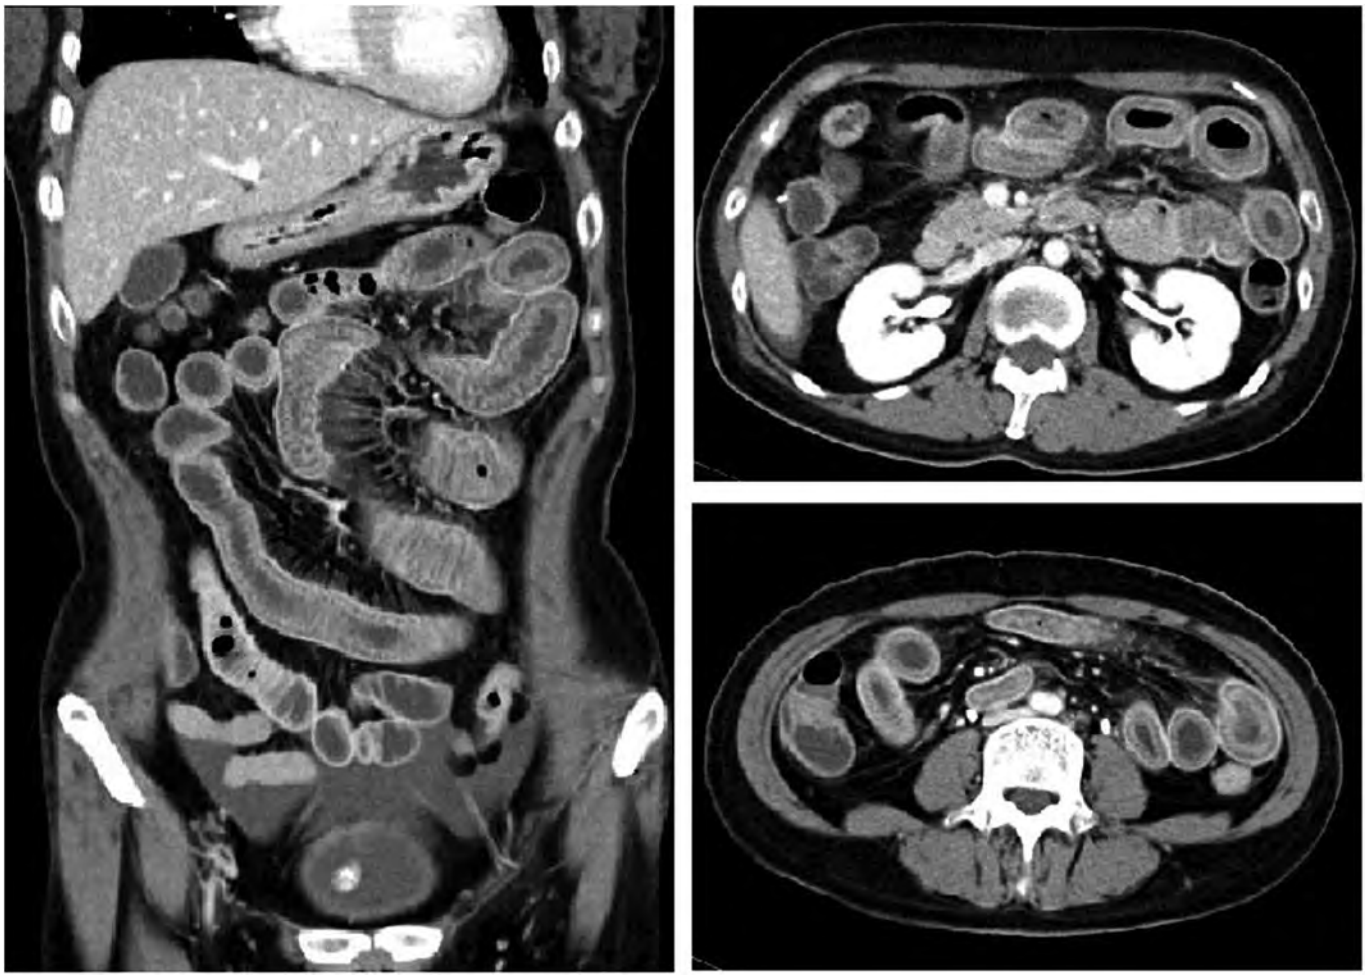

Figure. Lupus enteritis.

Methods: This retrospective study comprised adult patients with SLE who visited Hokkaido University Hospital from 2007 through 2019. A luciferase immunoprecipitation assay was performed to measure anti-gAChRα3 and β4 subunits Ab in the sera of these patients. The effect of immunosuppressants on anti-gAChR Ab levels was also evaluated. The Mann-Whitney U test was used for comparison of continuous data, while the Fisher's exact test was used for comparison of categorical variables. Predictors affecting clinical manifestations were assessed by logistic regression analysis. The cumulative recurrence rate was estimated by Kaplan-Meier analysis.

Results: Overall, 144 patients with SLE were enrolled in this study. The clinical manifestations of these patients included lupus nephritis (45.8%), neuropsychiatric SLE (31.9%), antiphospholipid syndrome (22.2%), pericarditis and/or pleuritis (18.8%), and lupus enteritis (LE, 14.6%, Figure). Among these patients, anti-gAChRα3 and β4 subunit Ab were positive for 29 (20.1%) and 8 (5.6%), respectively. The patients with anti-gAChRα3 Ab had LE more frequently than those without (37.9 vs. 8.7%, $p< 0.001$). The levels of anti-gAChRα3 Ab were significantly reduced ($p = 0.001$) after immunosuppressive treatment in the patients with LE. Logistic regression analysis revealed that anti-gAChRα3 Ab (odds ratio [OR] 11.1, 95% Confidence Interval [95%CI] 3.4-36.2, $p< 0.001$)and lupus cystitis (OR 16.3, 95%CI 2.07-127.8, $p=0.006$) were independent predictors for having LE. The ten-year cumulative LE relapse rate from the date of sera collection was significantly high in the patients with anti-gAChRα3 Ab compared to those without (27.0% vs. 2.3%, $p< 0.001$).

Conclusion: Anti-gAChRα3 Ab would be a new biomarker for the development and recurrence of LE in patients with SLE.

Abstract Number: 0345

Anti-MPP-1 Autoantibodies in Systemic Lupus Erythematosus: A Potential Biomarker for Neuropsychiatric Manifestations

Eugene Krustev[1], Katherine Buhler[1], Francesca Cardwell[2], Marvin Fritzler[1], Ann Clarke[1] and May Choi[3], [1]University of Calgary, Calgary, AB, Canada, [2]University of Waterloo, Burlington, ON, Canada, [3]Brigham and Women's Hospital | University of Calgary, Calgary, AB, Canada

SESSION INFORMATION

Session Date: Saturday, November 6, 2021
Session Title: SLE – Diagnosis, Manifestations, & Outcomes Poster I: Diagnosis (0323–0356)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Neuropsychiatric systemic lupus erythematosus (NPSLE) can involve the central (CNS) and peripheral nervous system (PNS). Several autoantibodies have been associated with CNS NPSLE including anti-phospholipid, anti-ribosomal P and anti-NMDA receptor 2; however, there are no known autoantibodies specifically

Table 1. Baseline demographic and clinical characteristics of SLE patients who were ever anti-MPP1 positive (MPP1+) vs those who were not (MPP1-)

	Entire Cohort (n=301)	MPP1- (n=241)	MPP1+ (n=60)	Odds Ratio (95% CI)	P value
Sex, % Female	**92.4%**	**94.6%**	**83.3%**	**0.3 (0.1, 0.7)**	**0.003**
Ethnicity, % white	61.1%	60.8%	65.2%	1.1 (0.6, 2.1)	0.824
Age of SLE Onset - years, mean ± SD	35.8 ± 15.3	36.2 ±15.2	34.5 ±16.0	--	0.452
Age at Enrollment - years, mean ± SD	**47.5 ± 15.5**	**48.4 ± 15.6**	**43.9 ± 15.0**	**--**	**0.044**
Disease Duration - years, mean ± SD	11.4 ± 11.5	11.9 ± 11.8	9.4 ± 10.0	--	0.127
Number of Follow up visits – mean ± SD	1.8 ± 0.8	1.7 ± 0.8	1.9 ± 0.8	--	0.115
SLEDAI-2K at Enrollment – mean ± SD	3.7 ± 3.8	3.4 ± 3.4	4.5 ± 5.0	--	0.059
SLICC Criteria[1]					
Lupus Nephritis[2]	20.4%	19.5%	24.1%	1.3 (0.6, 2.7)	0.460
Acute Cutaneous Lupus	58.4%	60.9%	48.1%	0.6 (0.3, 1.1)	0.088
Chronic Cutaneous Lupus	10.6%	11.4%	7.4%	0.6 (0.2, 1.9)	0.397

Direct Coombs'[3]	5.8%	4.5%	11.1%	2.6 (0.9, 7.6)	0.065

Bold indicates statistically significant result (p<0.05). Abbreviations: ANA, antinuclear antibody; Anti-dsDNA, anti-double-stranded DNA; Anti-Sm, anti-Smith; MPP1, M-phase phosphoprotein 1; SD, standard deviation; SLE, systemic lupus erythematosus; SLEDAI-2K, SLE disease activity index. 1. Excluding neurologic criteria, see **Table 2**. 2. Lupus nephritis defined by renal biopsy showing ISN class 2, 3, 4, or 5 and autoantibody (ANA or anti-dsDNA) and exclusion of other causes including viral (HIV, hepatitis B, hepatitis C) and malignancy. 3. Direct Coombs' test in absence of hemolytic anemia.

associated with PNS involvement. M-Phase Phosphoprotein 1 (MPP1; also known as kinesin family member 20B, KIF20B) is a protein involved in cytokinesis and anti-MPP1 autoantibodies have been associated with idiopathic ataxia. We examined the frequency of anti-MPP1 and its demographic and clinical associations including CNS and PNS NPSLE in our local SLE cohort.

Methods: Patients fulfilled the ACR or SLICC classification criteria (CC) for SLE. Age, sex, race, SLEDAI-2K, SLICC CC, and sera were collected at the time of enrolment and up to two follow up visits. NPSLE events fulfilling the ACR case definitions were identified from date of SLE diagnosis by medical record review. Anti-MPP1 titers were determined by an addressable laser bead immunoassay (ALBIA) utilizing a purified recombinant protein. ALBIA results were expressed as median florescence units (MFU). A dilution of ≥1:500 MFU was considered positive. Chi-squared and t-tests were performed to compare demographic and clinical characteristics, including NPSLE manifestations, between patients who were ever anti-MPP1 positive (MPP1+) vs those who were never positive (MPP1-). Multivariable logistic regression analysis was used to determine associations between MPP1+ and variables that were statistically significant in the univariable analysis ($p < 0.05$).

Results: Of the 301 SLE patients studied (mean disease duration 11.4 ± 11.5 years), 19.9% were MPP1+. When compared to MPP1- patients, MPP1+ patients had a lower proportion of females (OR 0.3, 95% CI 0.1-0.7), were younger at enrolment (43.9 ± 15.0 years vs 48.4 ± 15.6 years; p=0.04), had more leukopenia (OR 2.5, 95% CI 1.4-4.6), lymphopenia (OR 2.3, 95% CI 1.3-4.2), anti-Sm antibodies (OR 3.6, 95% CI 1.9-6.7) and hypocomplementemia (OR

Table 2. Neuropsychiatric SLE manifestations according to the American College of Rheumatology case definitions in patients who were ever anti-MPP1 positive (MPP1+) vs those who were not (MPP1-)

Neuropsychiatric SLE Manifestations	Entire Cohort (n=293)	MPP1- (n=234)	MPP1+ (n=59)	Odds Ratio (95%CI)	P value
Any Neurological Manifestation	72.4%	72.3%	72.9%	1.0 (0.5, 2.0)	0.934
Any Central Neurologic Manifestation	69.0%	70.2%	64.4%	0.8 (0.4, 1.4)	0.388
Headache	45.1%	45.3%	44.1%	1.0 (0.5, 1.7)	0.865
Mood Disorder	24.1%	25.1%	20.3%	0.8 (0.4, 1.5)	0.444

Autonomic Disorder	1.4%	1.3%	1.7%	1.3 (0.1, 13.0)	0.807
Plexopathy	0.0%	0.0%	0.0%	–	--
Myasthenia Gravis	0.7%	0.9%	0.0%	0.7 (0.0, 16.5)	0.476

Bold indicates statistically significant result (p<0.05). Abbreviations: MPP1, M-phase phosphoprotein 1.

3.9, 95% CI 2.1-7.3) (Table 1). 72.4% of patients met criteria for any NPSLE manifestation with no difference between MPP1+ and MPP1- patients (Table 2). When PNS NPSLE manifestations were examined, patients with any peripheral neuropathy (OR 3.2, 95% CI 1.7-6.2), mononeuropathy (OR 8.7, 95% CI 2.1-36.0), and cranial neuropathy (OR 6.5,

Table 3. Multivariable analysis for demographic and clinical associations of anti-MPP1 antibodies

Demographic and Clinical Characteristics	Model 1[1]	Model 2 [1]
Any Peripheral Neuropathy	**4.8 (2.2-10.8)**	--
Mononeuropathy	--	5.9 (1.0-36.7)
Cranial Neuropathy	--	**9.7 (2.9-32.2)**
Female	0.4 (0.1-1.1)	0.4 (0.1-1.1)
Age at Enrollment	1.0 (1.0-1.0)	1.0 (1.0-1.0)
Leukopenia	**2.3 (1.1-4.6)**	1.9 (0.9-3.9)
Lymphopenia	2.0 (1.0-4.0)	1.9 (0.9-4.0)
Anti-Sm	**3.3 (1.6-6.9)**	**3.4 (1.6-7.0)**
Hypocomplementemia	**2.7 (1.3-5.5)**	**3.1 (1.4-6.7)**

Results are expressed as odds ratios (95% CI) for the association between the corresponding variable and MPP1+. Covariables included significant variables from univariable analysis (p<0.05). 1. Model 1 includes any peripheral neurologic manifestation while in model 2 the specific subtypes mononeuropathy and cranial neuropathy were analyzed. Bold indicates statistically significant result (p<0.05). Abbreviations: Anti-Sm, anti-Smith.

95% CI 2.5-17.0) were more likely to be MPP1+. Multivariable analysis demonstrated that any peripheral neuropathy (OR 4.8, 95% CI 2.2-10.8) and cranial neuropathies remained significantly associated with MPP1+ (OR 9.7, 95% CI 2.9-32.2) (Table 3).

Conclusion: Anti-MPP1 may be an important biomarker for peripheral neuropathies, in particular, cranial neuropathies in SLE. These findings are being validated in a larger, multicentre SLE cohort.

Abstract Number: 0346

The CB-CAPillary™ Test Kit: A Tool for Point-of-Care Assays to Measure Cell-Bound Complement Activation Products

Joseph Ahearn[1], Susan Manzi[1] and Chau-Ching Liu[2], [1]Allegheny Health Network, Wexford, PA, [2]Allegheny Health Network, Pittsburgh, PA

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: SLE – Diagnosis, Manifestations, & Outcomes Poster I: Diagnosis (0323–0356)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Cell-bound complement activation products (CB-CAPs) have been validated as biomarkers for systemic lupus erythematosus (SLE) diagnosis, monitoring and stratification, and for identification of patients with pre-lupus. However, CB-CAP assays currently require live cells, are time and temperature sensitive, and must be performed by a dedicated technician with a flow cytometer. We have developed a CB-CAP assay that eliminates the need for live cells and a flow cytometer and can yield results in minutes.

Methods: Four different methods have been developed to measure CB-CAPs without the need for a flow cytometer. One method, described here, utilizes a CB-CAPillary™ Test Kit (patent pending), analogous to a urine dipstick, to rapidly measure levels of CB-CAPs in body fluids. Erythrocyte C4d (EC4d) levels determined by a traditional flow-cytometric assay were compared with those determined using the novel CB-CAPillary™ assay device. Assays were performed using fresh erythrocytes, freeze-thawed erythrocytes, and erythrocyte lysates. Blood samples were obtained from patients with SLE and from non-lupus subjects. Correlations between results obtained by flow cytometry and those generated by the CB-CAPillary™ assay device were analyzed by Pearson correlation.

Results: EC4d levels determined by FACS ranged from 2.93-70.42. The correlation between EC4d in erythrocyte lysates determined using a FACs cytometer and EC4d determined using a CB-CAPillary™ test kit was R^2=0.89. The correlation between EC4d in erythrocyte freeze-thawed samples determined using a FACs cytometer and EC4d determined using a CB-CAPillary™ test kit was R^2=0.99. TC4d/BC4d were also successfully detected in buffy coat lysates.

Conclusion: This proof-of-concept study demonstrates that CB-CAP assays can be performed within minutes, and without the need for flow cytometry, live cells, or a dedicated technician. The CB-CAPillary™ test kit enables a rapid

and inexpensive method for determining cell-bound complement activation levels for lupus diagnosis, monitoring and stratification and for identification of patients with pre-lupus. As a point-of-care test kit, it could be available to patients and physicians globally. CB-CAPillary™ test kits for measurement of BC4d, TC4d, PC4d and RC4d are also being developed with the methods described here.

Abstract Number: 0347

Longitudinal ANA Titers in SLE and ANA+ Controls

Emily Littlejohn[1], Lingxuan Kong[2], Kelly Speth[2], Lu Wang[2] and Emily Somers[2], [1]Cleveland Clinic, Cleveland, OH, [2]University of Michigan, Ann Arbor, MI

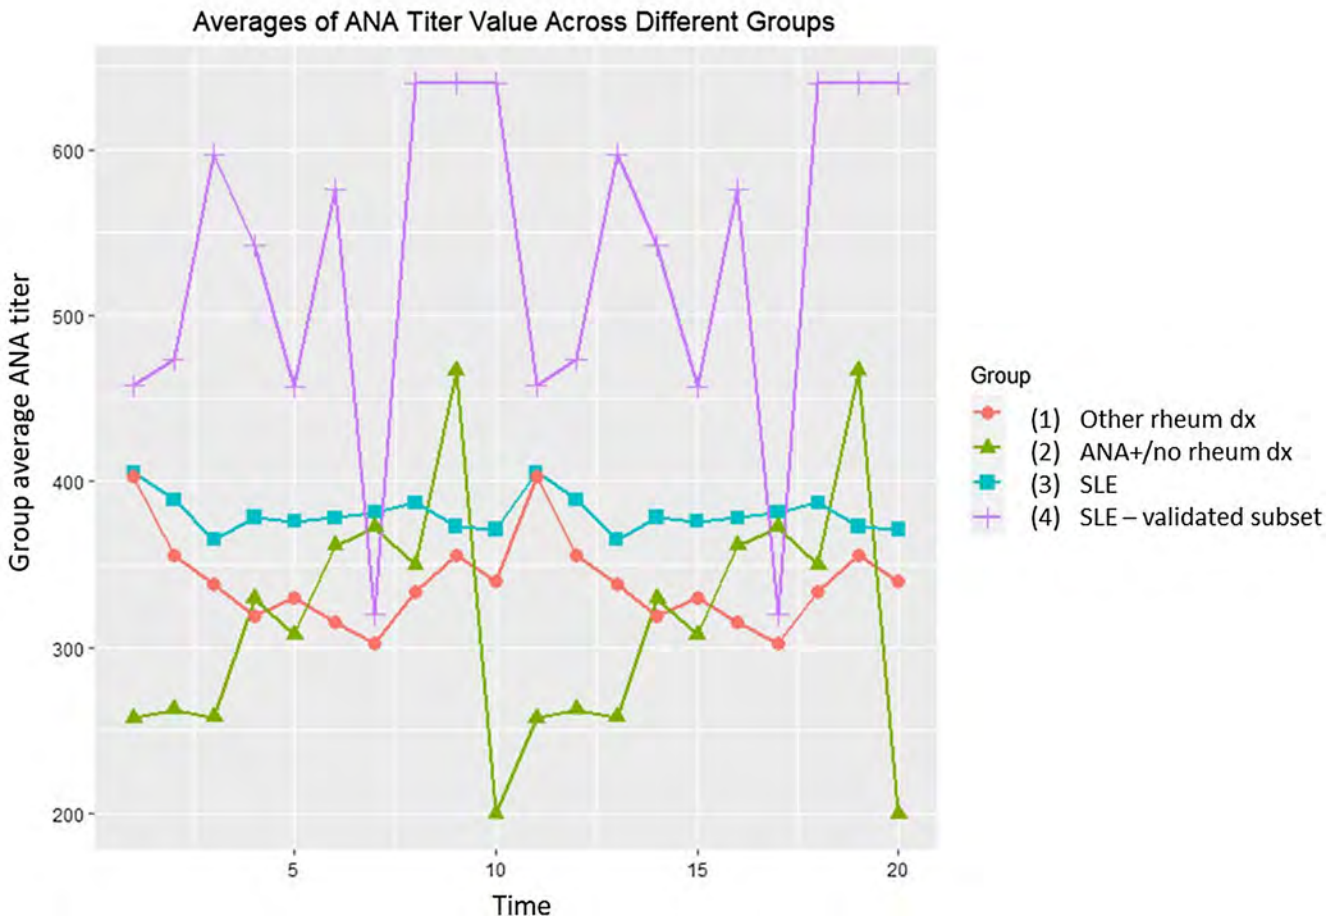
SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: SLE – Diagnosis, Manifestations, & Outcomes Poster I: Diagnosis (0323–0356)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Antinuclear or anticellular antibodies (ANAs), are a hallmark of systemic lupus erythematosus (SLE). ANAs are also a marker of subclinical autoimmunity, with ~13% of the general adult population ANA+. Risk factors for developing subclinical autoimmunity are poorly understood. An important step is to understand trajectories of ANA positivity and titers within individuals over time. We performed an exploratory analysis of electronic health record (EHR) data to assess intraindividual variation in ANAs longitudinally.

Methods: Utilizing our academic health center's EHR we formed a sub-cohort of all patients with at least 2 ANA tests (by immunofluorescence, IFA). A titer of ≥1:80 was considered positive. We evaluated the effect of time on the titer value using a longitudinal random effect model comparing across different patient groups defined by ICD codes: (1) ANA-associated rheumatic diseases (Sjogren's Syndrome, dermatomyositis, polymyositis, scleroderma, undifferentiated connective tissue disease, mixed connective tissue disease); (2) ANA+ controls without rheumatic disease; (3) SLE. A subset of SLE was validated by a rheumatologist and fulfilled ACR/SLICC criteria (4).

Results: 7226 patients had at least two valid ANA-IFA lab results (SLE by ICD n=1706, validated SLE n=54, alternate rheumatic diagnosis n=1644, ANA+/no rheumatic diagnosis n=3822). Of 5603 patients with a positive ANA at the first observation, 4 (7%) of SLE and 953 (17.2%) of non-SLE and had a subsequent negative ANA. Longitudinally, the strength of ANA titer changed over time ($p< 0.001$) among both SLE and non-SLE patients. Controlling for time, SLE patients had a higher odds of a positive ANA titer on average vs non-SLE [OR 1.44, 95% CI (1.19, 1.75)]. SLE patients also had a higher odds ratio on average of a positive ANA titer associated with time change compared to non-SLE [ratio of OR overtime 1.09, 95% CI (1.02, 1.17), $p< 0.001$].

Conclusion: While previous cross-sectional data have shown that ANAs tend to increase with age, longitudinal data of intra-individual patterns are lacking. Our data provide initial evidence of intra-individual variability over time, with SLE patients having increasing titers over time. Future work includes investigating demographic and other covariates to discern titers in SLE and non-SLE ANA+ clinical phenotypes. We seek to determine if pre-clinical (or subclinical) periods are opportunities for intervention to modify the course of autoimmunity and clinical progression.



Longitudinal trajectory of average ANA titers over the order of measurement across 4 different groups of patients.

[a]SLICC/ACR Damage Index
[b] Glucocorticoid.

Background/Purpose: We recently demonstrated that a EULAR/ACR classification Criteria score ≥ 20 predicts a higher disease activity throughout the first 5 years after diagnosis. Given that disease activity is associated with damage accrual and mortality, we aimed to determine the ability of a EULAR/ACR score ≥20 to predict these long-term outcomes.

Methods: Inception SLE patients recruited in the first 12 months after diagnosis were included.

For each patient a EULAR/ACR score was calculated based on the baseline clinical and laboratory information. The baseline information was obtained from the first 2 visits.

Patients were divided into 2 groups depending on their EULAR/ACR score < 20 or ≥20. In order to determine the ability of a EULAR/ACR ≥20 to predict damage accrual and mortality the following outcomes were assessed:

1. Time to first damage accrual, defined as any increase in the SLICC/ACR Damage Index (SDI) and time to death within the first 10 years after SLE diagnosis, analyzed using Kaplan Meier survival curves. For damage accrual, death within the 10 years was used as competing risk. Multivariable Cox Proportional regressions was performed to calculate the risk.

Table 2. Outcomes within 10 years of follow-up. Values are expressed as mean ± SD or n (%).			
Outcomes	**EULAR/ACR score < 20 N=415**	**EULAR/ACR score ≥ 20 N=452**	**P value**
Death	24 (5.8)	44 (9.7)	**0.03**
Time to death, years	5.0±2.9	3.6±3.1	0.07
Increase in SDI[a]	167 (40)	210 (46)	**0.02**
Time to SDI[a] increase, years	2.9±2.7	3.0±2.9	0.52
SDI[a] score[#]	0.97±1.42	1.28±1.47	**0.03**
SDI[a] Domains[#]			
Ocular	20 (10.26)	34 (15.96)	0.08
Neurologic	19 (9.74)	28 (13.15)	0.28
Renal	5 (2.56)	19 (8.92)	**0.006**

Skin	18 (9.23)	21 (9.86)	0.82
Gonadal	1 (0.51)	3 (1.41)	0.35
Diabetes	3 (1.54)	14 (6.57)	**0.01**
Malignancy	5 (2.56)	3 (1.41)	0.40
[#] At 10 years of follow-up, N = 190 and 206 in the low and high score groups respectively. [a] SLICC/ACR Damage Index			

2. Mean SDI score at the 10th year of follow-up was calculated.

Results: A total of 867 inception patients were included. **Table 1** shows baseline clinical characteristics of the cohort.

The proportion of patients who accrued damage within the first 10 years and the mean SDI at 10 years were significantly higher in the group of ≥ 20**.** When looking at the specific domains in SDI, the group with a score ≥ 20 at 10 years of follow-up had significantly more renal damage and a higher percentage of diabetes (**Table 2)**.

On multivariable regression analysis, after adjusting for age and ethnicity, a score ≥ 20 continued to significantly predict damage accrual, HR 1.28 (1.04-1.57), p=0.02. When we excluded patients who had damage at enrollment the results were similar (**Table 3**).

Sixty-eight (7.8%) of patients died within the first 10 years of follow-up, the percent of deaths was higher in the group with a score ≥ 20, (**Table 2**). Individuals in the ≥ 20 group had twice the probability of dying compared to patients with the lower score, the hazard ratios with significant p values confirmed this finding (**Table 3**).

Conclusion: A EULAR/ACR score ≥20 is an indicator of damage accrual and mortality in SLE.

Table 3: Univariate and Multivariable Cox Regression analysis. Factors associated with damage accrual and death within 10 years of follow-up.				
	Univariate Cox Regression		Multivariable Cox Regression

Abstract Number: 0349

Performance of the 2019 EULAR/ACR Classification Criteria for Systemic Lupus Erythematosus in a Predominantly African American Cohort

Jessica English[1], Dulaney Wilson[2], Gary Gilkeson[2], Jim Oates[2] and Diane Kamen[2], [1]Medical University of South Carolina, Johns Island, SC, [2]Medical University of South Carolina, Charleston, SC

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: SLE – Diagnosis, Manifestations, & Outcomes Poster I: Diagnosis (0323–0356)

Session Type: Poster Session A

Session Time: 8:30AM–10:30AM

Background/Purpose: Classification criteria for systemic lupus erythematosus (SLE) were recently published by the European League Against Rheumatism (EULAR) and American College of Rheumatology (ACR) to reflect current diagnostic approaches and improve statistical performance with addition of entry criterion and item weighting. The

Table 1. Comparison of Clinical Characteristics Between Patients Fulfilling and Patients Not Fulfilling the EULAR/ACR Criteria for SLE

Characteristics	Fulfills 2019 EULAR/ACR Criteria – No (n=61, 8.9%)	Fulfills 2019 EULAR/ACR Criteria – Yes (n=621, 91.1%)	P-value
African American %	37 (60.7%)	487 (78.4%)	<0.01
Hispanic %	0 (0%)	20 (3.2%)	0.24 (NS)
Female %	55 (90.2%)	563 (90.7%)	0.90 (NS)
Age at diagnosis	38.2 ± 15.7 yrs	30.1 ± 13.4 yrs	<0.01
Smoking history	15 (24.6%)	150 (25.3%)	0.90 (NS)
Insured	43 (95.6%)	483 (94.0%)	0.67 (NS)
High school graduate	42 (93.3%)	430 (83.3%)	0.09 (NS)
Disease duration	17.6 ± 9.3 yrs	19.0 ± 9.0 yrs	0.88 (NS)
Childhood onset SLE (≤18)	4 (6.6%)	121 (19.5%)	0.01
Overlap syndrome	13 (27.1%)	153 (31.1%)	0.57 (NS)
SLICC Damage Index: Any damage*	28 (45.9%)	406 (65.4%)	<0.01
SLICC Damage Index: High damage**	16 (26.2%)	274 (44.1%)	0.01
Fulfilling ACR 1997 Criteria	34 (55.7%)	582 (93.7%)	<0.01
Not fulfilling ACR 1997 criteria	27 (44.2%)	39 (6.3%)	<0.01

*Any damage defined as a SLICC Damage index score of ≥1
**High damage defined as a SLICC Damage index score of ≥2

validation cohort included a small proportion of African American patients, a population disproportionately affected by early and severe SLE. We evaluated the performance of the EULAR/ACR 2019 criteria within a predominantly African American well-characterized cohort of patients with SLE.

Methods: Patients enrolled in a single center longitudinal prospective study of SLE were included, excluding patients without a confirmed expert clinical rheumatologist diagnosis of SLE. Demographic, clinical, and immunologic features were compared between the EULAR/ACR Classification Criteria for SLE and the 1997 ACR criteria. Chart review was completed for missing values. Fulfilling criteria for SLE was defined as the presence ≥4 ACR criteria or ≥10 points for the EULAR/ACR criteria. ”Any damage” on the Systemic Lupus International Collaborating Clinics (SLICC) Damage Index is a score ≥1 and “high damage” is a score ≥2.

Results: A total of 682 patients with SLE were included. Of the 682 patients, 524 identified as black (76.3%), 20 as non-black Hispanic (2.9%), and 90.6% female. Patients with childhood onset SLE (diagnosed at ≤ 18 years) comprised 18.3% of the cohort. A proportion of the SLE patients have an additional overlapping autoimmune disease (n=166, 30.7%) most commonly Sjogren’s, RA, or autoimmune thyroid disease. SLICC damage was present in 63.6% of patients (n=434), with 42.5% (n=290) having high damage. The mean 1997 ACR criteria score was 5.6 (median 5) out of 11 possible. The mean EULAR/ACR criteria score was 20.6 (median 20) out of 51 possible.

Table 1 compares patients fulfilling EULAR/ACR criteria to the 8.9% who did not. Table 2 compares patients fulfilling ACR criteria to those fulfilling EULAR/ACR criteria. Of patients who meet ACR criteria, blacks were more likely to meet EULAR/ACR criteria compared to whites (96.4% vs 87.9%, respectively, p< 0.01). EULAR/ACR criteria had

Table 2. Comparison of Clinical Characteristics Between Patients Fulfilling the 1997 ACR Criteria and Patients Fulfilling the EULAR/ACR Criteria for SLE

Characteristics	Fulfills 1997 ACR Criteria	Fulfills 2019 EULAR/ACR Criteria	p-value
Number of patients *n* (%)	616 (90.3%)	621 (91.1%)	<0.01
African American	476 (77.3%)	487 (78.4%)	0.21 (NS)
Hispanic	16 (2.6%)	20 (3.2%)	0.11 (NS)
Female %	559 (90.5%)	563 (90.7%)	0.69 (NS)
Age at diagnosis	30.4 ± 13.4 yrs	30.1 ± 13.4 yrs	0.35 (NS)
Smoking history	148 (25.0%)	150 (25.3%)	0.71 (NS)
Insured	482 (94.0%)	483 (94.0%)	0.91 (NS)
High school graduate	435 (84.1%)	430 (83.3%)	0.56 (NS)
Disease duration	19.3 ± 9.0 yrs	19.0 ± 9.0 yrs	0.28 (NS)
Childhood onset SLE (≤18)	114 (18.5%)	121 (19.5%)	0.06 (NS)
Overlap syndrome	151 (91%)	153 (31.1%)	0.69 (NS)
SLICC Damage Index: Any damage*	400 (64.9%)	406 (65.4%)	0.43 (NS)
SLICC Damage Index: High damage**	273 (44.3%)	274 (44.1%)	0.86 (NS)

*Any damage defined as a SLICC Damage index score of ≥1

**High damage defined as a SLICC Damage index score of ≥2

a sensitivity of 91.1% overall (92.9% among black patients, p< 0.01) and the ACR criteria had sensitivity of 90.3% overall (90.8% among black patients, p< 0.01). Contributing to this gap were differences in ANA positivity (99.0% of blacks compared to 96.2% of non-blacks, p=0.01) and lupus nephritis, especially Class III and IV by biopsy (59.5 % of blacks compared to 33.5% of non-blacks, p< 0.01).

Conclusion: In this cohort of predominately African American patients with SLE, the sensitivities of the ACR 1997 criteria and EULAR/ACR 2019 criteria differed significantly by race. ANA positivity as an entry criterion, in addition to higher weighting for renal disease, accounts for some of the higher sensitivity of the EULAR/ACR criteria among African Americans. The importance of knowing the performance characteristics of these criteria, particularly for African American patients, cannot be understated, as the need for identifying patients for early intervention is critical.

EPI-SIGN: Epigenetic SLE Indicators of Glomerular Nephritis

Ashira Blazer[1], Olusola Ayanlowo[2], Will Liao[3], Dzifa Dey[4], Jasmin Divers[5], Uyiekpen Ima-Edomwonyin[6], Hakeem Olaosebikan[7], Cristina Lanata[8], Girish Nadkarni[9], Jill Buyon[1], Peter Izmirly[10] and Timothy Niewold[11], [1]NYU School of Medicine, New York, NY, [2]College of Medicine University of Lagos, New York, NY, [3]New York Genome Center, New York, NY, [4]University of Ghana, Accra, Ghana, [5]NYU Langone Hospital - Long Island, Mineola, NY, [6]Lagos State University Teaching Hospital, Lagos, Nigeria, [7]Lagos University State Teaching Hospital, Lagos, Nigeria, [8]University of California San Francisco, Moss Beach, CA, [9]Icahn School of Medicine at Mount Sinai, New York, NY, [10]New York University School of Medicine, New York, NY, [11]Colton Center for Autoimmunity NYU School of Medicine, New York, NY

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: SLE – Diagnosis, Manifestations, & Outcomes Poster I: Diagnosis (0323–0356)

Session Type: Poster Session A

Session Time: 8:30AM–10:30AM

Background/Purpose: Systemic Lupus Erythematosus (SLE) is more common and severe in those of African Ancestry (AA) who, relative to Europeans, are twice as likely to develop lupus nephritis (LN)[1]. Early nephritis detection can improve outcomes; however, current strategies rely on clinically apparent kidney injury and invasive biopsies, representing a barrier to care in socioeconomically marginalized patients[2]. Urine sediment epigenetics, which contains invading immune cells, offers a conveniently accessible window into the SLE kidney[3, 4].

Methods: This pilot study tested the feasibility of urine epigenetic signature to identify LN in 14 SLE patients in the USA and Nigeria and 2 healthy controls (HC). Consenting participants provided up to 10mL of urine, which was processed fresh (n=4) or treated with 40mM EDTA and 20µl Penicillin/Streptomycin before freezing at -80°C. Samples from Nigeria were shipped on dry ice for processing at the USA site. Urine was centrifuged, and DNA extracted from sediment with the Zymo Research Quick-DNA Urine kit. Methylation of purified DNA was assessed with the Illumina Methylation EPIC BeadChip. Data was analyzed in R using the minfi v1.32.0 software suite. Probe intensities were background corrected and annotated with the IlluminaHumanMethylationEPICanno.ilm10b5.hg38 package. Clus-

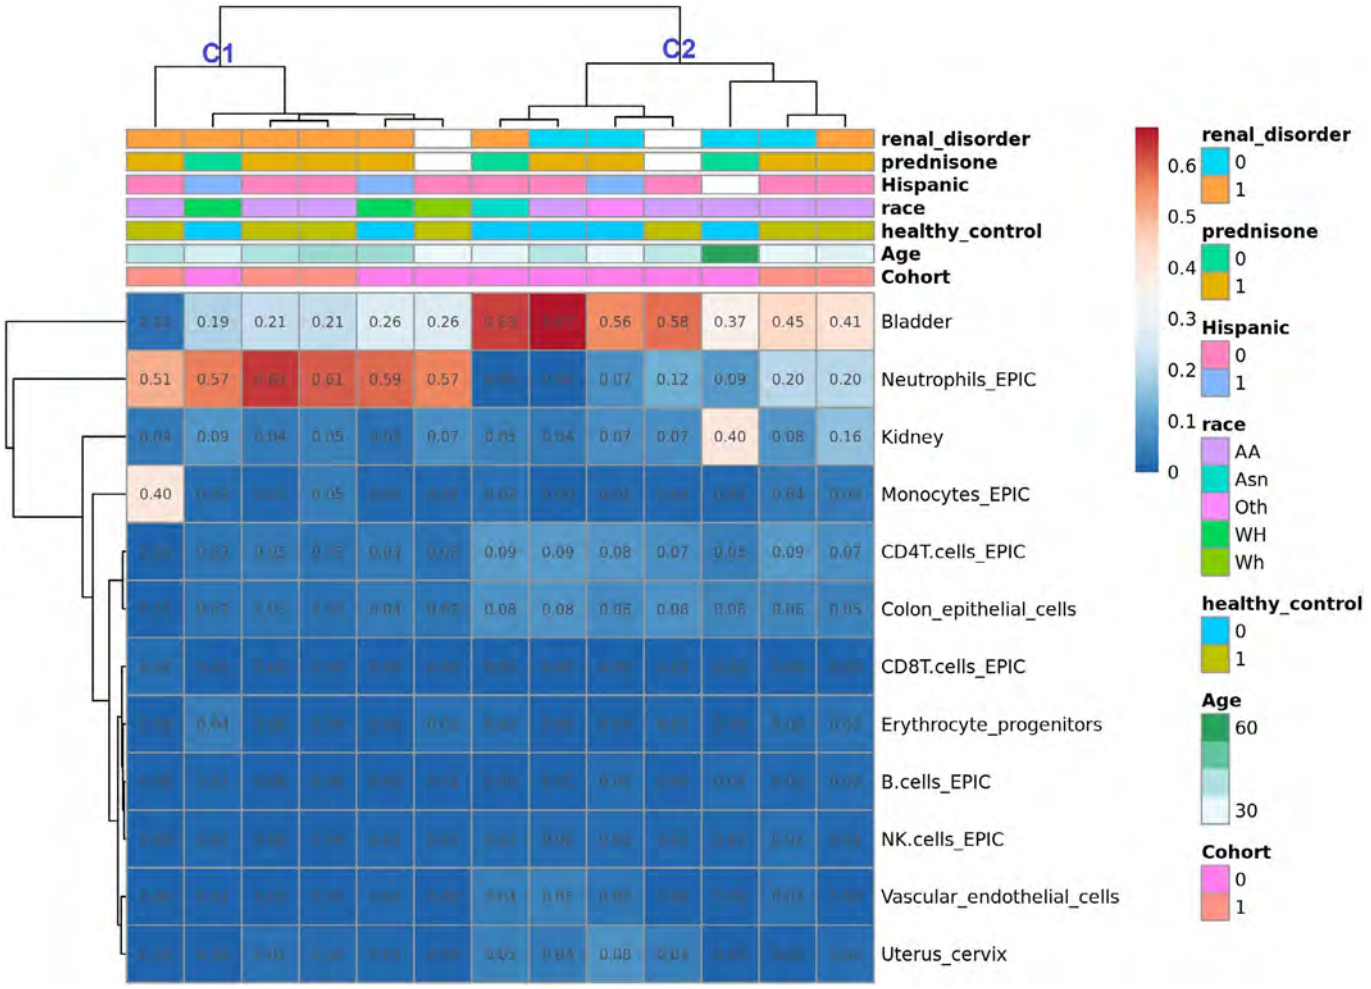
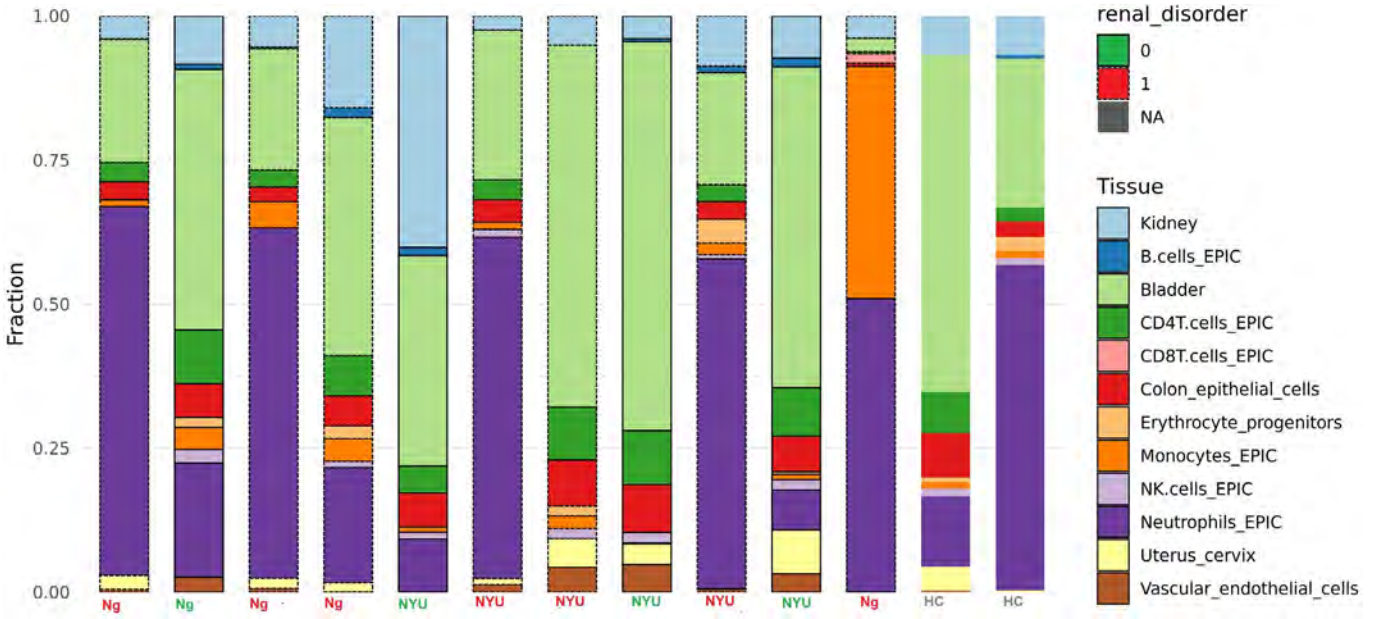
Serositis (%)	2 (33.3)	2 (25.0)	1.0
Lupus nephritis (%)	3 (50.0)	5 (62.5)	1.0
Neurologic (%)	0 (0.0)	1 (12.5)	1.0
Hematologic (%)	5 (83.3)	4 (50.0)	0.5
Immunologic (%)	5 (83.3)	8 (100.0)	0.9



Heatmap showing participants (Y axis) clustered by identified urinary cell types (X axis). Metadata including renal disorder are annotated on the upper X axis. Two clusters, C1 and C2 differentiate renal disorder as defined by ACR criteria.

tering was performed with principal component analysis (PCA) or multidimensional scaling (MDS) with the top 1000 most variable CpG probes or the 59 control SNP probes on-board the EPIC BeadChip. Intra-sample cell heterogeneity was deconvolved using EpiDISH v2.2.2[5]. Associations between nephritis and differential proportions of each reference cell methylome were tested using a Mann Whitney test.

Results: Participant demographics by cohort (USA=6, Nigeria=8) and clinical features are shown in Table 1. In the NYU cohort (and HC), 3 participants were Hispanic, 2 were Asian, and 3 were AA. LN was present in 50% and 62% of the NYU and Nigerian cohorts respectively. At least 100ng of DNA was extracted from 13/16 samples. Fresh, frozen, and shipped-frozen samples produced similar quality DNA; beta distributions and probe intensities were sufficient for CpG calling. PCA analysis of the top 1000 differentially methylated CpG sites revealed clusters by ancestry. Cell type deconvolution revealed that bladder, neutrophils, kidney epithelial, monocytes, CD4 T cells, CD8T Cells, erythrocyte progenitors, B cells, and NK cells were among the most highly represented. A dendrogram of cell type reference fractions produced two major clusters (C1 and C2) which differentiated LN from non-nephritis with 6/7 in C1 and 2/7 in C2 having LN (OR: 12.5, p=0.06; Figure 1). In C2, one LN participant was in complete remission, and the other had predominantly proteinuric disease without active sediment. LN samples were characterized by higher relative fractions of neutrophils and monocytes, and lower fractions of CD4T cells and NK cells compared to non-nephritis samples (Figure 2).



Stacked bar chart showing estimated urinary sediment cell proportion by participant donor. The cohort is indicated along the X axis: Ng=Nigeria cohort; NYU= USA cohort. The label color indicates the presence or absence of renal disorder with green labels indicating non-nephritis and red labels indicating nephritis participants.

Conclusion: These preliminary data support the feasibility of bulk urine sediment as an epigenetic biomarker of LN, and further analysis looking at pathways and genes within cell proportions associated with LN in larger studies.

Values are expressed as N (%) for categorical variables and mean± standard deviation (SD) for continuous variables. Categorical variables compared using Fischer's exact test; continuous variables compared using the two-sample T-test or Mann Whitney U Test.

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: SLE – Diagnosis, Manifestations, & Outcomes Poster I: Diagnosis (0323–0356)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Clinical phenotyping and predicting treatment responses in Systemic Lupus Erythematosus (SLE) patients is challenging. Extensive blood transcriptional profiling has identified various gene modules that seem promising for stratification of SLE patients. This study was undertaken to translate transcriptomic data into gene signatures suitable for introduction into clinical practice and to associate these signatures with disease activity.

Methods: RT-PCR of multiple genes from the Interferon M1.2, Interferon M5.12, neutrophil (NPh)- and plasma cell (PLC) modules followed by a principle component analysis was used to identify indicator genes per gene signature. Gene signatures were measured in longitudinal samples from two childhood onset SLE cohorts (n=101 and n=34, respectively) and associated with clinical features. Disease activity was measured using SELENA-SLEDAI. Cluster analysis subdivided patients into three fingerprint groups termed 1) all-signatures-low, 2) only IFN high (M1.2 and/or M5.12) and 3) high NPh and/or PLC.

Results: All gene signatures were significantly associated with disease activity in cross-sectionally collected samples. The PLC signature showed the highest association with disease activity. Also, in longitudinally collected samples, the PLC signature was associated with disease activity and showed a decrease over time. When patients were divided into fingerprints, the highest disease activity was observed in the high NPh and/or PLC group. The lowest disease activity was observed in the all-signatures-low group. The same distribution could be reproduced in samples from an independent SLE cohort.

Conclusion: Gene signatures are associated with disease activity and can be suitable tools to sub-classify SLE patients into groups with similar pathogenically activated immunological pathways.

Abstract Number: 0352

Native American and African American Rheumatic Disease Patients Exhibit Accelerated Biological Aging Compared to European Americans

Joseph Kheir, Carla Guthridge, Nicolas Dominguez, Wade DeJager, Sarah Cooper, Joel Guthridge and Judith James, Oklahoma Medical Research Foundation, Oklahoma City, OK

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: SLE – Diagnosis, Manifestations, & Outcomes Poster I: Diagnosis (0323–0356)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: The universal process of aging is associated with increased risk of disease and death as a result of changing physiologic and molecular processes. In autoimmune patients, the process of aging can be exac-

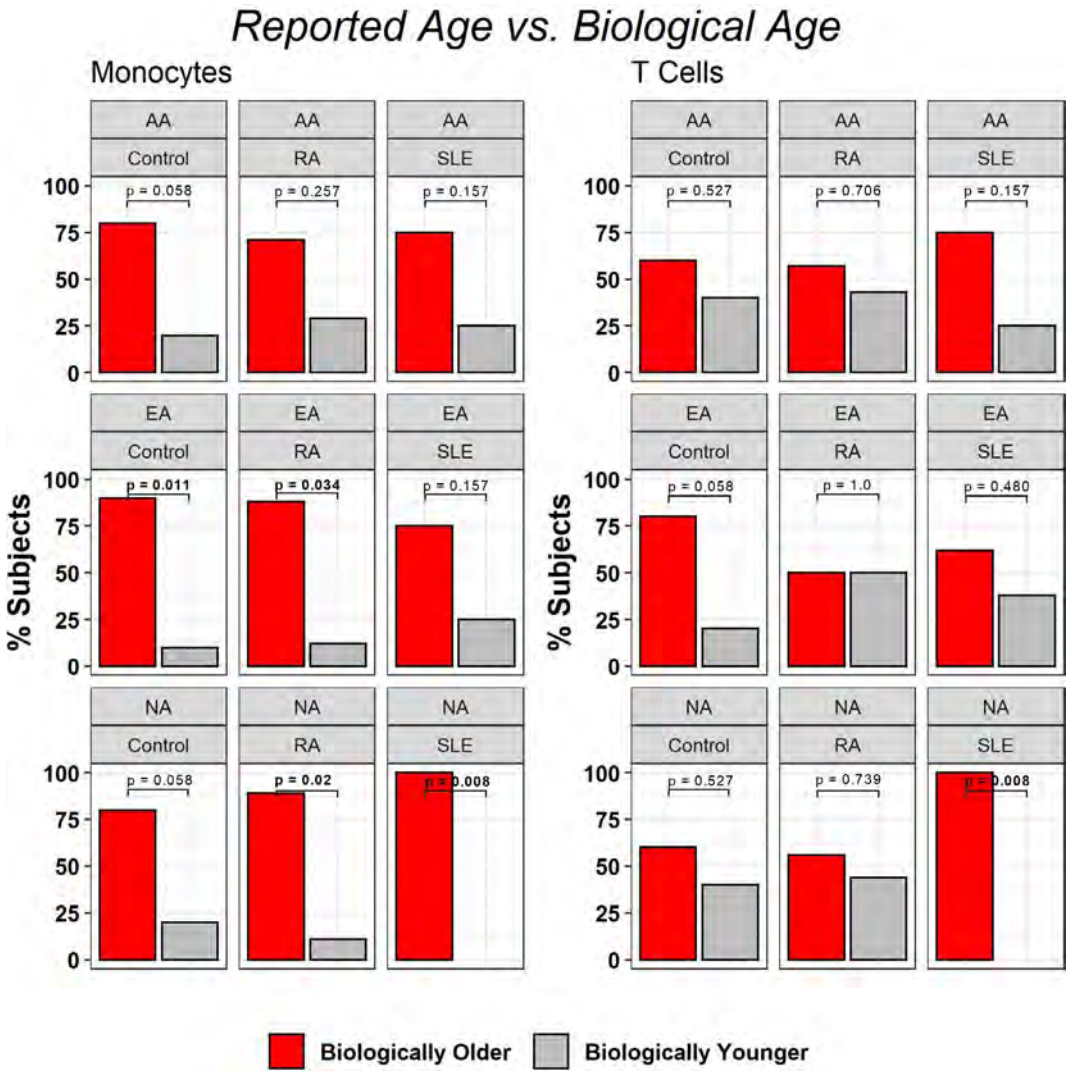

Figure 1. Biologically older versus younger patients by DNA methylation age.

erbated by chronic low-grade inflammation and the accumulation of biologic damage. We have previously demonstrated that Native American rheumatic disease patients present unique clinical and serological phenotypes with regards to systemic lupus erythematosus (SLE) and rheumatoid arthritis (RA). Because of such unique presentations of autoimmune disease, we hypothesize that Native American RA and SLE patients will exhibit an older biological age compared to chronological age relative to other racial groups.

Methods: Age matched (+/- 8 years) SLE, RA and control patients were selected across three racial groups, Native American (NA, n = 26), African American (AA, n = 25) and European American (EA, n = 26). T cells, B cells and Monocytes were isolated from PBMCs and DNA extracted. DNA was used for whole methylome analysis using the Illumina Infinium Human MethylationEpic BeadChip microarray. DNAm age, an indicator of biological age, was calculated using the Grimage algorithm leveraging differences in methylation at key CpG sites. Telomere length and mitochondrial DNA copy number were assayed using the absolute human telomere length and mitochondrial DNA copy number dual quantification qPCR (AHDQ) assay from ScienCell Research Laboratories.

Results: All NA SLE patients (n = 7) exhibited a biologically older age for T cells and monocytes compared to reported age (p = 0.008). Although not significant, a similar trend was observer for AA (75%, n = 6) SLE patients. EA SLE patients had similar biologic and stated ages. 89% of NA RA patients (n = 8, p = 0.02) exhibited a biologically older age in monocytes but not in T cells (p = 0.739). Similarly, 88% of EA RA patients (n = 7, p = 0.034) exhibited a biologically

older age in monocytes but not in T cells (p = 1.0) relative to reported age. AA RA patients had similar biologic and stated ages. The difference in biological age and reported age for NA SLE patients ranged from 1.2 years to 13 years with an average age difference of 7.1 years for monocytes and 3.5 years to 10.5 years with an average difference of 7.2 years for T cells. Interestingly, the age difference in biologically older NA RA patients ranged from 0.7 to 7.2 with an average of 3.7 years and 5.6 to 15 with an average of 7.9 years for monocytes and T Cells respectively. No statistical differences were observed in telomere length or mitochondrial DNA copy number.

Conclusion: Aging and the accumulation of low-grade chronic inflammation can lead to an increased susceptibility to disease and death. Our study demonstrated that 100% of Native American SLE patients in our cohort were biologically older than their reported age. This stark difference between biological and reported age coupled with unique clinical and laboratory phenotypes underscores the importance of further multi-omic investigation of Native American rheumatic diseases in order to elucidate causal biological pathways.

Soluble Urine ALCAM Reflects Renal Disease Activity in Lupus Nephritis

Dalena Chu[1], Noa Schwartz[2], Jeanette Ampudia[1], Joel Guthridge[3], Judith James[3], Jill Buyon[4], Stephen Connelly[1], Maple Fung[5], Cherie Ng[1], Chandra Mohan[6] and Chaim Putterman[7], [1]Equillium, Inc., La Jolla, CA, [2]Albert Einstein College of Medicine/Montefiore Medical Center, New York, NY, [3]Oklahoma Medical Research Foundation, Oklahoma City, OK, [4]NYU School of Medicine, New York, NY, [5]Equillium, Inc., San Diego, CA, [6]University of Houston, Houston, TX, [7]Albert Einstein College of Medicine, Bronx, NY

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: SLE – Diagnosis, Manifestations, & Outcomes Poster I: Diagnosis (0323–0356)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Lupus nephritis (LN) is a leading cause of morbidity and mortality in systemic lupus erythematosus (SLE) patients. While LN pathogenesis has yet to be fully elucidated, T cells have been strongly implicated in mechanisms of disease. CD6 is a co-stimulatory receptor on T cells, that binds to activated leukocyte cell adhesion molecule (ALCAM), a ligand expressed on antigen presenting cells and epithelial and endothelial tissues. The CD6-ALCAM pathway plays an integral role in modulating T cell activation and trafficking and is central to immune-mediated inflammation. Previously, we reported that soluble urine ALCAM is a potential biomarker of disease in LN. Here, we evaluated the correlation of serum and urine ALCAM and CD6 with disease activity over time.

Methods: Patient samples were acquired through the Accelerating Medicines Partnership (AMP), a public-private partnership to accelerate development of therapeutics for diseases such as LN. Serum and urine samples were obtained from patients with biopsy proven LN (n=345) and living kidney donor controls (n=68). Follow-up longitudinal sampling (3, 6, and 12 months) was available for 143 LN patients. ALCAM levels were quantified by ELISA, while CD6 levels were quantified by an electrochemiluminescent assay. Levels were analyzed cross-sectionally (first visit) and longitudinally against disease measures that included proteinuria, SLEDAI, the renal components of the SLEDAI score (R-SLEDAI), ISN-RPS histological class of the lesion, serological parameters, and patient characteristics.

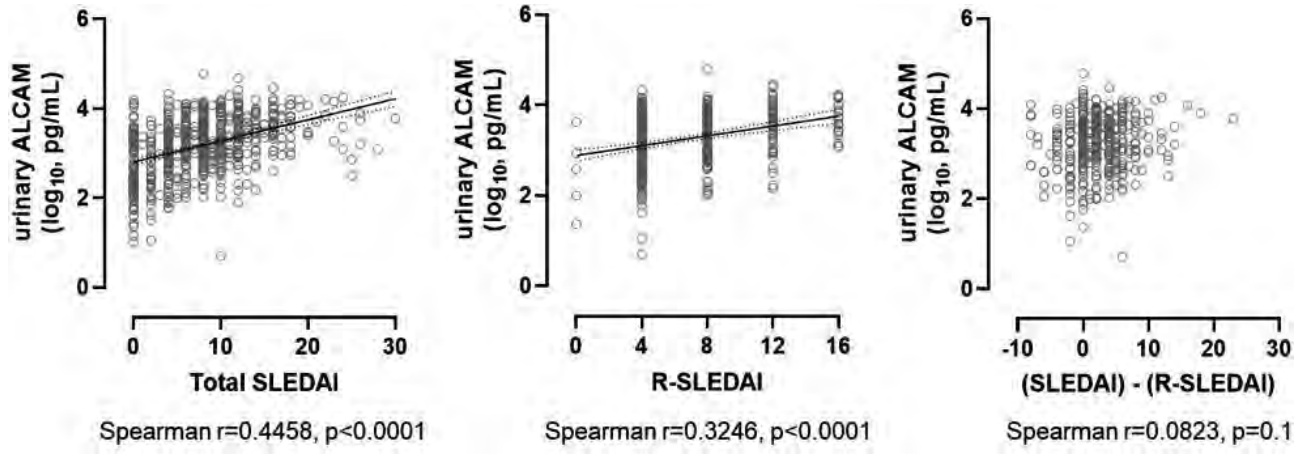

Figure 1. Urinary ALCAM correlates with renal but not non-renal SLEDAI scores. Correlation of urinary ALCAM with SLEDAI (left panel), R-SLEDAI (middle panel), and the non-renal portion of SLEDAI (calculated by subtracting R-SLEDAI from the total SLEDAI; right panel).

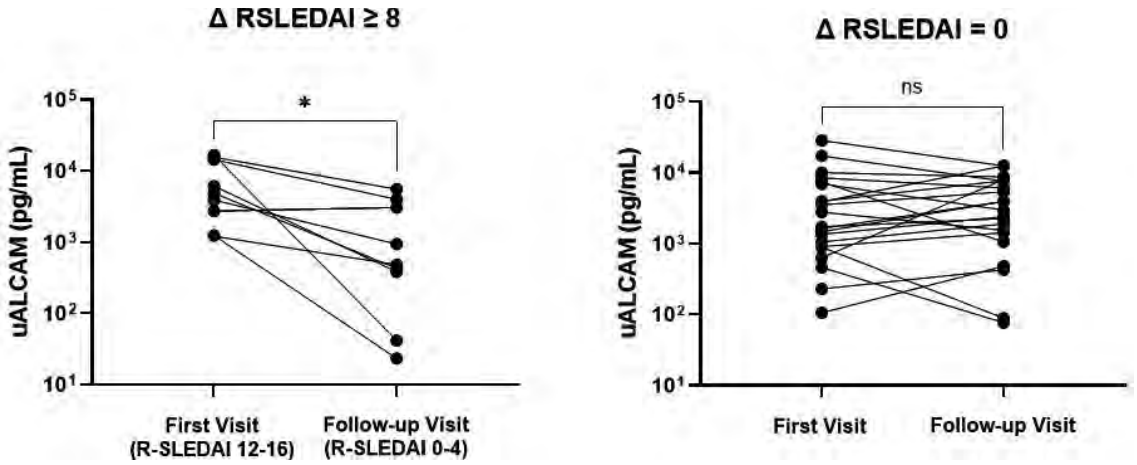

Figure 2. Urinary ALCAM decreases with decreased R-SLEDAI score over time. (Left panel) Urinary ALCAM levels in patients (n=10) with a decrease in R-SLEDAI ≥ 8 over a 6-12 month period were compared at the two timepoints. ALCAM levels decreased at the subsequent visit consistent with change in R-SLEDAI. No patients were available to analyze with an increase in R-SLEDAI. (Right panel) In comparison, subjects with no change in R-SLEDAI over the 12 months did not exhibit significant decreases in urinary ALCAM. Paired t-test, *p<0.05.

Results: Consistent with our previous findings, cross-sectional analysis showed that urinary ALCAM was significantly elevated in LN patients (mean 4333.5 pg/mL, 95% CI [3614.0, 5053.0]) compared to control subjects (mean 214.4 pg/mL, 95% CI [152.9, 276.0]) (*p< 0.001*), but that there were no differences in serum ALCAM levels. Urinary ALCAM levels significantly correlated with SLEDAI and R-SLEDAI scores (but did not correlate to the non-renal portion of SLEDAI (SLEDAI – R-SLEDAI) (Figure 1), suggesting that ALCAM level is associated with the renal activity. This was supported by near-significant correlations with C3 (*p=0.07*) and C4 levels (*p=0.05*). Serum and urine levels of CD6 were similar between cases and control subjects and did not change with disease activity, suggesting that the differences observed in urinary ALCAM levels are not due to hemodynamic changes or non-specific loss of glomerular permeability. In patients followed with longitudinal sampling, urinary ALCAM reflected changes in SLEDAI and R-SLEDAI. Furthermore, in preliminary analysis of a subset of patients who exhibited significant changes in R-SLEDAI across visits, intra-patient comparison of the respective timepoints reflected concomitant significant changes in urinary ALCAM levels (Figure 2).

Conclusion: Here, we expand upon previous studies and provide additional support in a large multi-center cohort, by showing that urinary ALCAM levels are elevated in SLE patients with active LN and decline with clinical improvement. Studies in progress are evaluating the implications of these findings in predicting therapeutic responses in LN, as well as longer term disease outcomes and prognosis.

Abstract Number: 0354

A Cross-Sectional Study of Rheumatoid Arthritis Diagnoses in Patients with Systemic Lupus Erythematosus

Kathryn Starzyk[1], Gary Curhan[2] and Julia Brault[2], [1]OM1, Inc, Boston, MA, [2]OM1, Boston, MA

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: SLE – Diagnosis, Manifestations, & Outcomes Poster I: Diagnosis (0323–0356)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Features of autoimmune conditions may coexist in individual patients, which may represent an overlapping single disease with features of both (i.e., 'rhupus'), or the presence of two distinct diseases. Rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE) share some genetic etiologies and distinguishing between lupus arthropathy and RA features poses clinical challenges. Given the potential for drug-induced or exacerbation of SLE with some of the available biologic treatment options, understanding the benefit-risk scenarios in the context of real-world phenotypes is important.

Methods: The OM1 SLE Registry (OM1, Inc; Boston, MA) follows more than 46,900 SLE patients in the U.S. managed by rheumatologists longitudinally with deep clinical data, including laboratory, patient-reported and disease activity information, and linked administrative claims starting from 2013. Index date was set by the first registry encounter with an SLE diagnosis code and ≥18 months of baseline available. Potential RA comorbidity was defined as at least 2 outpatient RA diagnosis codes ≥365 days apart or inpatient RA codes. Other comorbidities were defined by the pres-

Patient-reported RAPID3 (Routine Assessment of Patient Index Data 3, range 0-10)*		
Result available, n (%)	16,524 (37)	1,012 (48)
Mean score closest to index (SD)	4.0 (2.0)	4.0 (2.0)

ence of at least 2 outpatient diagnosis codes ≥30 days apart or one inpatient diagnosis code prior to index. Obesity was defined as BMI ≥30 kg/m2. Medications were identified by prescriptions, administrations and/or fills. RAPID3 (Routine Assessment of Patient Index Data 3) at index date was also explored.

Results: The study included 44,186 patients (92% female) from the OM1 SLE Registry, 2096 (4.7%) of whom met RA code criteria (Table 1). Over 46% of SLE-RA cohort patients had ≥1 RA diagnosis codes in at least 3 calendar years during follow-up. The SLE-RA cohort was older (56 versus 51 years), with a higher proportion of white and non-hispanic patients than the SLE patients overall. Mean patient-reported joint-related disease activity was moderate (mean RAPID-3 = 4) across all patients. Autoimmune (e.g., Sjögren's) and other comorbidities were more common in the SLE-RA cohort (Table 2). Recent treatment with systemic steroids, methotrexate, leflunomide and biologic DMARDs was more commonly seen in SLE-RA patients (Table 2).

Conclusion: RA diagnoses in patients within the SLE Registry was higher than expected based on the literature. Classification for this study was based upon clinical diagnosis in routine practice by a rheumatologist and ACR diagnostic criteria may or may not have been applied. Further research is needed to better understand the chronologic path of these conditions (or their features) and implications for treatment.

Utilization of a Clinical Data Research Network to Assess Systemic Lupus International Collaborating Clinics Classification Criteria Attributes in Patients with Systemic Lupus Erythematosus

Noah Forrest[1], Kathryn Jackson[2], Al'ona Furmanchuk[2], Anika Ghosh[2], Jennifer Pacheco[2], Vesna Mitrovic[2], Abel Kho[2], Rosalind Ramsey-Goldman[2] and Theresa Walunas[2], [1]Feinberg School of Medicine, Chicago, [2]Northwestern University, Chicago, IL

SESSION INFORMATION

Session Date: Saturday, November 6, 2021
Session Title: SLE – Diagnosis, Manifestations, & Outcomes Poster I: Diagnosis (0323–0356)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Systemic Lupus Erythematosus (SLE) is an autoimmune disease characterized by a heterogenous clinical phenotype that may present differently over time and between patients, which can create challenges for identification and treatment of individuals being seen at multiple care centers. Clinical data research networks (CDRN) aim to pool electronic health records (EHR) to provide more complete clinical information for patients shared across care centers. We sought to determine whether algorithms to identify Systemic Lupus International Coordinating Clinics (SLICC) classification criteria attributes, using structured EHR data, could be applied to a CDRN to describe people with SLE.

Methods: The attribute identification frequency of SLICC criteria are represented in Table 1. We identified 6,488 persons ≥ 3 SLE diagnoses and 1,201,999 persons with no diagnosis codes for SLE. The following SLICC attributes were identified from each group and identified at the following rates (No diagnosis vs. ≥3 diagnoses): Oral Ulcers: 2.1% vs. 3.5%, Alopecia: 2.5% vs. 5%, Neurological: 18% vs. 23%, Arthritis: 2.5% vs. 6.8%, Serositis: 7.1% vs. 17%, Acute Cutaneous: 0.17% vs. 19%, Chronic Cutaneous: 0.1% vs. 18%, Renal: 10% vs. 29%, Thrombocytopenia: 6.3% vs. 14%, Leukopenia: 67% vs. 77%, Hemolytic Anemia: 1.4% vs. 4.8, Antinuclear Antibodies: 2.2% vs. 26%, Anti-dsDNA Antibodies: 1.6% vs. 42%, Anti-Sm Antibodies: 0.078% vs. 6%, Antiphospholipid Antibodies: 0.26 % vs. 7.1%, Low complement: 0.56% vs. 37%, Direct Coombs Test: 0.057% vs. 1.4%. The percent of patients satisfying the SLICC definition of SLE 0.81% among those without a SLE diagnosis and 43% among those with ≥3 SLE diagnoses.

Table 1. SLICC Classification Criteria Attribute Identification Rates

Criterion	All Patients N (%)	No SLE Diagnoses N (%)	≥ 3 SLE Diagnoses N (%)	P-Value No SLE vs. ≥ 3 Diagnoses

Results: The attribute identification frequency of SLICC criteria are represented in Table 1. We identified 6,488 persons ≥ 3 SLE diagnoses and 1,201,999 persons with no diagnosis codes for SLE. The following SLICC attributes were identified from each group and identified at the following rates (No diagnosis vs. ≥3 diagnoses): Oral Ulcers: 2.1% vs. 3.5%, Alopecia: 2.5% vs. 5%, Neurological: 18% vs. 23%, Arthritis: 2.5% vs. 6.8%, Serositis: 7.1% vs. 17%, Acute Cutaneous: 0.17% vs. 19%, Chronic Cutaneous: 0.1% vs. 18%, Renal: 10% vs. 29%, Thrombocytopenia: 6.3% vs. 14%, Leukopenia: 67% vs. 77%, Hemolytic Anemia: 1.4% vs. 4.8, Antinuclear Antibodies: 2.2% vs. 26%, Anti-dsDNA Antibodies: 1.6% vs. 42%, Anti-Sm Antibodies: 0.078% vs. 6%, Antiphospholipid Antibodies: 0.26 % vs. 7.1%, Low complement: 0.56% vs. 37%, Direct Coombs Test: 0.057% vs. 1.4%. The number of patients satisfying the SLICC definition of "Definite SLE" was 7684 persons (0.64%) among those without a SLE diagnosis and 2487 persons (38%) among those with ≥3 SLE diagnoses.

Conclusion: The results demonstrate that we can identify all SLICC classification criteria attributes in the CAPriCORN data set. We observed an increased rate of attribute identification for all SLICC criteria and an increased rate of definite SLE classification via SLICC in patients with ≥3 SLE diagnoses when compared with patients without any SLE diagnoses, consistent with an expected higher occurrence rate for persons with SLE. This suggests that SLE presentation can be characterized in CDRN data.

Abstract Number: 0356

The Role of Neutrophils in the Clinical Severity of Lupus Nephritis Patients with Concurrent Skin Disease

Lais Osmani, Sicong Shan, Zoe Chafouleas, Jason Pettus and Sladjana Skopelja-Gardner, Dartmouth Hitchcock Medical Center, Lebanon, NH

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: SLE – Diagnosis, Manifestations, & Outcomes Poster I: Diagnosis (0323–0356)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Skin disease affects >80% of lupus patients and has been linked to lupus nephritis (LN) flares. We recently found that skin inflammation caused by UV light can trigger both local and systemic immune responses, in the blood and the kidney. This inflammation also led to kidney injury, associated with increased expression of renal inflammatory and injury markers and proteinuria. The observed renal injury was mediated by neutrophils, which migrated from the inflamed skin to the kidneys, localizing predominantly to the tubulointerstitial areas. These data prompted the hypothesis that presence of concurrent skin disease in lupus patients leads to worse nephritis mediated by neutrophils.

Methods: Kidney biopsies from 43 LN patients (2005-2020, IRB# 02000844) were retrieved from the Dartmouth Hitchcock Medical Center tissue bank and grouped into: i) LN with concurrent skin rash (malar, subacute, or discoid n =15) and ii) LN without skin rash (EMR review and/or skin biopsy, n=6) at the time of LN diagnosis (class IV). Patients with inconclusive or incomplete skin findings were excluded. The study included only female patients. Clinical and laboratory data (absolute neutrophil (ANC) and lymphocyte (ALC) counts, serum creatinine, estimated glomerular filtration rate (GFR), autoantibody titers, and complement levels) were collected by retrospective chart review. Histologic and immunofluorescence data were extracted from kidney biopsy reports. Student's t-test was performed to detect statistically significant differences between patient groups.

Results: Presence of skin rash at the time of LN flare was indicative of more active disease, reflected by higher ANA and anti-dsDNA IgG titers, and low complement C3 and C4 levels. Of interest, LN patients with concurrent skin disease had higher absolute neutrophil counts ($p < 0.05$) and neutrophil-lymphocyte ratio ($p< 0.01$), but not lymphocyte absolute counts, compared to LN patients without a concurrent skin rash. High neutrophil counts in the presence of skin disease associated with lower glomerular filtration rate (GFR < 60; $p< 0.01$). This association was not seen in the absence of concurrent skin disease and rash alone did not predict GFR. Analysis of kidney immunofluorescence revealed that concurrent skin disease at the time of LN flare associated with greater IgA deposition. In particular, increased renal IgA levels associated with higher neutrophil but not lymphocyte counts ($p < 0.01$). This was specific to IgA as no associations with IgG or IgM deposition were detected.

Conclusion: Our study provides several novel findings that suggest neutrophils may be the pathogenic link between skin inflammation and lupus nephritis flares: i) higher neutrophil counts are found in the presence of a skin rash at the time of LN flare, ii) neutrophilia but not lymphocytosis in the presence of a skin rash associates with worse kidney function (low GFR), and iii) high neutrophil levels in the presence of skin rash associate with increased renal IgA deposition. The newly identified relationship between neutrophil levels and kidney IgA provides a novel model of IgA-driven activation of neutrophils leading to kidney injury initiated by skin inflammation.

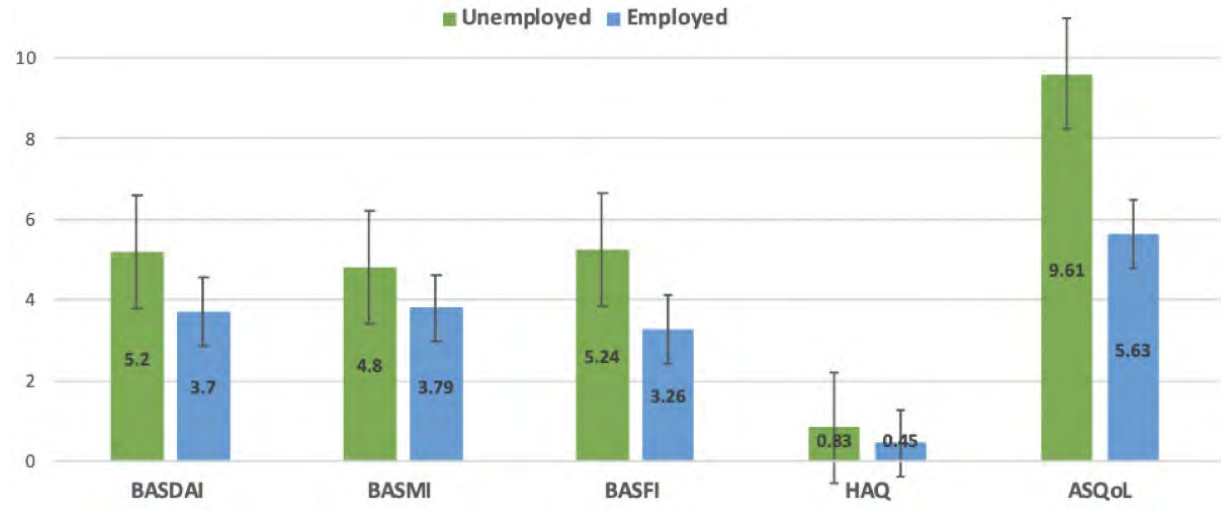

Figure 1. Comparison of mean outcomes on the basis of employment, all differences were statistically significant at the p<0.01 level.

Spondylitis Registry of Ireland (ASRI) is a source of epidemiological data on axSpA in Ireland. The aim of this study was to examine the prevalence of unemployment in axSpA and quantify the impact on burden of disease, level of function and quality of life.

Methods: For the purposes of this analysis data was extracted from the ASRI on participants with employment data recorded. Patients were analysed on the basis of employment and categorised as employed or unemployed. A two tailed t-test was used to test for statistical significance in mean continuous variables between groups. For categorical variables, an independent chi-squared test of independence determined statistical significance. An alpha level of p< 0.05 was deemed significant. IBM SPSS v.26 was used for data and statistical analysis.

Results: Employment status was available for 876 patients enrolled in the ASRI. Overall 21.6% (189) of the population was unemployed, which is considerably higher than national averages of 6.2-13.1% during the same period. In addition, 24% (213) reported axSpA as a limitation in work ability. Unemployed patients reported significantly worse BASDAI (5.2 vs 3.7, p< 0.01), BASMI (4.8 vs 3.79, p< 0.01), BASFI (5.24 vs 3.26, p< 0.01), HAQ (0.83 vs 0.45, p< 0.01), and ASQoL scores (9.61 vs 5.63, p< 0.01) compared to employed axSpA patients(figure 1). A higher proportion of males were unemployed as compared to females (table 1). No significant differences were noted in pattern of disease, medication usage or baseline demographics. Male sex (OR 2.31, 95% CI 1.32-4.04), worse BASMI (OR 1.19,

Table 2. Prediction model for risk of unemployment in AxSpA

	Odds Ratio	95% CI	*p value*
Gender	2.31	1.32 - 4.04	**<0.01**
Age	0.98	0.95 - 0.99	**0.02**
Delay to diagnosis	0.99	0.96 - 1.02	0.51
Disease duration	1.00	0.98 - 1.02	0.81
BASDAI	1.09	0.96 - 1.23	0.19
BASMI	1.19	1.05 - 1.35	**0.01**
BASFI	1.02	0.93 - 1.13	0.68
HAQ	1.48	0.84 - 2.16	0.18
ASQoL	1.07	1.01 - 1.14	**0.02**

95% CI 1.05-1.35) and worse ASQoL scores (OR 1.07, 95% CI 1.01-1.14) were found to be significant predictors of unemployment (table 2).

Conclusion: Prevalence of unemployment in axSpA is notably higher than nationally reported averages from the general population. Despite a high uptake of biologic therapy in this group, these patients have higher levels of disease activity, poorer levels of function and worse quality of life compared to employed axSpA patients. Predictors of unemployment were male sex, worse spinal mobility and poorer quality of life. In males, higher average BASMI scores were a significant contributing factor to the higher rates of unemployment observed. Prompt intervention for patients with worsening outcome measures, in particular spinal restriction, would provide an opportunity for occupational supports and prevent progression to unemployment.

Session Date: Saturday, November 6, 2021

Session Title: Spondyloarthritis Including PsA – Diagnosis, Manifestations, & Outcomes Poster I: Clinical Aspects of Axial Spondyloarthritis (0357–0386)

Session Type: Poster Session A

Session Time: 8:30AM–10:30AM

Background/Purpose: Axial spondyloarthritis (axSpA) is a chronic inflammatory condition often associated with impaired working participation[1] not only translating to devastating outcomes for patients (pts) but also increased economic and social burden due to a significant amount of indirect costs. Data on the different work participation domains in axSpA pts with access to biologic therapies are limited. The objective of this survey is to characterise the different domains of work participation [presenteeism, absenteeism, sick leave, unemployment, disability pensions] in axSpA pts and their associations with demographic and clinical confounders.

Methods: Pts with confirmed clinical diagnosis of axSpA were enrolled in a multicenter, observational ATTENTUS survey conducted across Germany (Nov-2019 to Jul-2020). To ensure high data quality, inclusion criteria was verified by external monitoring, followed by evaluation of the domains of impaired work participation, including absenteeism and presenteeism (WPAI). Demographics, clinical parameters and patient related outcomes (PROs) were collected via tablet This analysis included all working patients ≥18 years.; and excluded students and retired pts. Pts without absenteeism (value=0) and presenteeism ≤20% were defined as no impairment at work.

Results: A total of 787 axSpA pts were enrolled in the survey. Seven students, 68 retired pts and 17 pts not fulfilling the inclusion criteria were excluded from this analysis, leaving 695 pts with complete data sets. Baseline data are outlined in **Table**. 50 pts received disability pensions, 29 pts received unemployment benefits, 590 (84.9%) pts reported

ASAS-HI, Assessment of SpondyloArthritis International Society-Health Index; BASDAI, Bath Ankylosing Spondylitis Disease Activity Index; BASFI, Bath Ankylosing Spondylitis Functional Index; BMI, basal metabolic index; n, number of pts; SD, standard deviation; WP, work productivity; years, yrs				

paid work [part-time: n=132 (22.4%); full-time: n=458 (65.9%)], with 242 (41.0%) pts having no impairments at work. 379 (64.2%) employed pts took sick leave within the previous 12 months (mo) (< 3 mo: n=351; 3–6 mo: n=17; >6 mo: n=11). Absenteeism and presenteeism occurred in 140 (23.7%) and 496 (84.1%) pts, respectively. Pts without impairments were mostly of young age, male sex, well-educated, with low disease activity, less fatigue and shorter duration of morning stiffness, and preserved global and physical functioning. No apparent differences between pts with and without impairment of work participation were observed in terms of biologic treatment, disease duration and BMI.

Conclusion: There was a substantial impact on work participation for axSpA pts. Despite numerous available therapeutic options physical function was still impaired and lead to high rates of impairment of work participation. Pts with impaired work participation compared to pts with no impairment, reported increased fatigue, longer duration of morning stiffness, decreased functional capacity, female sex and a lower level of education.

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Spondyloarthritis Including PsA – Diagnosis, Manifestations, & Outcomes Poster I: Clinical Aspects of Axial Spondyloarthritis (0357–0386)

Session Type: Poster Session A

Session Time: 8:30AM–10:30AM

Background/Purpose: The journey of axial spondyloarthritis (axSpA) for most patients is slow and arduous. The goal of this analysis is to assess the journey to diagnosis and further management in axSpA patients.

Methods: Data from 2,846 unselected patients from EMAS, generated through an online survey (2017-2018) across 13 European countries were analysed. Descriptive analysis of sociodemographic factors, insurance scheme, diagnostic journey and post diagnosis healthcare utilization was performed. The Mann-Whitey test was used to analyse possible differences between BASDAI and the number of visits to healthcare professionals and followup tests undertaken.

Results: The mean age was 43.9 years, 61.3% were female, 48.1% university educated, 67.9% married, 53.9% employed and 81.7% had public health insurance. Mean age at symptoms onset was 26.6 (11.1), while mean age at diagnosis was 33.7 (11.5) and mean diagnostic delay was 7.4 years. Over 50% had a diagnostic delay of >4 years. Prior to receiving a diagnosis, patients visited on average 2.6 specialists. The most commonly performed diagnostic

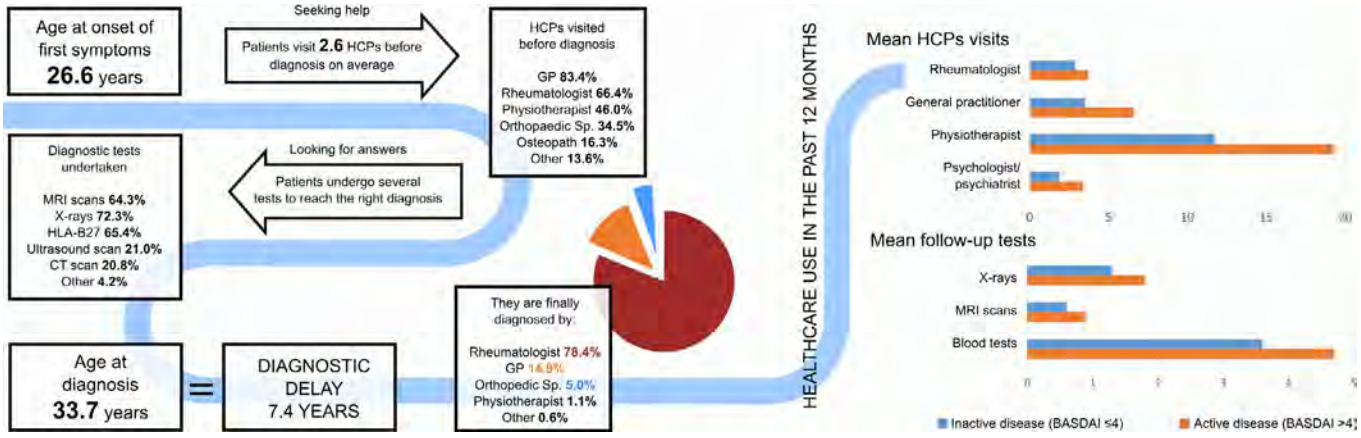

Figure 1. Diagnostic pathway of EMAS axSpA patients.

tests were x-rays (72.3%), HLA B27 tests (65.4%) and MRIs (64.3%). 78.4% were diagnosed by a rheumatologist while 14.9% received their diagnosis by a General Practitioner (GP). Patients who experienced a diagnostic delay of more than a year (n=2,208) undertook a considerable number of visits to specialists and medical tests in the year prior to participating in EMAS, which increased with disease activity. Patients with active disease (BASDAI >4) reported a higher number of visits to rheumatologists (3.7±3.5 vs 2.9±2.6), general practitioners (6.6±10.0 vs 3.5±4.1), physiotherapists (19.3±25.0 vs 11.7±17.0), and psychologists/psychiatrists (3.4±10.7 vs 1.9±7.7). Regarding follow-up tests, they also undertook more x-rays (1.8 ± 2.8 vs. 1.3 ± 1.9), MRI scans (0.9 ± 1.2 vs. 0.6 ± 1.1), and blood tests (4.7 ± 4.4 vs 3.6 ± 3.2) compared to patients with inactive disease (Figure 1). However, one in five patients visited the rheumatologist only once in the year prior to EMAS (21.1%).

Conclusion: Diagnostic delay continues to be a key challenge in the axSpA patient journey, with patients waiting an average of 7.4 years and visiting multiple doctors and undertaking a significant number of medical tests prior to diagnosis. Once diagnosed, disease management presents a further challenge, as patients with higher disease activity reported more healthcare professional visits as well as medical tests. Safeguarding health and controlling healthcare utilization requires effective disease management, greater education for non-specialists, rapid referral routes for diagnosis and collaborative care between specialists and nonspecialists.

Session Title: Spondyloarthritis Including PsA – Diagnosis, Manifestations, & Outcomes Poster I: Clinical Aspects of Axial Spondyloarthritis (0357–0386)

Session Type: Poster Session A

Session Time: 8:30AM–10:30AM

Background/Purpose: Pain is a hallmark of axial spondyloarthritis (axSpA) and can significantly deteriorate patients' health status. This analysis aims to investigate factors associated with pain intensity in a large sample of European axSpA patients.

Methods: 2,846 unselected patients participated in EMAS, an online survey (2017-2018) across 13 European countries. Data from 2,636 participants who reported pain were analysed. Pain was measured by the mean of two BASDAI

Table 1. Regression analysis of the association of pain intensity (0-10 NRS) with demographic, socioeconomic and axSpA-related factors (N = 850)

[1]Female vs Male; [2]No university studies (no schooling, primary and high school) vs University studies; [3]Divorced/separated vs single, married and widow; [4]Obese vs not obese (underweight, normal and overweight).

questions (range 0 “no pain” to 10 “most severe pain”): "How would you describe the overall level of AS neck, back or hip pain you have had?” and “How would you describe the overall level of pain/swelling in joints other than neck, back, hips you have had?”. Linear regression analysis was applied to identify associations between pain intensity and sociodemographic factors, patient-reported outcomes [BASDAI (0-10), spinal stiffness (3-12), functional limitation (0-54), mental health using the 12-item General Health Questionnaire GHQ-12 (0-12)], work life, physical activity and comorbidities (N= 850).

Results: The mean age of the sample was 44 years, 61.4% were female, 49.4% had a university degree and 67.7% were married. The average reported pain intensity was 5.3 (±2.2); 76.2% reported pain intensity ≥4, with the greatest intensity reported by women (5.5 vs 4.9, p< 0.001), those not university educated (5.6 vs 5.0, p< 0.001), separated or divorced compared to singles (5.8 vs 5.2, p=0.004), and not physically active (5.7 vs 5.2, p< 0.001). In addition, employed patients who experienced work-related issues reported greater pain (5.2 vs 3.9) as did those who experienced/ believed they would face difficulties finding work due to axSpA (5.9 vs 4.3), and those whose employment choice was determined by axSpA (5.7 vs 4.9; all p< 0.001). Moreover, associations with anxiety (5.9 vs 5.0), depression (6.1 vs 5.0) and sleep disorders (5.9 vs 4.9; all p< 0.001) were also found. The multiple linear regression model showed that those with higher pain intensity reported at least one work-related issue (B= 0.65), difficulties finding work due to axSpA (B= 0.48), not having attended university (B=0.38), greater spinal stiffness (B= 0.29), being female (B= 0.26) and poorer mental health (GHQ-12; B= 0.10; Table 1).

Conclusion: Pain was most strongly associated with working life impairment, as well as with spinal stiffness. Pain was also associated with suffering from depression, anxiety and sleep disorders. Understanding how pain affects individuals and shared-decision making between rheumatologists and patients are essential for long-term disease management and preserving quality of life of axSpA patients.

Session Title: Spondyloarthritis Including PsA – Diagnosis, Manifestations, & Outcomes Poster I: Clinical Aspects of Axial Spondyloarthritis (0357–0386)

Session Type: Poster Session A

Session Time: 8:30AM–10:30AM

Background/Purpose: Physical activity is an essential component in axial spondyloarthritis (axSpA) care, improving physical and mental wellbeing. This analysis aims to identify factors associated with engaging in physical activity among axSpA patients.

Methods: Data from 2,846 unselected patients participating in EMAS, an online survey (2017-2018) across 13 European countries, were analysed. Engaging in physical activity was assessed by the following item: "Do you do any physical or sporting activity?" for which participants could report at least 1 physical activity or that they did not do any physical activity. BASDAI (0-10), spinal stiffness (3-12), functional limitation (0-54), and mental health using General Health Questionnaire GHQ-12 (0-12) were assessed. Mann-Whitney and Pearson's $\chi 2$ tests were used to analyse

[1]Male vs Female; [2]University vs no university (no schooling, primary, high school); [3]Married vs single, separated/divorced and widow;[4] Member vs not; [5]Not obese (underweight, normal and overweight) vs obese; [6]Employed vs not (unemployed, sick leave, early retirement/retirement, housework and student).[7]p-value for test H_0: OR = 1 [8]p-value for test H_0 B = 0.

relationships between engaging in physical activity and sociodemographic factors, patient-reported outcomes, employment, lifestyle and comorbidities. Univariable and multivariable binary logistic regression were used to analyse variables possibly explaining engagement in physical activity (N= 2,424).

Results: Mean age of the sample was 43.9±12.3 years, 61.3% were female, 48.1% had a university degree and 67.9% were married. 81.8% (n= 2,329) engaged in at least one kind of physical activity. Those physically active were typically male (85.3% vs 79.7% female, p< 0.001), university educated (86.0% vs 78.0%, p< 0.001), married (83.1% vs 79.2%, p=0.046), and members of a patient organisation (86.4% vs 78.9%, p< 0.001). 25.1% of obese patients (n=533) did not engage in physical exercise (v. 16.6%, p< 0.001). Those who did not engage in physical activity reported greater disease activity (6.0±1.9 vs 5.4±2.0 BASDAI, p< 0.001), functional limitation (21.6±15.0 vs 20.2±16.5, p=0.010), spinal stiffness (8.3±2.6 vs 7.6±2.5, p< 0.001), and poorer mental health (5.9±4.2 vs 4.8±4.1 GHQ-12, p< 0.001). Furthermore, 83.9% of those employed (n=1,457) were physically active, versus 73.7% of unemployed (n=205; p< 0.001). In the multivariable binary logistic regression, the qualitative variables associated with engaging in physical activity were belonging to a patient organisation (OR=1.91), not being obese (OR= 1.58), being university educated (OR= 1.54), and being male (OR= 1.39). The quantitative variables associated were lower spinal stiffness (B= -0.110), better mental health (B= -0.042), and one year age increase (B= 0.017; Table 1).

Conclusion: These results show that increasing age, being male, university educated, member of a patient organisation, not obese, having lower spinal stiffness, and better mental health increase the probability of engaging in physical activity. Physical activity is an important part of axSpA care and patient organizations play a critical role in enhancing access to and participation in physical activity.

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Spondyloarthritis Including PsA – Diagnosis, Manifestations, & Outcomes Poster I: Clinical Aspects of Axial Spondyloarthritis (0357–0386)

Session Type: Poster Session A

Session Time: 8:30AM–10:30AM

Background/Purpose: Axial spondyloarthritis (axSpA) is associated with increased absence from work and reduced work productivity, which can impact employment status.[1] TNF inhibitors such as certolizumab pegol (CZP) have been shown to improve work productivity in patients (pts) with axSpA.[2,3] However, the association between the extent of clinical improvement and work/household productivity over long-term CZP treatment has not been evaluated. The objective of this study was to evaluate the association between the extent of improvement in clinical outcomes and burden on paid work and household productivity in pts with axSpA over 4 years' CZP treatment.

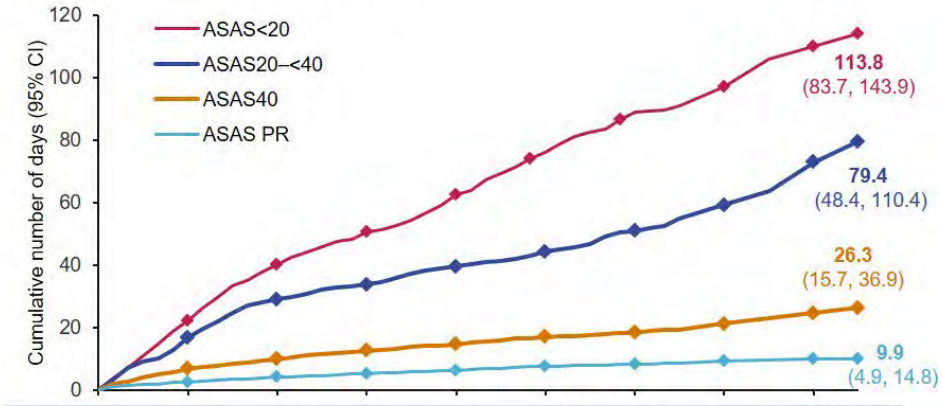
Paid work absenteeism refers to missed work because of arthritis (Q2 of WPS). Reported estimates are from a weighted generalized estimating equations model and the inverse probability of study discontinuation was used as the weight. The estimates are cumulative mean numbers from baseline (Day 1) through each time point. ASAS<20: <20% improvement; ASAS20–<40: ≥20–<40% improvement; ASAS40: ≥40% improvement; ASAS PR: a score of ≤2 in all 4 ASAS domains; ASDAS-CII: change ≥1.1–≤2.0 units; ASDAS-MI: change >2.0 units; ASDAS non-response: change ≤1.1 unit; ASDAS ID: ASDAS <1.3. ASAS: Assessment of SpondyloArthritis international Society; ASDAS: Ankylosing Spondylitis Disease Activity Score; CII: clinically important improvement; CI: confidence interval; ID: inactive disease; MI: major improvement; PR: partial remission; WPS: Work Productivity Survey.

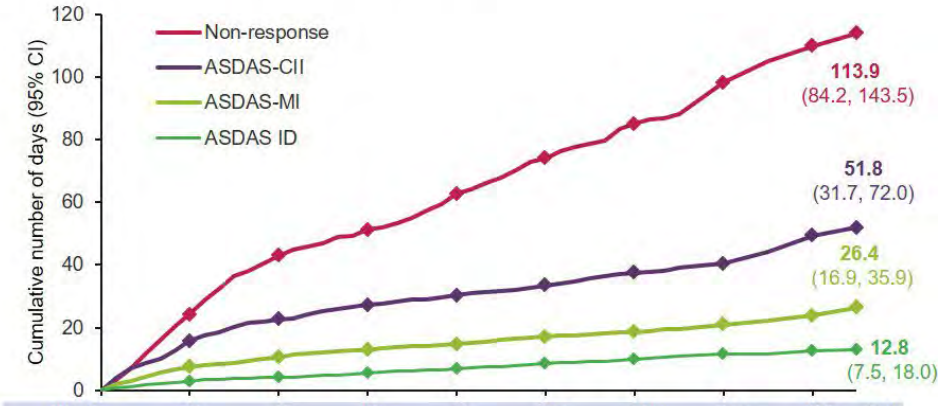
Figure 2. Paid work presenteeism by (A) ASAS response and (B) ASDAS response

A) Paid work presenteeism by ASAS response



Weighted n	Week	24	48	72	96	120	144	168	192	204
	ASAS<20	56	38	34	32	31	33	26	23	21
	ASAS20–<40	37	31	25	29	23	18	23	25	22
	ASAS40	111	124	116	109	111	108	106	98	92
	ASAS PR	66	64	63	63	61	64	59	53	52

B) Paid work presenteeism by ASDAS response



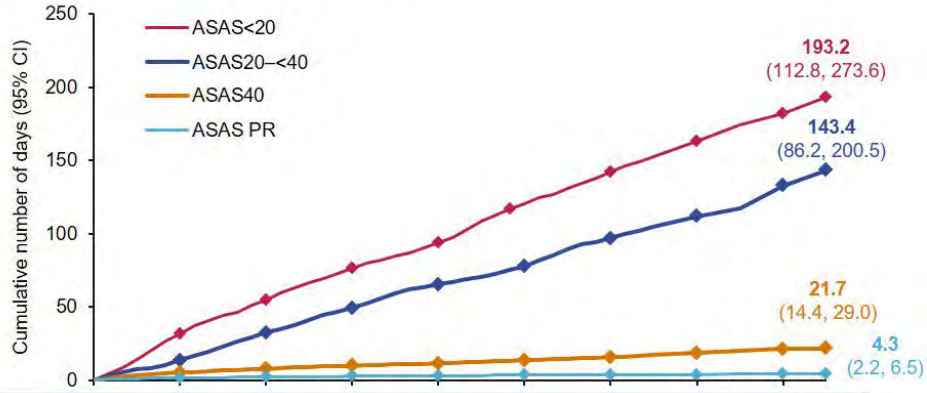
Weighted n	Week	24	48	72	96	120	144	168	192	204
	Non-response	58	45	39	42	34	33	32	27	25
	ASDAS-CII	57	50	44	38	43	47	41	47	47
	ASDAS-MI	92	101	97	95	92	83	86	74	69
	ASDAS ID	65	62	53	59	59	56	54	54	45

Paid work presenteeism refers to reduced productivity at work (WPS Q3). Reported estimates are from a weighted generalized estimating equations model and the inverse probability of study discontinuation was used as the weight. The estimates are cumulative mean numbers from baseline (Day 1) through each time point. ASAS<20: <20% improvement; ASAS20–<40: ≥20–<40% improvement; ASAS40: ≥40% improvement; ASAS PR: a score of ≤2 in all 4 ASAS domains; ASDAS-CII: change ≥1.1–≤2.0 units; ASDAS-MI: change >2.0 units; ASDAS non-response: change ≤1.1 unit; ASDAS ID: ASDAS <1.3. ASAS: Assessment of SpondyloArthritis international Society; ASDAS: Ankylosing Spondylitis Disease Activity Score; CII: clinically important improvement; CI: confidence interval; ID: inactive disease; MI: major improvement; PR: partial remission; WPS: Work Productivity Survey.

Methods: These analyses use observed data from pts originally randomized to CZP in the phase 3 RAPID-axSpA study (NCT01087762).[4] Paid work absenteeism and presenteeism, and household work productivity, assessed using the validated arthritis-specific Work Productivity Survey (WPS),[5] are reported for pts who had: ASAS< 20, ASAS20–< 40, ASAS40 and ASAS partial remission (PR); ASDAS clinically important improvement (CII), major improvement (MI)

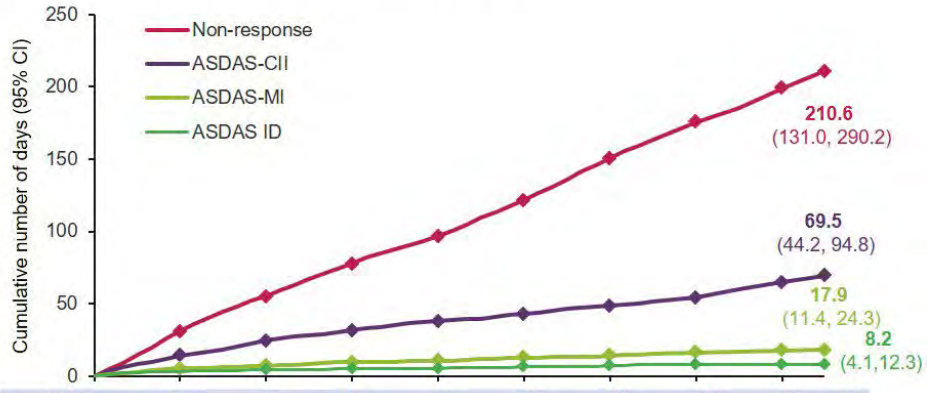
Figure 3. Household work absenteeism by (A) ASAS response and (B) ASDAS response

A) Household work absenteeism by ASAS response



Weighted n	Week	24	48	72	96	120	144	168	192	204
	ASAS<20	56	38	34	32	31	33	26	23	21
	ASAS20–<40	37	31	25	29	23	18	23	25	22
	ASAS40	111	124	116	109	111	108	106	98	92
	ASAS PR	66	64	63	63	61	64	59	53	52

B) Household work absenteeism by ASDAS response



Weighted n	Week	24	48	72	96	120	144	168	192	204
	Non-response	58	45	39	42	34	33	32	27	25
	ASDAS-CII	57	50	44	38	43	47	41	47	47
	ASDAS-MI	92	101	97	95	92	83	86	74	69
	ASDAS ID	65	62	53	59	59	56	54	54	45

Household work absenteeism refers to days not performing household work (WPS Q5). Reported estimates are from a weighted generalized estimating equations model and the inverse probability of study discontinuation was used as the weight. The estimates are cumulative mean numbers from baseline (Day 1) through each time point. ASAS<20: <20% improvement; ASAS20–<40: ≥20–<40% improvement; ASAS40: ≥40% improvement; ASAS PR: a score of ≤2 in all 4 ASAS domains; ASDAS-CII: change ≥1.1–≤2.0 units; ASDAS-MI: change >2.0 units; ASDAS non-response: change ≤1.1 unit; ASDAS ID: ASDAS <1.3. ASAS: Assessment of SpondyloArthritis international Society; ASDAS: Ankylosing Spondylitis Disease Activity Score; CII: clinically important improvement; CI: confidence interval; ID: inactive disease; MI: major improvement; PR: partial remission; WPS: Work Productivity Survey.

or non-response; and ASDAS inactive disease (ID). Mean number of days missed or days with reduced productivity each month was calculated by concurrent disease activity/response level and summarized across months to estimate cumulative burden over 204 weeks (wks) using a weighted generalized estimating equations model. An inverse probability-weighted (IPW) model was used to account for predictors of dropout which assigned greater weight to pts who remained in the study vs similar pts who dropped out.

Results: Of 218 CZP-randomized pts, 203, 191 and 142 completed Wks 24, 48 and 204, respectively; at baseline, 157 (72%) were employed outside the home. At Wk 204, 15.8% of pts had ASAS< 20, 16.4% ASAS20–< 40, 67.8% ASAS40 and 37.9% ASAS PR. Up to Wk 204, achievement of the more stringent ASAS PR and ASAS40 was associated with fewer days (4.0 and 8.6, respectively) of paid work absenteeism compared to pts who achieved ASAS< 20 or ASAS20–< 40 (69.2 and 29.4, respectively) (Figure 1A). At Wk 204, 49.0% and 33.1% of pts achieved ASDAS-MI and ASDAS-CII, and 31.8% reached ASDAS ID. ASDAS ID was associated with fewer days of paid work absenteeism over 204 wks (5.0) compared to ASDAS-MI (9.2), ASDAS-CII (21.9) or non-response (57.9) (Figure 1B). Similar findings were observed for paid work presenteeism and household work productivity (Figures 2 and 3), with achievement of more stringent responses associated with fewer days of work presenteeism or days unable to perform housework.

Conclusion: Achievement of optimal thresholds of clinical response in pts with axSpA after 4 years' treatment was associated with reduced burden on paid work and household productivity, indicating the importance of targeting stringent thresholds of disease control to limit the impact of axSpA on pts' daily lives.

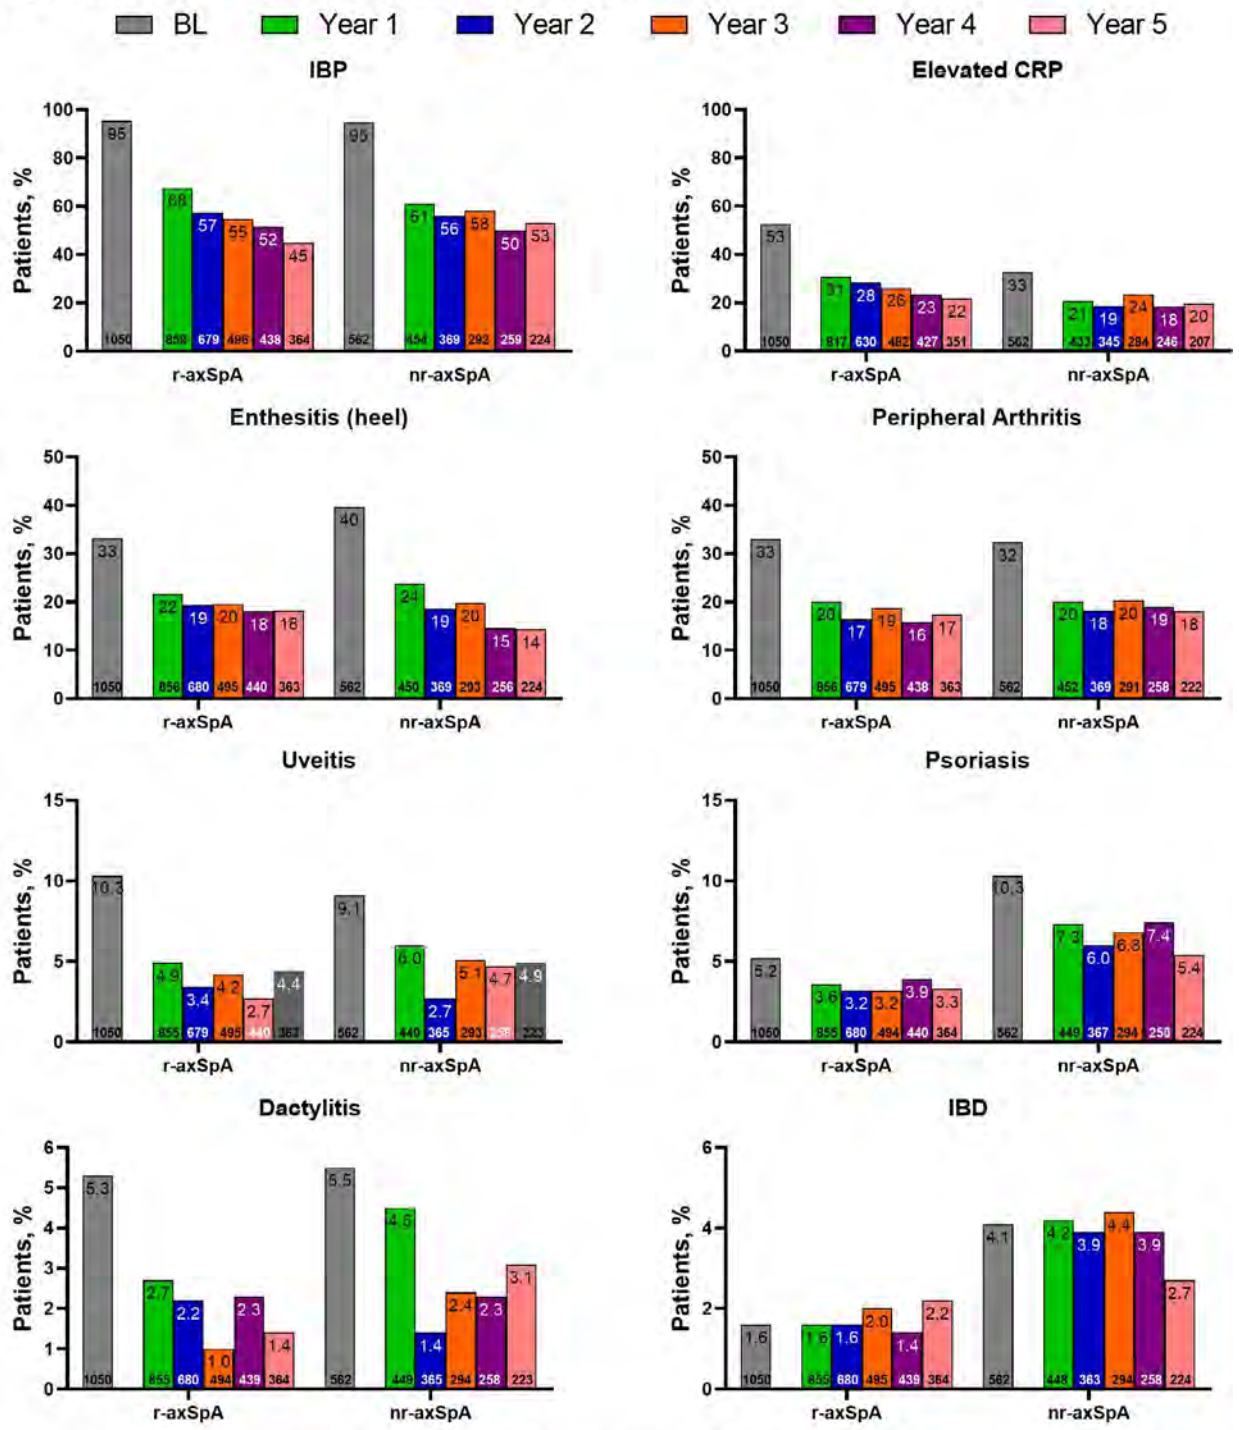
TNF inhibitors	181 (17)	60 (11)
axSpA, axial spondyloarthritis; HLA-B27, human leukocyte antigen B27; IBD, inflammatory bowel disease; nr, non-radiographic; r, radiographic.		

Background/Purpose: Patients (pts) with axial SpA (axSpA) can be classified into radiographic axSpA (r-axSpA) and non-radiographic axSpA (nr-axSpA) based on the presence or absence of radiographic sacroiliitis. The PROOF study evaluated disease course and disease burden of pts with nr-axSpA and r-axSpA over 5 years.

Methods: PROOF was a real-world, prospective, observational study conducted in rheumatology clinical practices in 29 countries in 6 geographic regions. The study enrolled adults with current/past chronic back pain for ≥3 months and onset before 45 years of age. Study visits occurred at baseline (BL) and yearly thereafter. Clinical characteristics and disease burden of axSpA over 5 years were evaluated. Flares of SpA features (mean number over the previous year) were also assessed.

Results: Of 2633 enrolled pts, 2165 (82%) were diagnosed with axSpA and fulfilled the Assessment of SpondyloArthritis international Society (ASAS) classification criteria for axSpA. Among these, 1612 (74%) were classified as having r-axSpA (1050 [65%]) or nr-axSpA (562 [35%]) based on fulfilling ASAS criteria by central reading; 27% and 53%, respectively, had active sacroiliitis on MRI (Table 1). Compared with r-axSpA, higher proportion of nr-axSpA pts had enthesitis (40% vs 33%), psoriasis (10% vs 5%), and inflammatory bowel disease (IBD, 4% vs 2%) at BL. Consistent with previous studies,[1] higher proportions of r-axSpA vs nr-axSpA pts were men (71% vs 48%) and had elevated CRP (53% vs 33%; Table 1). A similar trend was observed over 5 years: higher proportion of pts with r-axSpA had elevated CRP, whereas psoriasis and IBD were more common among pts with nr-axSpA; occurrence of enthesitis was similar between r-axSpA and nr-axSpA on subsequent visits (Figure 1). The use of medications was similar between r-axSpA and nr-axSpA pts at BL (Table 1) and changes in treatment patterns (eg, reduced use of NSAIDs, corticosteroids,

Figure 1. Proportion of Patients With SpA Features Over Time*

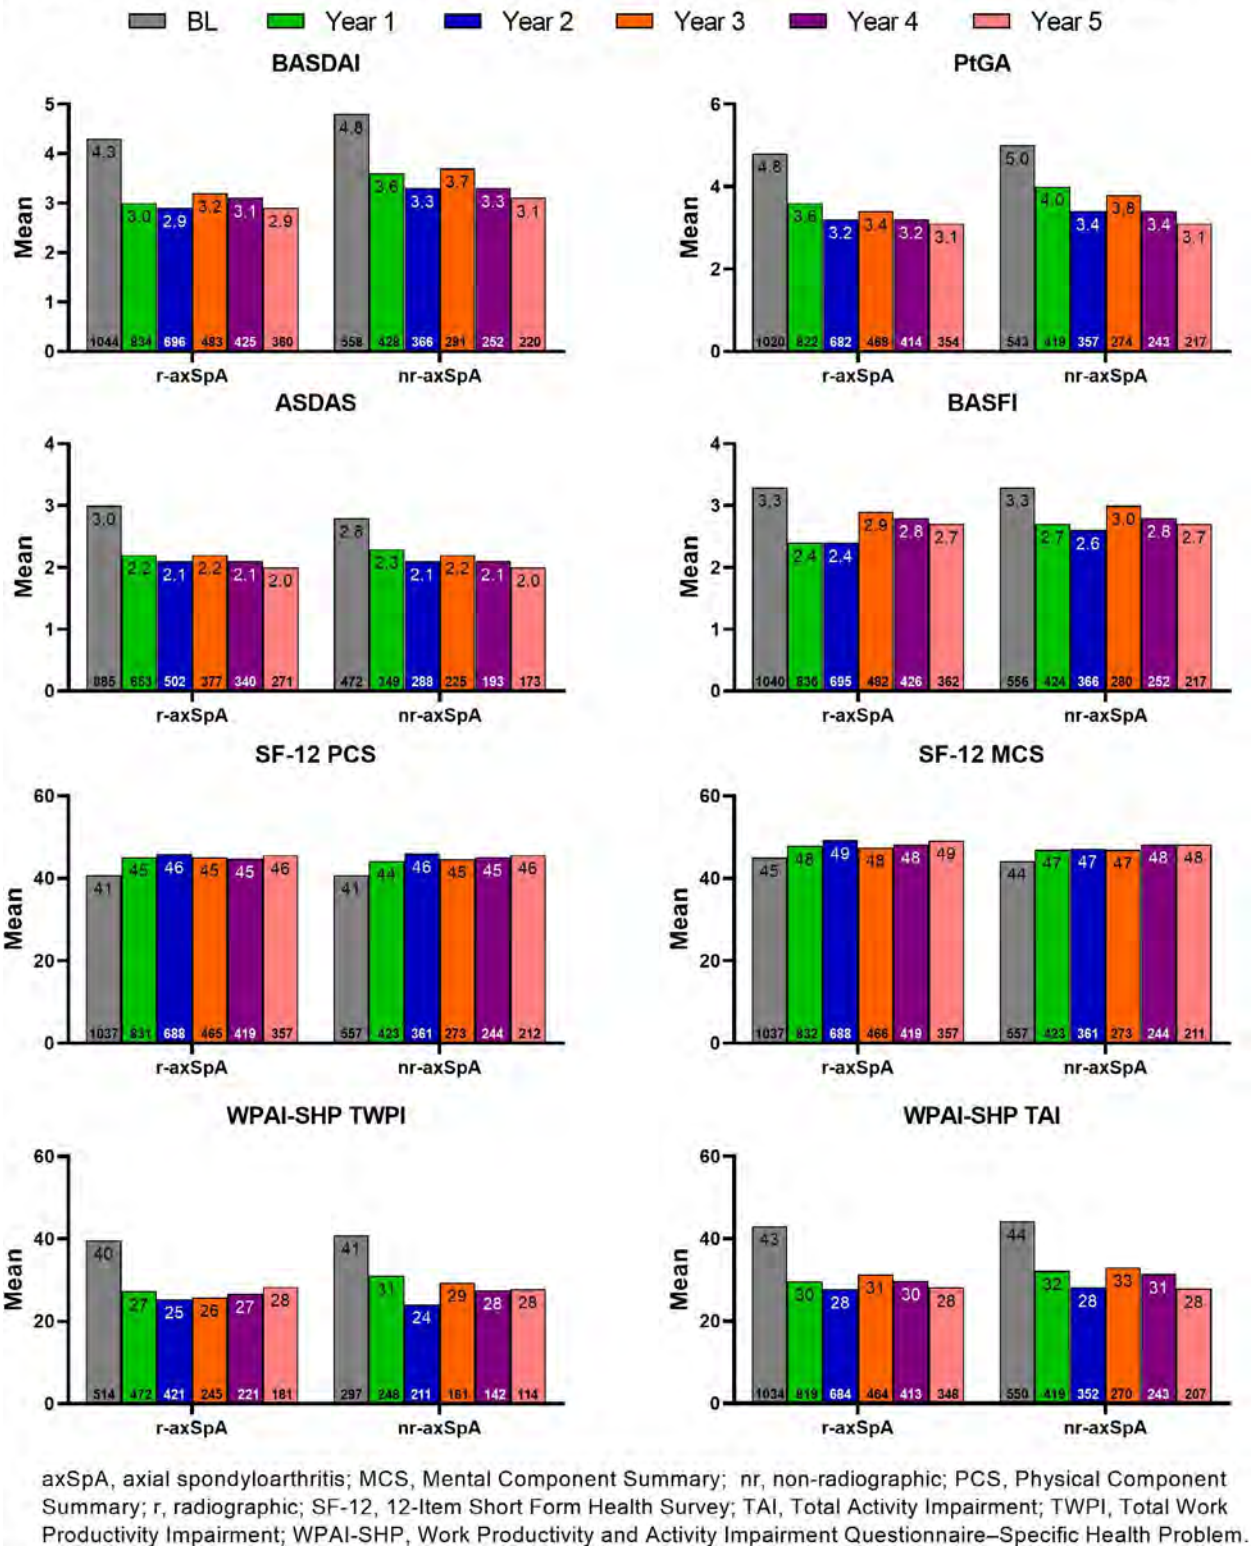


axSpA, axial spondyloarthritis; IBD, inflammatory bowel disease; IBP, inflammatory back pain; nr, non-radiographic; r, radiographic.

*Values at baseline are for proportions of patients with ever presence of the SpA feature, and values at yearly visits are proportions of patients with presence of the SpA feature since last visit.

sulfasalazine, and other DMARDs and increased use of TNF inhibitors) were similar between populations over time. Pts with r-axSpA had a higher mean frequency of inflammatory back pain (IBP) flares per year at years 1 and 2 (22.2 and 17.4, respectively [vs 13.8 and 5.3 with nr-axSpA]) and peripheral arthritis flares per year at years 1 and 2 (8.9 and

Figure 2. Disease Activity, Quality of Life, and Work Impairment Outcomes Over Time



axSpA, axial spondyloarthritis; MCS, Mental Component Summary; nr, non-radiographic; PCS, Physical Component Summary; r, radiographic; SF-12, 12-Item Short Form Health Survey; TAI, Total Activity Impairment; TWPI, Total Work Productivity Impairment; WPAI-SHP, Work Productivity and Activity Impairment Questionnaire–Specific Health Problem.

19.0 [vs 4.2 and 4.5 with nr-axSpA]); however, no differences were observed throughout the rest of the study. Mean number of IBD (0.8–9.0 vs 0.5–0.9) and psoriasis (2.2–4.2 vs 1.1–1.5) flares was higher among pts with nr-axSpA vs r-axSpA, respectively, at each study visit. Disease activity decreased in both r-axSpA and nr-axSpA populations over

time; results on physical function, pt global assessment of disease activity, quality of life, and work impairment were similar between populations through 5 years (Figure 2).

Conclusion: In this study, a higher proportion of pts were diagnosed with r-axSpA at baseline. Patients with r-axSpA and nr-axSpA share a similar clinical presentation, except for certain extra-articular manifestations (eg, psoriasis and IBD), which were more prevalent among nr-axSpA pts. Both groups showed a comparable burden of disease and treatment over 5 years.

SESSION INFORMATION

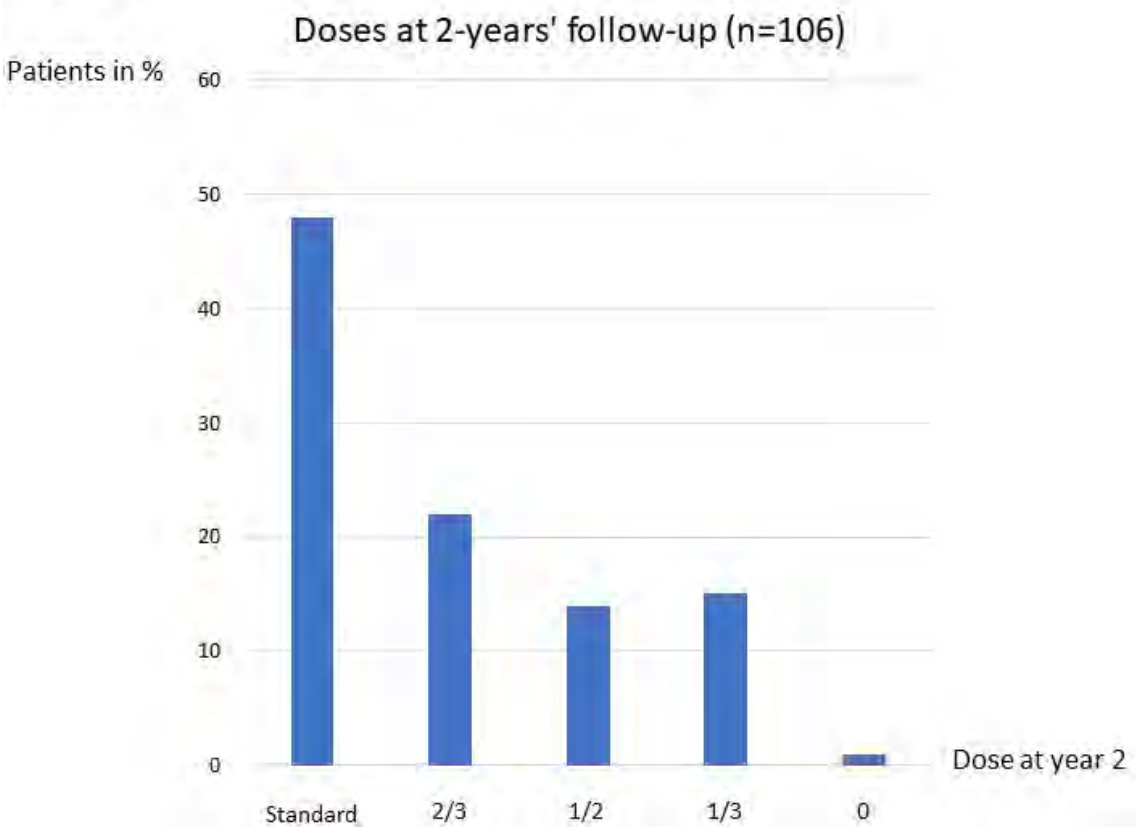
Session Date: Saturday, November 6, 2021

Session Title: Spondyloarthritis Including PsA – Diagnosis, Manifestations, & Outcomes Poster I: Clinical Aspects of Axial Spondyloarthritis (0357–0386)

Session Type: Poster Session A

Session Time: 8:30AM–10:30AM

Figure 1



Background/Purpose: In a 2-year follow-up study of patients with axial spondyloarthritis (axSpA) in clinical remission who tapered Tumor Necrosis Factor inhibitor (TNFi) treatment according to a clinical guideline, we aimed to investigate 1) the proportion who successfully tapered/discontinued therapy, 2) baseline predictors of successful tapering/discontinuation, 3) the proportion regaining clinical remission after flare and 4) the progression on magnetic resonance imaging (MRI) and radiography.

Methods: One-hundred-and-nine patients (78 (72%) on standard, 31 (28%) on reduced dose) in clinical remission with Bath ankylosing spondylitis disease activity index (BASDAI)< 40, physician global score< 40 and no signs of disease activity the previous year tapered TNFi to 2/3 of standard dose at baseline, 1/2 at week 16, 1/3 at week 32 and withdrew at week 48. Patients who experienced clinical, BASDAI or MRI flare stopped tapering and escalated to the previous dose. Prediction analyses were done by multivariable regression.

Results: Of the 106 patients who completed 2-year follow-up, 55 patients (52%) had successfully tapered (Table 1): 23 patients (22%) receiving 2/3, 15 (14%) 1/2, 16 (15%) 1/3 dose and 1 (1%) discontinued (Figure 1). In the entire patient group (all doses patients) lower physician global score (Odds ratio (OR)=0.86 (95% Confidence Interval=0.75-0.98); p=0.017), lower Spondyloarthritis Research Consortium of Canada Sacroiliac Joint Erosion score (OR=0.78 (0.57-0.98); p=0.029) and current smoking (OR=3.28 (1.15-10.57); p=0.026) were independent predictors for successful tapering. In patients at standard dose at baseline (standard dose patients) lower physician score was the only independent predictor of successful tapering (OR=0.79 (0.64-0.93); p=0.003) (Table 2). At 2 years, 97% of patients were in clinical remission. Minimal changes in imaging variables were observed.

Table 1. Baseline characteristics at 2 years, stratified by successful tapering in All Doses Cohort (109 patients) and Standard Dose Cohort (78 patients)

	All Doses Cohort				Standard Dose Cohort			
	All (n=109)	No successful tapering (n=51)	Successful tapering (n=55)	p-value	All (n=78)	No successful tapering (n=45)	Successful tapering (n=31)	p-value

Conclusion: Fifty-two % of patients with axSpA in clinical remission could successfully taper TNFi by following a clinical guideline and maintain remission at 2-years' follow-up, while only 1% discontinued. Baseline physician global score was an independent predictor of successful tapering.

Table 2. Univariate and multivariable logistic regression analyses for prediction of successful tapering at 2-year follow-up in Standard Dose Prediction Cohort (75 patients) and All Doses Prediction Cohort (101 patients)

Values are median (IQR) unless otherwise stated. Mann Whitney U test, chi-square test or Fisher's exact test (as appropriate) was used for analysing between-group differences; bold indicates statistically significant p-values; P<0.05 was considered statistically significant. "-" indicates that p-value could not be calculated.

Predictors were selected by applying backward selection in stacked data. p-values by likelihood ratio tests. Bold indicates p-values<0.1 in univariate analyses. *Results were derived in all imputed datasets (missing values in selected predictors), where model estimates are pooled based on Rubin's rules. Profile likelihood CIs were calculated according to the Pseudo-Variance modification of Rubin's rule (PVR). AUC was estimated based on internal validation by bootstrapping with 100 samples per imputed dataset. **Results were derived in non-imputed data (no missing values in selected predictors). CIs given as profile likelihood CIs. AUC was estimated based on internal validation by bootstrapping with 1000 samples. #The bootstrap 0.632+ estimate was calculated to correct for optimism.

A Cluster Analysis in Patients with Axial Spondyloarthritis Using TNFi Based on Clinical Characteristics

Seulkee Lee, Seonyoung Kang, Yeonghee Eun, Hyungjin Kim, Hoon-Suk Cha, Eun-Mi Koh and Jaejoon Lee, Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, Republic of Korea

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Spondyloarthritis Including PsA – Diagnosis, Manifestations, & Outcomes Poster I: Clinical Aspects of Axial Spondyloarthritis (0357–0386)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Previous studies using cluster analysis technique in axial spondyloarthritis (axSpA) patients have consistently identified distinct groups of patients in terms of their clinical characteristics: those with pure axial symptoms and those with a high frequency of peripheral manifestations. Due to the cross-sectional nature of these studies, however, prognostic information such as drug survival of anti-TNF agents in these group were not provided.

Methods: Clinical characteristics and demographic data of axSpA patients in KOBIO registry were analyzed using hierarchical clustering analysis. After clustering, drug survivals of anti-TNF agents were compared between these groups.

Results: 1,042 patients were included in the study with no missing data. The hierarchical cluster analysis classified patients in two groups; one with predominant isolated axial manifestations (axial group, n=828) and the other with more frequent extra-axial symptoms (extra-axial group, n=214). Almost all extra-axial symptoms (peripheral arthritis, enthesitis, uveitis, and psoriasis) were more frequently observed in extra-axial group than axial group. In addition,

Table 1. Clinical characteristics of divided groups

Group	Axial group (n = 828)	Extra-axial group (n = 214)	*p*-value
Age at starting TNFi (years, %)	38.18 (12.76)	38.85 (14.28)	0.618
Sex (male, %)	651 (78.6)	142 (66.4)	0.001
Late onset (age ≥ 40 years, %)	247 (29.8)	82 (38.3)	0.034
Long disease duration (≥ 2 years, %)	380 (45.9)	46 (21.5)	< 0.001
HLA-B27 positivity (%)	740 (89.4)	189 (88.3)	0.782
Inflammatory back pain (%)	704 (85.0)	183 (85.5)	0.943
Radiographic sacroiliitis (%)	745 (90.0)	189 (88.3)	0.618
Peripheral arthritis (%)	203 (24.5)	185 (86.4)	< 0.001
Enthesitis (%)	68 (8.2)	150 (70.1)	< 0.001
Uveitis (%)	168 (20.3)	54 (25.2)	0.197
Psoriasis (%)	16 (1.9)	11 (5.1)	0.029
IBD (%)	9 (1.1)	4 (1.9)	0.618
Good response to NSAIDs (%)	212 (25.6)	146 (68.2)	< 0.001
csDMARD use (%)	75 (9.1)	32 (15.0)	0.029
NSAID use (%)	714 (86.2)	190 (88.8)	0.486
SJC	0.50 (2.37)	1.21 (1.80)	< 0.001
TJC	0.71 (2.67)	2.32 (4.00)	< 0.001
BASDAI	5.94 (1.92)	6.37 (1.81)	0.005
BASFI	3.42 (2.56)	3.66 (2.56)	0.305
ASDAS-ESR	3.65 (1.00)	4.05 (1.08)	< 0.001
ASDAS-CRP	3.61 (1.00)	3.87 (1.07)	0.003
ESR (mm/h)	35.65 (28.76)	46.46 (33.21)	< 0.001
CRP (mg/dL)	2.11 (2.74)	2.89 (3.60)	0.006

patients with shorter disease duration, late disease onset, and high disease activity were classified in extra-axial group (Table 1). Interestingly, the extra-axial group had lower drug survival probability than the axial group (p=0.001, Figure 1).

Conclusion: Cluster analysis of AS patients using anti-TNF agents classified two distinct groups of patients in terms of their clinical phenotypes and revealed that the patients with prominent extra-axial manifestations had lower drug survival with anti-TNF agents.

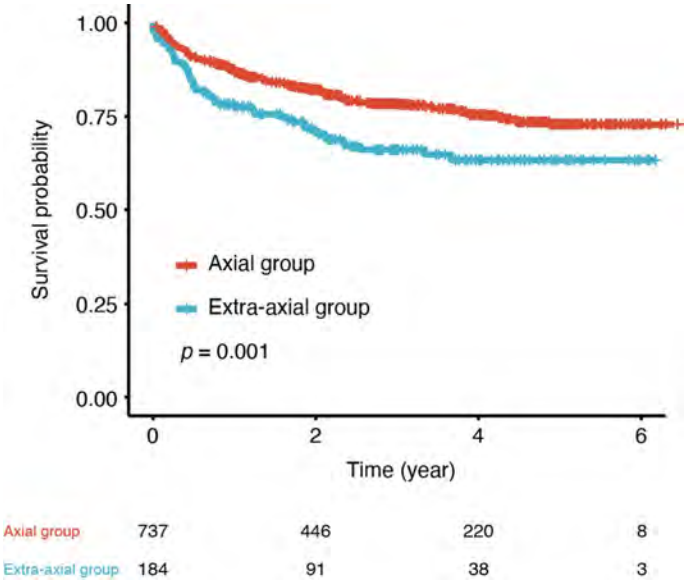

Figure 1. Drug survival probabilities of TNFi compared by Kaplan-Meier survival analysis between axial and extra-axial groups.

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Spondyloarthritis Including PsA – Diagnosis, Manifestations, & Outcomes Poster I: Clinical Aspects of Axial Spondyloarthritis (0357–0386)

Session Type: Poster Session A

Session Time: 8:30AM–10:30AM

Background/Purpose: AxSpA is associated with substantial negative consequences regarding work status and career prospects. The aim is to identify factors associated with barriers to job access among European axSpA patients.

Methods: Data from 2,846 unselected patients participating in EMAS, an online survey (2017-2018) across 13 European countries, were analyzed. Difficulties in finding a job was assessed by the following item: "Do you think it is or it would be difficult for you to find a job because of your Spondylitis/Spondyloarthritis? (Yes/No)". Differences in sociodemographic factors, patient-reported outcomes [BASDAI (0-10), spinal stiffness (3-12), functional limitation (0-54), and mental health status using the 12-item General Health Questionnaire (0-12)], employment, lifestyle habits, and comorbidities were assessed through Mann-Whitney and $\chi 2$ tests. Univariable and multivariable binary logistic regression were used to identify variables possibly explaining difficulties/perceived difficulties finding a job due to axSpA.

Quantitative factors	**B**	**95% CI**	**B**	**95% CI**
BASDAI (0-10)	1.55	**1.46, 1.64**	1.18	**1.09, 1.28**
GHQ-12 (0-12)	1.21	**1.18, 1.25**	1.09	**1.05, 1.14**
Functional Limitation Index (0-54)	1.08	**1.07, 1.09**	1.04	**1.02, 1.06**
Spinal Stiffness (3-12)	1.35	**1.29, 1.41**	1.13	**1.06, 1.21**
Diagnostic delay, years	1.04	**1.02, 1.05**	1.00	0.99, 1.02

Results: Among the 1,823 patients who responded to difficulties/perceived difficulties in finding a job due to axSpA, mean age was 41.4±10.7 years, 62.6% female, 50.7% had a university degree, and 65.6% were married. 56.8% were employed, 8.4% unemployed, and 28.2% on sick leave. 1,357 (74.4%) reported they had or would have difficulties finding a job. Compared to those without difficulties, patients with difficulties were typically separated/divorced (11.4% vs 5.2%, p=0.001), less university educated (45.2% vs 66.5%, p< 0.001), and overweight/obese (50.6% vs

44.8%, p=0.034). Those with difficulties had increased restrictions when driving (37.0% vs 13.3%), or when using public transportation (40.2% vs 10.9%), had previously changed jobs because of axSpA (35.7% vs 21.7%), required adaptions to their car (26.3% vs 17.2%) or shoes (60.1% vs 40.6%), had longer diagnostic delay (7.7 vs 5.8 years), higher disease activity (BASDAI 6.0 vs 4.4), poorer mental health through GHQ-12 (6.0 vs 3.1), greater functional limitation (22.8 vs 9.2), and spinal stiffness (8.2 vs 6.4), as well as higher rates of anxiety (38.8% vs 18.8%), depression (35.2% vs 15.6%), and sleep disorders (47.0% vs 26.6%, all p< 0.001). In the logistic regression analysis, the qualitative factors associated with difficulties finding a job were restrictions using public transportation (OR=2.22), use of customized shoes (OR=1.58), not having university education (OR=0.53) and having had previously changed jobs due to barriers created by axSpA (OR=1.44). The quantitative factors associated were disease activity (OR=1.18), spinal stiffness (OR=1.13), poorer mental health (OR=1.09), and functional limitation (OR=1.04).

Conclusion: Three out of four axSpA patients had, or perceived they would have, difficulties in finding a job. Poor physical and mental health, together with the need for mobility adaptations, lower educational level, having changed job due to axSpA were factors associated with difficulties/perceived difficulties in finding a job. Early diagnosis, effective treatment and greater advocacy in the workplace are needed to enable axSpA patients to search for and remain in employment.

Session Title: Spondyloarthritis Including PsA – Diagnosis, Manifestations, & Outcomes Poster I: Clinical Aspects of Axial Spondyloarthritis (0357–0386)

Session Type: Poster Session A

Session Time: 8:30AM–10:30AM

Background/Purpose: Patient organizations (POs) provide education and support services aimed to improve the quality of life of axSpA patients. This analysis aims to identify factors associated with PO membership among European axSpA patients.

Methods: Data from 2,846 unselected patients participating in EMAS, an online survey (2017-2018) across 13 European countries, were collected. Membership of patient organizations was assessed by the following item: “Are you a member of any Spondylitis Support Group or Association? (Yes/No)”. Differences in sociodemographics, patient-

Table 1. Bivariate analysis between members and non-members of POs (N= 2,846 unless specified)

Biologics (ever). Yes	1.64	**1.38, 1.95**	1.87	**1.50, 2.32**

reported outcomes [BASDAI (0-10), spinal stiffness (3-12), and mental health through GHQ-12 (0-12)], employment, lifestyle habits, comorbidities, and treatments between PO members/non-members were assessed through Mann-Whitney and Pearson's χ^2 tests. Univariable and multivariable binary logistic regression were used to identify variables possibly explaining PO membership.

Results: 1,654 patients were included. Mean age was 43.0 (±12.3) years, 59.6% were female, 46.8% had a university degree, and 66.5% were married. 1,107 patients (38.9%) were members of a PO. Compared to non-members, members were more frequently male (41.5% vs 36.9%, p=0.014), married (73.3% vs 64.5%, p< 0.001), more overweight/obese (55.6% vs 50.0%, p=0.003), physically active (86.4% vs 78.9%, p< 0.001), had relatives affected by axSpA (48.1% vs 33.1%), longer disease duration (21.0 vs 14.8 years, p< 0.001), better mental health (4.7 vs 5.1, p=0.036), longer diagnostic delay (8.6 vs 6.7, p< 0.001), and were more likely to have ever taken biologics (49.1% vs 37.0%, p< 0.001). In the multivariable logistic regression analysis, the variables associated with PO membership were having ever taken biologics (OR= 1.87), being physically active (OR= 1.43), having relatives affected by axSpA (OR= 1.34), and disease duration (OR= 1.03).

Conclusion: PO members were more likely to have advanced disease, as suggested by the disease duration. Greater experience with biologics among PO members could be attributed to higher disease severity but also to having access to lay-level information on treatment options. Notably, members were also more likely to engage in physical activity, a complementary treatment strongly promoted by POs and recommended by ASAS/EULAR. Engaging patients earlier and throughout their disease journey is likely to improve long-term health and quality of life.

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Spondyloarthritis Including PsA – Diagnosis, Manifestations, & Outcomes Poster I: Clinical Aspects of Axial Spondyloarthritis (0357–0386)

Session Type: Poster Session A

Session Time: 8:30AM–10:30AM

Background/Purpose: Research has shown that in patients with axial spondyloarthritis (axSpA), the most common form of spondyloarthritis (SpA) in a family history is axSpA. Moreover, the association between a positive family history of spondyloarthritis (PFH) and HLA-B27 carriership is driven by a PFH of axSpA and possibly acute anterior uveitis (AAU), but not by other forms of SpA. However, this research was limited to mostly Western European patients and it is unknown if this holds true in axSpA patients in other parts of the world. Therefore, we aimed to investigate the impact of geographical region on family history and its association with HLA-B27 carriership in patients with axSpA around the world.

Methods: Data from the Assessment in SpondyloArthritis international Society (ASAS) peripheral involvement in Spondyloarthritis (ASAS-perSpA) study was used. Analyses were restricted to patients with an axSpA diagnosis who had information available on HLA-B27 status and family history. The frequencies of any PFH, as well as a PFH for axSpA, psoriasis, AAU, inflammatory bowel disease (IBD) and reactive arthritis (ReA), were determined per geographical region. Logistic regression models were built to assess the effect of HLA-B27 status on the occurrence of any PFH and occurrence of each disease in a PFH in the total population and also stratified per geographical region.

Results: In total, 2,048 patients were included from 4 regions: Asia (n=545), Europe & North America (n=840), Latin America (n=202), and Middle East & North Africa (n=461). Patients had a median age (IQR) of 40 (31-50) years, 31% were female, and had a disease duration of 11 (5-20) years.

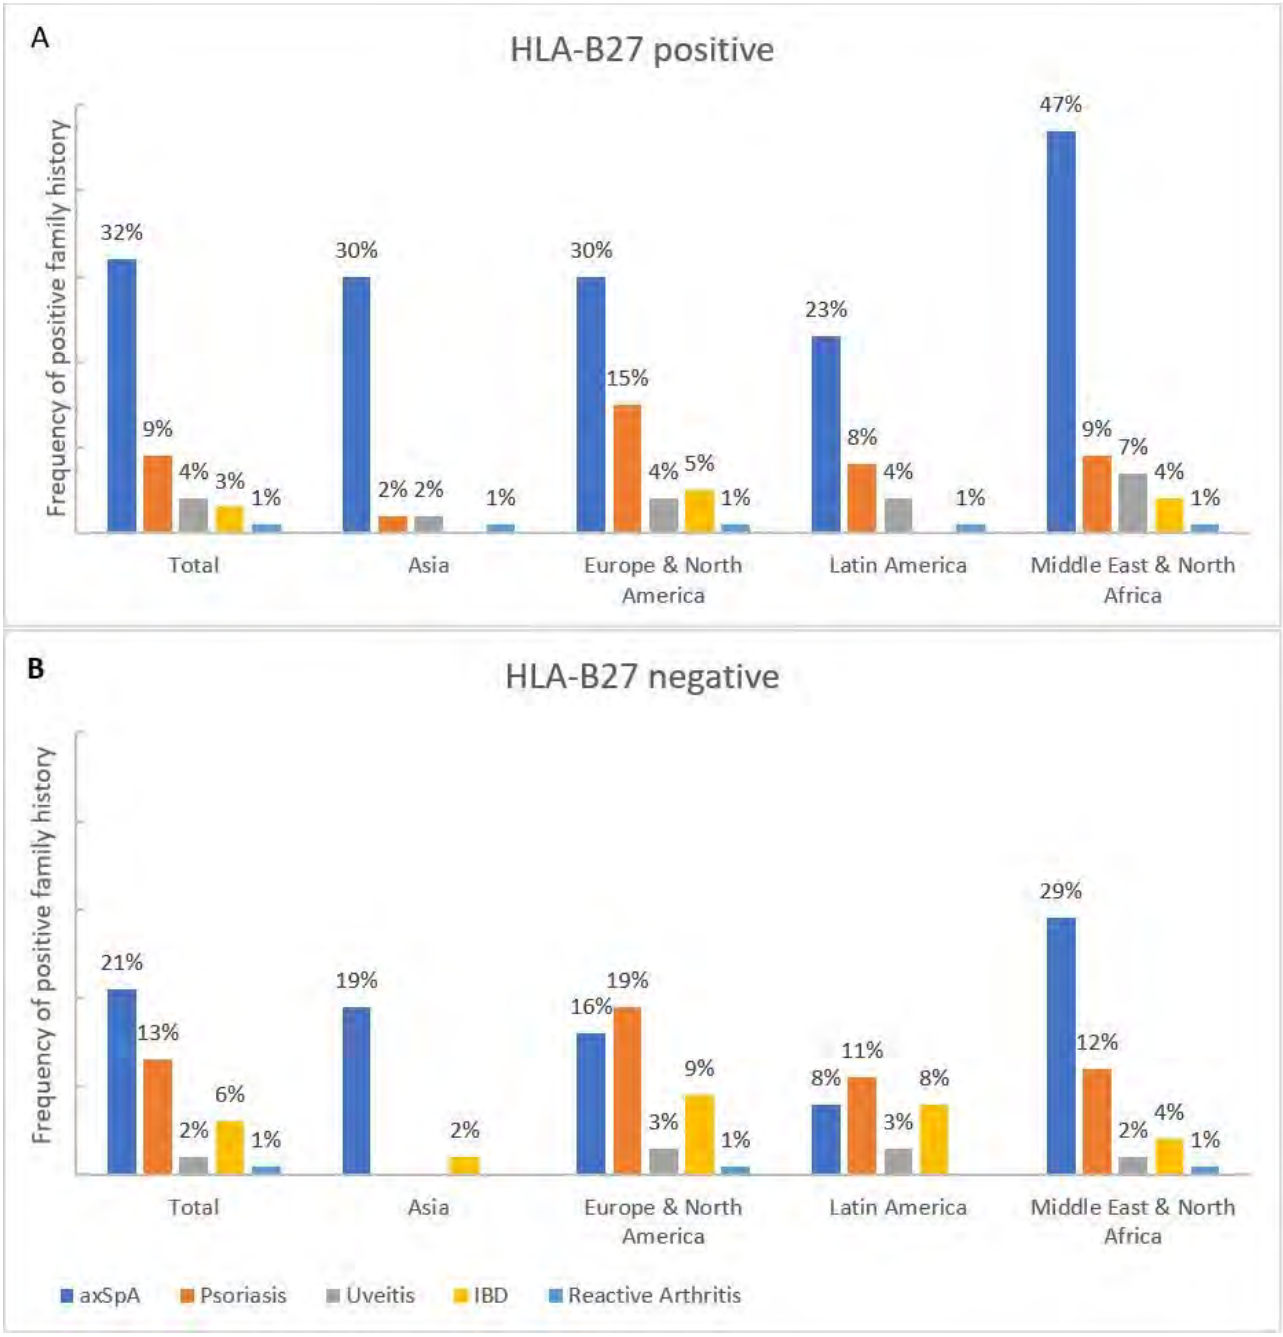

Figure. Frequency of positive family history per disease split per region for HLA-B27 positive patients (A) and HLA-B27 negative patients (B).

A PFH of axSpA was the most common in all geographical regions, regardless of HLA-B27 carriership. A PFH of psoriasis and IBD appeared to be more common in HLA-B27 negative patients, and a PFH of ReA was rare in all patients (Figure).

Univariable logistic regression models showed an association between a PFH and HLA-B27 carriership in the Asian population, but this association does not seem apparent in the other geographical regions (Table). Contrary, a PFH of axSpA was associated with HLA-B27 carriership in all geographical regions except the Middle East & North Africa (Table). An association between HLA-B27 carriership and a PFH of psoriasis was solely present in Middle East & North Africa (OR=0.4, 95% CI 0.2-0.7), and an association with a PFH of IBD was solely present in Europe & North America (OR=0.5, 95% CI 0.3-0.9). No associations were found for HLA-B27 carriership and a PFH of AAU and ReA in any geographical region.

Table Univariable associations between HLA-B27 carriership and a positive family history of axSpA patients in the ASAS-perSpA cohort stratified per geographical region

	HLA-B27+ n=1,609	HLA-B27- n=439	OR (95% CI)	p-value

Middle East & North Africa	141/300	46/161	0.98 (0.69-1.40)	0.917

axSpA, axial spondyloarthritis; **CI,** confidence interval; **HLA-B27,** human leucocyte antigen B27; **OR,** odds ratio

Conclusion: Throughout the world, axSpA was the most common form of SpA in a family history. In all regions except one, a PFH of axSpA was associated with HLA-B27 carriership in axSpA patients. These results suggest that the current expert definition of a PFH of SpA should be revaluated.

Abstract Number: 0369

High Frequency of Complications in Axial Spondyloarthropathy Pregnancies: Emerging Data from the Ankylosing Spondylitis Registry of Ireland

Sinead Maguire[1], Phil Gallagher[2] and Finbar (Barry) O'Shea[1], [1]St James's Hospital, Dublin, Ireland, [2]St Vincent's Hospital, Dublin, Ireland

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Spondyloarthritis Including PsA – Diagnosis, Manifestations, & Outcomes Poster I: Clinical Aspects of Axial Spondyloarthritis (0357–0386)

Session Type: Poster Session A

Session Time: 8:30AM–10:30AM

Background/Purpose: National registries are excellent sources of data to allow analysis of inflammatory arthritis such as axial spondyloarthropathy (axSpA). Our understanding of axSpA has evolved rapidly over time resulting in improved recognition of the disease. Unfortunately, for women with axSpA there is limited data on pregnancy outcomes in this population. To address this issue, data was collected on pregnancy within the Ankylosing Spondylitis Registry of Ireland (ASRI), which is a source of epidemiological data on axSpA in Ireland. The aim of this study is to examine the prevalence of pregnancy and fetal complications in females with axSpA.

Methods: The ASRI records information on baseline demographics, imaging, medications, patient outcomes and comorbidities. To be considered for enrolment patients must have been diagnosed with axSpA by a Rheumatologist and meet the ASAS criteria for axSpA. Informed consent was obtained from all patients by a trained investigator, with ethical approval obtained from local hospital ethics committees. A dedicated section within the ASRI collects data on pregnancy, fertility and breastfeeding. Data on these outcomes was then recorded retrospectively for axSpA females enrolled in the ASRI.

Results: At the time of analysis 220 females were enrolled in the ASRI, representing 24.3% of the total population of the registry. Mean age of females was 43.9 years, with a mean disease duration of 18 years and mean delay to diagnosis 7.86 years. 68.6% (151) had radiographic sacoiliitis, while 49.5% (109) had sacroiliitis on MRI. Mean scores for females in the ASRI were: BASDAI 4.6, BASFI 3.82, BASMI, HAQ 0.6, and ASQoL 7.65.

Data on pregnancy was available in 76 women, with 61 women reporting a total of 210 pregnancies resulting in 166 live births. Of these pregnancies 58.1% (122) were uncomplicated and 41.9% (88) were complicated, with 11.4% (24) of pregnancies encountering multiple complications (figure 1).

The frequency of miscarriage was high affecting 20.5% (43) of pregnancies overall in 37.7% (23) of women with a history of pregnancy. Of the pregnancies resulting in live births, the most common pregnancy complication was caesarean section in 10.8% (18) followed by preterm delivery in 11.4% (15), while the most common fetal complication was NICU admission in 11.4% (19) (figure 2). Only 4 women (5.3%) reported difficult conceiving and need for fertility specialist referral, but none underwent assisted reproductive therapy. Prevalence of breastfeeding was low, reported in 33.7% (56) of live births.

Conclusion: Data from the ASRI indicates a high frequency of pregnancy and fetal complications in women with axSpA. These results represent a preliminary analysis of pregnancy outcomes in axSpA pregnancies collected via a

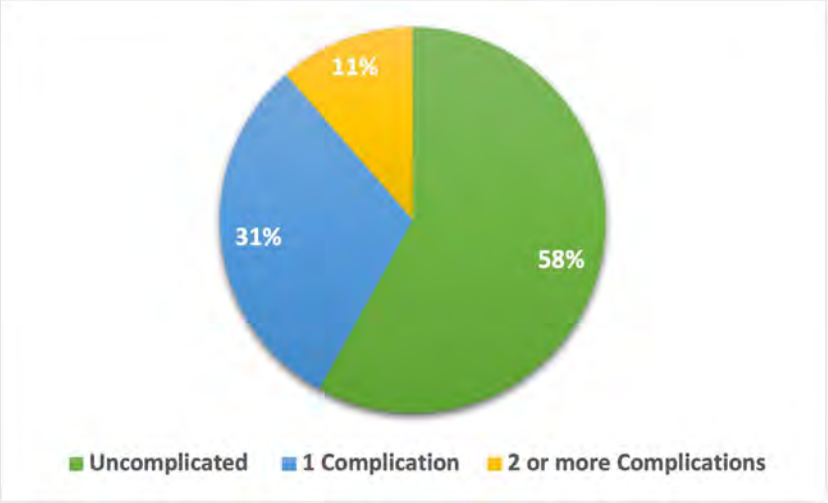

Figure 1. Frequency of Complications per Pregnancy.

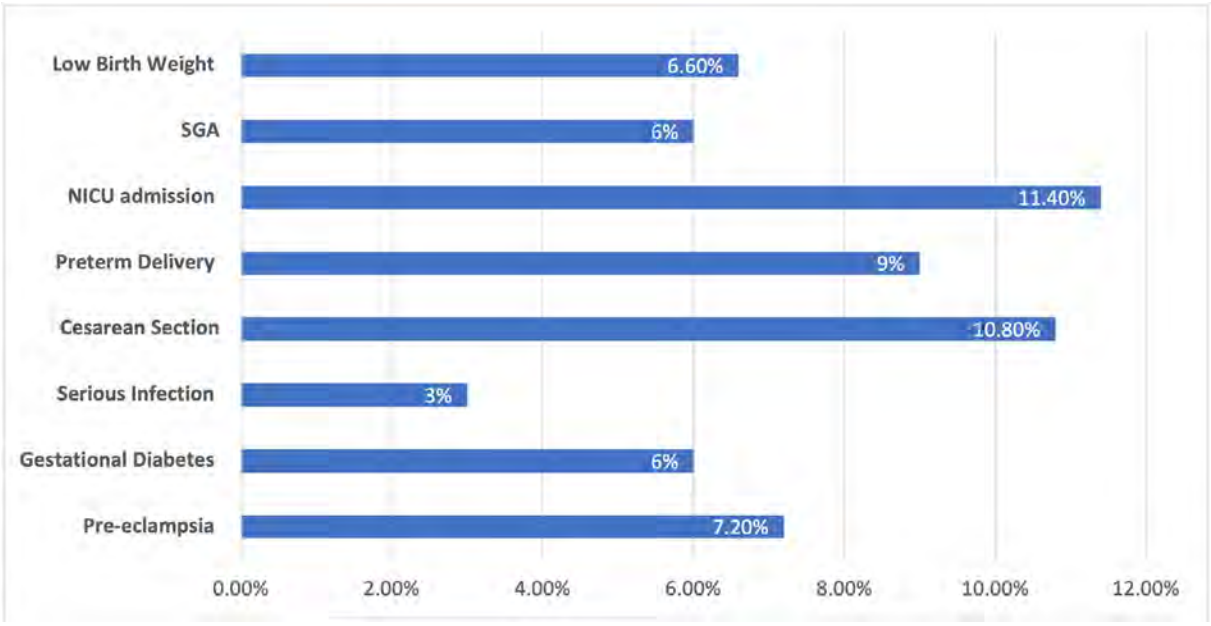

Figure 2. Prevalence of Pregnancy & Fetal Complications in Pregnancies resulting in Live Births.

large national registry. Ongoing data collection will allow comparison to national averages. This provides much needed insight into the impact of axSpA on pregnancy, which can be used to improve monitoring and management of axSpA women during their pregnancies. Furthermore, data on prevalence of breastfeeding can be used to encourage discussion of benefits and safety while on medication of breastfeeding between Rheumatologists and axSpA women.

Awareness and Attitudes Regarding Axial Spondyloarthritis Among Primary Care Providers

Yuliya Afinogenova[1], Swetha Ann Alexander[2], Narinder Maheshwari[3], Sonam Kiwalkar[4] and Abhijeet Danve[5], [1]Yale School of Medicine, Hamden, CT, [2]University of Connecticut, Hartford, CT, [3]UConn Health, West Hartford, CT, [4]The Vancouver Clinic, Portland, OR, [5]Yale University, Rocky Hill, CT

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Spondyloarthritis Including PsA – Diagnosis, Manifestations, & Outcomes Poster I: Clinical Aspects of Axial Spondyloarthritis (0357–0386)

Session Type: Poster Session A

Session Time: 8:30AM–10:30AM

Background/Purpose: There is significant discrepancy between population and diagnostic prevalence of axial spondyloarthritis (axSpA) and ankylosing spondylitis (AS) in the US. Delayed and missed diagnosis of axSpA in clinical practice may result from lack of timely referral by non-rheumatologists. Primary care providers (PCPs) are the main source for referral of back pain patients to rheumatologists in the US. In this study, we aim to assess knowledge, awareness and attitudes about axSpA among PCPs to identify gaps in knowledge and devise strategies for early referral.

Methods: In this ongoing study, we distributed a HIPAA compliant secure electronic survey created through Yale Qualtrics Survey tool to select PCPs within several academic institutions and affiliated practices. Our survey includes questions on demographics, practice setting, practice patterns and knowledge assessment surrounding axSpA.

Results: One hundred and thirty-eight providers completed the survey, with response rate of 40%. Among respondents, 68% were female, 76% MDs and 24% advanced practioners. Practice setting included 21% in academic practice and 46% in multi-specialty group. PCPs at different stages in their careers were surveyed. Twenty two percent saw < 30 patients/week, 55% saw 30-60 patients/week and 22% saw 61-90 patients/week. Ninety six percent were at least somewhat familiar with the term inflammatory back pain (IBP). Fifty eight percent reported that they never or rarely assess for IBP; 40% reported that they are not comfortable with making the diagnosis of IBP. Majority (83%) never or rarely ordered HLA B27, and 65% never or rarely ordered CRP for young patients with chronic back pain. Seventy six percent ordered X-ray lumbar spine at least often, and 54% rarely or never ordered MRI lumbar spine in chronic back pain patients. Seventy two percent rarely or never ordered X-ray sacroiliac joint and 97% rarely or never ordered MRI sacroiliac joint. At least fifty percent reported that they never or rarely asked about peripheral arthritis, psoriasis or inflammatory back pain, and at least 75% reported that they rarely or never asked about uveitis or enthesitis. Fifty percent of the providers reported that they never or rarely asked about family history of spondyloarthritis. Forty six percent were not familiar with the change in nomenclature around the terms axSpA and AS. Forty percent were not comfortable with making diagnosis of AS, and seventy percent were not comfortable with making diagnosis of AxSpA.

Conclusion: Our preliminary results confirm lack of knowledge and awareness regarding IBP and changed nomenclature of axSpA among PCPs. PCPs may not be evaluating chronic back pain patients for axSpA, which can contribute to lack of referral and delay in diagnosis.

tis (FaxSpA) study, we are evaluating the effectiveness of a self-referral strategy where the screening tool is directly distributed to at risk patients using electronic medical record and social media.

Methods: In a prospective single center study, we developed a screening tool (A-tool) that consists of 3 question prescreen and 8 question screening questionnaire (SQ). Patients who pass all questions in prescreen can access the SQ. A-tool is considered positive in case of 3 or more positive responses to SQ. A-tool is distributed online via patient portal (Mychart) to those age 18 to 65 yr with CBP listed on the problem list. A-tool is also distributed via Facebook to those in our geographical area. Patients with positive A-tool are contacted to confirm eligibility and are invited for a visit. Patients with known diagnosis of axSpA, age >65 yr and previous spine surgery are excluded. Patients undergo history and physical, labs (CRP and HLA-B27) and imaging studies (X-ray and MRI of pelvis). Clinician's judgement is considered gold standard for diagnosis of axSpA. DNA and plasma samples are stored for biomarker research. Statistical analysis was done with descriptive statistics, T-test and chi-square tests.

Results: Total 634 patients took the survey through MyChart (52%) or Facebook (48%) from April 2019 to March 2020 (Table 1). Among the responders, 428 (68%) had positive pre-screen and 268 (42%) had positive A-tool. We were unable to reach 90 subjects. Sixty-seven were ineligible after a phone interview (11 had confirmed axSpA, 15 had previous surgery, 18 changed answers to A-tool). Another 38 were unable to come or were no longer interested. As of November 2020, 51 patients came for study visit and 43 completed labs and imaging. Out of 43 patients, 15 (34.9%) were diagnosed with axSpA (6 with AS and 9 with nr-axSpA) (Table 2). There was a trend suggesting that as the number of positive responses on SQ increases, likelihood of axSpA diagnosis was greater.

Conclusion: Our preliminary findings suggest that A-tool based self-referral strategy for early diagnosis of axSpA among patients with CBP is practical and feasible approach. We need larger prospective study to validate our findings and confirm the effectiveness of the A-tool based referral strategy.

Impact of Gender and Age on Ankylosing Spondylitis Patient Profiles at Golimumab Initiation and 12-Month Outcomes

Ariel Masetto[1], Proton Rahman[2], Michelle Teo[3], Pauline Boulos[4], Emmanouil Rampakakis[5], Meagan Rachich[6], Allen Lehman[6], Francois Nantel[7] and Odalis Asin-Milan[6], [1]Universite de Sherbrooke, Sherbrooke, QC, Canada, [2]Department of Medicine, Eastern Health and Memorial University of Newfoundland, St John's, NL, Canada, [3]Penticton Regional Hospital, Penticton, BC, Canada, [4]., Hamilton, ON, Canada, [5]JSS Medical Research, Montréal, QC, Canada, [6]Janssen Inc., Toronto, ON, Canada, [7]., Montréal, QC, Canada

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Spondyloarthritis Including PsA – Diagnosis, Manifestations, & Outcomes Poster I: Clinical Aspects of Axial Spondyloarthritis (0357–0386)

Session Type: Poster Session A

Session Time: 8:30AM–10:30AM

Background/Purpose: Gender and age have been previously identified as independent predictors of response to anti-TNFs. The aim of this analysis was to compare, between genders and age groups, the profile and outcomes of ankylosing spondylitis (AS) patients treated with golimumab during routine Canadian care.

Methods: This is a post-hoc analysis of data from the Biologic Treatment Registry Across Canada (BioTRAC). Patients with AS who initiated treatment with subcutaneous golimumab were included. Patients were grouped into age tertiles (Young: 18.5–39.1 years; Middle: 39.2–51.2; Old: 51.3–90.2) and further stratified by gender. The impact of age and gender on outcomes (ASDAS clinically important improvement [CII; $\Delta \geq 1.1$], major improvement [MI; $\Delta \geq 2.0$], and HAQ< 0.5) and treatment retention were assessed with multivariate logistic and cox regressions, respectively, adjusting for age tertile, gender, HLA-B27 and respective outcome at baseline.

Results: 421 patients were included with a mean (SD) age of 45.7 (13.3) years and disease duration of 6.0 (10.1) years. Across age tertiles, significant differences ($p < 0.05$) were observed at baseline in disease duration, employment status, insurance coverage, previous smoking status, number of previous DMARDs, previous use of NSAIDs or MTX, concomitant use of DMARDs or oral steroids, and BASFI. Gender, RF status, anti-CPP status, family history, current smoking status, previous use of DMARDs or oral steroids, experience with biologics, concomitant NSAIDs or MTX, ASDAS, BASDAI, HAQ, enthesitis, and dactylitis were comparable. Between genders, significant differences were observed in weight, current/previous smoking status, and BASDAI.

Based on multivariate regression, patients in Young age tertile vs. Old were more likely to achieve ASDAS-MI at 12 months (OR [95% CI]: 3.53 [1.00–12.41]) and HAQ< 0.5 at both 6 (2.84 [1.37–5.89]) and 12 (2.63 [1.22–5.70]) months. Achievement of ASDAS-MI at 12 months was also more likely among male patients (4.16 [1.31–13.23]). There was no impact of gender or age tertiles on ASDAS-CII achievement.

With respect to treatment retention, male patients were more likely to stay on golimumab treatment (HR [95%]: 2.32 [1.11-4.76]). However, age tertile was not associated with retention.

Across age tertiles, AE incidence was comparable; however, SAE incidence was substantially higher among older patients. Between genders, AE incidence was lower among males, with no differences in SAE incidence.

Conclusion: Significant variations in baseline characteristics, treatment outcomes, and safety profile exist across age groups and gender.

Self-monitoring of Disease Activity with a Smartphone App Is Feasible in Routine Clinical Management of Patients with Axial Spondyloarthritis – a Proof of Concept Study

Uta Kiltz[1], Robin Kempin[1], Jutta Richter[2], Anna Schlegel[1], Xenofon Baraliakos[1], Styliani Tsiami[1], Bjoern Buehring[1], David Kiefer[3] and Juergen Braun[1], [1]Rheumazentrum Ruhrgebiet Herne, Ruhr-Universität Bochum, Herne, Germany, [2]Rheumatology and Hiller Research Unit, Heinrich-Heine-University Duesseldorf, Medical Faculty, Duesseldorf, Germany, [3]Rheumazentrum Ruhrgebiet Herne, Ruhr-Universität Bochum, Essen, Germany

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Spondyloarthritis Including PsA – Diagnosis, Manifestations, & Outcomes Poster I: Clinical Aspects of Axial Spondyloarthritis (0357–0386)

Session Type: Poster Session A

Session Time: 8:30AM–10:30AM

Background/Purpose: Assessment and monitoring of disease activity and functioning is of major importance for qualified management of patients with axial spondyloarthritis (axSpA). This includes tight control strategies with strict monitoring and adaptation of therapy. Although closer monitoring is superior to routine care, more intensive treatment schedules can often not be realized because of time constraints and shortage of personal resources. Using a health app for the recording of patient reported outcomes (PRO) in clinical routine may facilitate patient monitoring but there is a lack of data on this strategy.

The aim of this study was to investigate the practical use and the adherence to a commercialised health app by axSpA patients with respect to usability, feasibility, and equivalence of data in clinical management.

Table 1. Demographic data of the studied group at baseline and characteristics of app-adherent and non-app-adherent patients Table legend on the bottom: * Values given as mean (SD) otherwise indicated

	Patients (n=69)	adherent (n=20)	non-adherent (n=49)	Significance
Age, years	41.5 (11.3) *	46.1 (10.6)	39.6 (11.2)	**0.040**
Male, n (%)	40 (58%)	12 (60%)	28 (57%)	0.827
Symptom duration, years	16.7 (11.6)	17.8 (12.9)	16.3 (11.2)	0.686
Diagnosis since, years	11.2 (9.8)	12.9 (10.5)	10.5 (9.3)	0.542
University education, n (%)	15 (22%)	4 (20%)	11 (22%)	0.823
Employed, n (%)	49 (71%)	39 (77.6%)	11 (55 %)	0.061
Frequent use of electronic media, n (%)	62 (89.9%)	19 (95%)	43 (87.8%)	0.366
Current use of health apps, n (%)	35 (50.7%)	10 (50%)	25 (51%)	0.939
Biologic DMARD therapy, n (%)	53 (76.8%)	11 (55%)	42 (85.7%)	**0.006**
Patients starting a new therapy at baseline, n (%)	16 (23.2%)	6 (30%)	10 (20.4%)	0.392
ASDAS > 2,1 at Baseline, n (%)	44 (63.8%)	17 (85%)	27 (55.1%)	**0.019**
Elevated CRP at Baseline, n (%)	24 (34.8%)	11 (55%)	13 (26%)	**0.024**

Table 2. Clinical data on face-to-face visits. Table legend on the bottom: * Values given as mean (SD) otherwise indicated. a Due to the COVID-19 pandemic, a part of the visits had to be made by telephone and mail. Thus, for V2 (n=57) and V3 (n=56), CRP and ASDAS values are not available for all patients.

	V1 (n=69)	V2 (n=67)	V3 (n=64)
Pain level (NRS 0-10)	5.0 (2.5) *	4.0 (2.3)	4.3 (2.4)
BASDAI	4.3 (2.0)	3.7 (2.0)	4.1 (2.3)
CRP (mg/dl)	0.7 (1.6)	0.7 (1.9) (n=57)[a]	0.5 (0.8) (n=56)[a]
ASDAS	2.5 (1.0)	2.1 (0.8) (n=57)[a]	2.4 (1.0) (n=56)[a]
NSAID-Score	33.6 (33.4)	37.6 (32.3)	38.4 (31.0)

Methods: Consecutively included patients with a clinical diagnosis of axSpA were asked to submit electronic patient-reported outcomes (ePROs) such as pain and BASDAI scores regularly but at least every 2 weeks over a period of 6 months. All patients were instructed to handle the free of charge AxSpA Live App, a Class I certified medical device, that was available for Android and iOS operating systems. In addition to patient and disease characteristics, information on previous experience with health apps was collected. The first clinical visit was followed by two face-to-face visits, each 3 months apart, in which patients completed BASFI, pain (NRS 0-10), ASDAS, and the Mobile App Rating Scale (MARS) and the System Usability Scale (SUS) to assess the quality and usability of the app.

Results: Out of 103 axSpA patients asked, 69 agreed to use the AxSpA Live App (67%) on a regular basis. Five patients did not have a smartphone, one was unable to download the app for technical reasons, and 28 had other personal reasons (Tables 1 and 2). Among the participating patients 62 reported to use electronic media frequently (89.9%), and they had previously used health apps (mean number of apps used 1.0 ± 1.3). The majority (64 (92.8%))

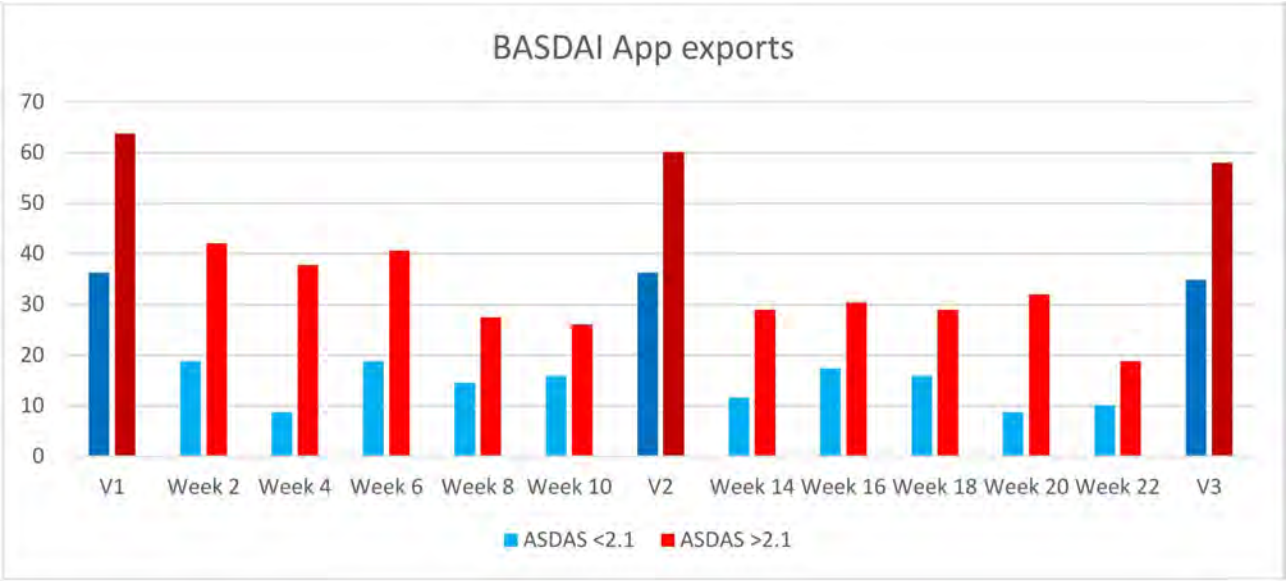

Figure 1. Number of patients with export of electronic BASDAI scores (light colour) and BASDAI scores at face-to-face visit (dark colour) stratified by disease activity.

of patients completed 6 months (92.8%). Patients' adherence for app transmissions every 2 weeks was low, with 29% and 28.6% after 3 and 6 months, respectively. Significant predictors for a good adherence were high disease activity as assessed by ASDAS (P = 0.019) and older age (P = 0.04). There were no systematic differences between BASDAI scores documented on paper or by app (ICC 0.99 (95%CI 0.98 – 0.99). The quality and usability of the app was rated with a mean MARS and SUS scores of 3.6 and 71.2, respectively, which corresponds to a good to acceptable rating.

Conclusion: The majority of patients with axSpA was able to use the AxSpA Live App but adherence over 6 months was poor. Poor adherence rate can possibly be explained by the high number of required transfers. High disease activity and older age had a positive influence on the frequency of reporting. Our data suggest that the use of apps should focus on more severely affected patients. Interventions with use of a digital application seems feasible for axSpA patients with high disease activity who are in need for intensified treatment.

Session Title: Spondyloarthritis Including PsA – Diagnosis, Manifestations, & Outcomes Poster I: Clinical Aspects of Axial Spondyloarthritis (0357–0386)

Session Type: Poster Session A

Session Time: 8:30AM–10:30AM

Table 1. Disease activity categories by ASDAS-qCRP vs. ASDASCRP

		ASDAS-qCRP (n = 251)			
		Inactive Disease (< 1.3)	Low Disease Activity (1.3 - < 2.1)	High Disease Activity (2.1 - 3.5)	Very high Disease Activity (> 3.5)
ASDAS-CRP	Inactive Disease (< 1.3)	56 (22.3%)	2 (0.8%)		
	Low Disease Activity (1.3 - < 2.1)		62 (24.7%)	7 (2.8%)	
	High Disease Activity (2.1 - 3.5)			97 (38.6%)	
	Very high Disease Activity (> 3.5)				27 (10.8%)

The fields highlighted in red indicate that disease activity categories do not match.
ASDAS = Ankylosing Spondylitis Disease Activity Score, CRP = C-reactive protein, qCRP = quick quantitative CRP

Background/Purpose: According to international recommendations, the Ankylosing Spondylitis Disease Activity Score (ASDAS) is the preferred score for assessing disease activity in axial spondyloarthritis (axSpA) [1]. However, routine determination of C-reactive protein (CRP) to calculate ASDAS values takes hours to days. This limits the use of ASDAS in clinical routine and clinical trials and hinders the implementation of treat-to-target approaches in axSpA.

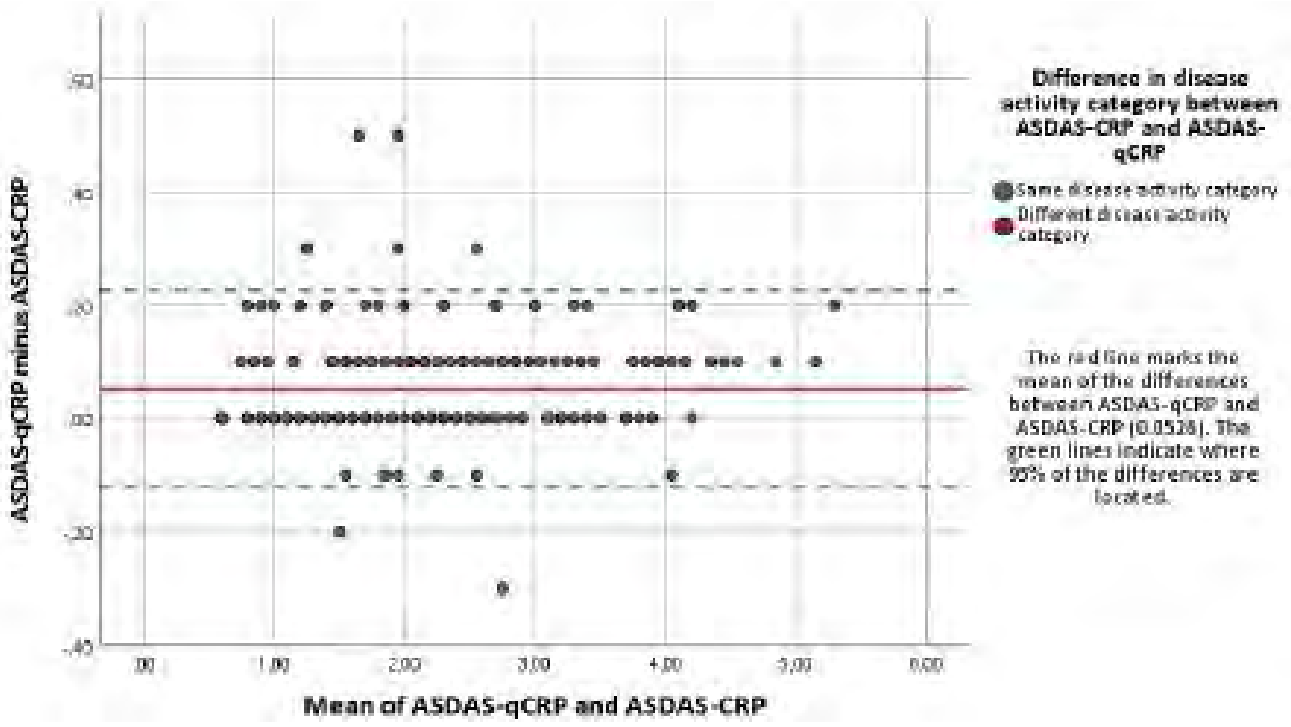

Figure 1. Bland-Altman plot for ASDAS-qCRP and ASDAS-CRP.

Whereas quick quantitative CRP (qCRP) tests allow CRP assessment within a few minutes. In a pilot project the performance of qCRP-based ASDAS assessment (ASDAS-qCRP) was already investigated in a single center study of 50 newly diagnosed, bDMARD-naïve axSpA patients with promising results [2]. Therefore, the objective of our study was to validate the ASDAS-qCRP in a prospective, multicenter study of axSpA patients in a typical axSpA cohort with an appropriate sample size.

Methods: The study was conducted in five centers in Germany. Consecutive adult (≥ 18 years) axSpA patients were included. In addition to a rheumatological assessment, including patient reported outcomes (PROs), routine CRP and erythrocyte sedimentation rate (ESR) were measured in the local labs. Additionally, a qCRP testing with the „QuikRead go instrument“ (Aidian Oy, Finland) was performed at the study center (measurement range 0.5 - 200 mg/l for hematocrit concentrations of 40 – 45%). Statistical analysis included descriptive statistics, cross tabulation and weighted Cohen´s kappa comparing disease activity categories, Bland-Altman plots and intraclass correlation coefficient (ICC) for ASDAS-CRP and ASDAS-qCRP.

Results: In this study 251 axSpA patients were included between January and September 2020 (mean age: 38.4 years; mean disease duration: 6.2 years, 159 patients (63.3%) were male, 211 (84.1%) HLA-B27 positive and 195 (77.7%) were classified as radiographic axSpA). 143 patients (57.0%) were treated with bDMARDs. CRP and qCRP showed mean values of 2.12 and 2.17 mg/l, respectively. With the ASDAS-qCRP, 242 patients (96.4%) were assigned to the same disease activity category as compared to the ASDAS based on the conventional lab CRP measurement (Table 1). Weighted Cohen´s kappa was 0.966 (95%CI: 0.943; 0.988). ICC for ASDAS-CRP- and ASDAS-qCRP-values was 0.997 (95%CI: 0.994; 0.999). The agreement of ASDAS-qCRP and ASDAS-CRP is shown in a Bland-Altman plot (Figure 1).

Conclusion: The ASDAS-qCRP and ASDAS-CRP showed an almost perfect agreement on the assignment to disease activity categories (96%) with the important advantage of time. With ASDAS-qCRP, rheumatologists could base their clinical decision-making on a disease activity measurement by using a composite score immediately. ASDAS-qCRP, therefore, can be integrated in clinical routine and clinical trials in the future and may facilitate implementation of the treat-to-target concept in axial SpA.

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Spondyloarthritis Including PsA – Diagnosis, Manifestations, & Outcomes Poster I: Clinical Aspects of Axial Spondyloarthritis (0357–0386)

Session Type: Poster Session A

Session Time: 8:30AM–10:30AM

Background/Purpose: One of the most important prerequisites for a timely diagnosis of axial spondyloarthritis (axSpA) is the early referral of a patient with back pain to a rheumatologist. In the past years a number of referral strategies has been proposed, most of them in line with the ASAS referral recommendations [1] and with a similar performance – about 30-40% of the referred patients can be diagnosed with axSpA after examination by a rheumatologist. In addition to physicianbased strategies, an online self-referral (OSR) strategy has been recently proposed and evaluated about 20% of the patients being diagnosed with axSpA after rheumatologic evaluation [2]. The objective of the current analysis was to investigate the role of age and symptom duration for the optimization of a physician-based and an OSR strategy for axSpA.

Methods: In the OptiRef study, patients with chronic back pain and suspicion of axSpA either referred by primary care physicians /orthopedists using the Berlin referral tool (=physician based) or based on a referral recommendation of an OSR were evaluated by rheumatologists in a specialized center [2]. All patients underwent a structured examination including imaging that resulted into the final diagnosis of axSpA or no axSpA. The relationship between age, symptom duration and the likelihood of axSpA diagnosis was evaluated in this analysis.

Table 1. Patient characteristics: Total

	Total N=360	Berlin tool N=180	Self-referral N=180	p-value
Diagnosis of axial SpA, n (%)	106 (29.4%)	71 (39.4%)	35 (19.4%)	<0.0001
Age, years, mean (SD)	36.9 (10.4)	37.2 (11.5)	36.6 (9.2)	>0.99
Male sex, n (%)	177 (49.2%)	100 (55.6%)	77 (42.8%)	0.02
Back pain duration, years, mean (SD)	7.9 (7.6)	6.5 (6.9)	9.2 (8.1)	<0.0001
HLA-B27 positive, n (%)	141 (40.9%)	104 (59.8%)	37 (21.6%)	<0.0001
CRP elevation, n (%)	52 (14.8%)	34 (19.4%)	18 (10.2%)	0.02
Inflammatory back pain, n (%)	204 (56.7%)	103 (57.2%)	101 (56.1%)	0.92

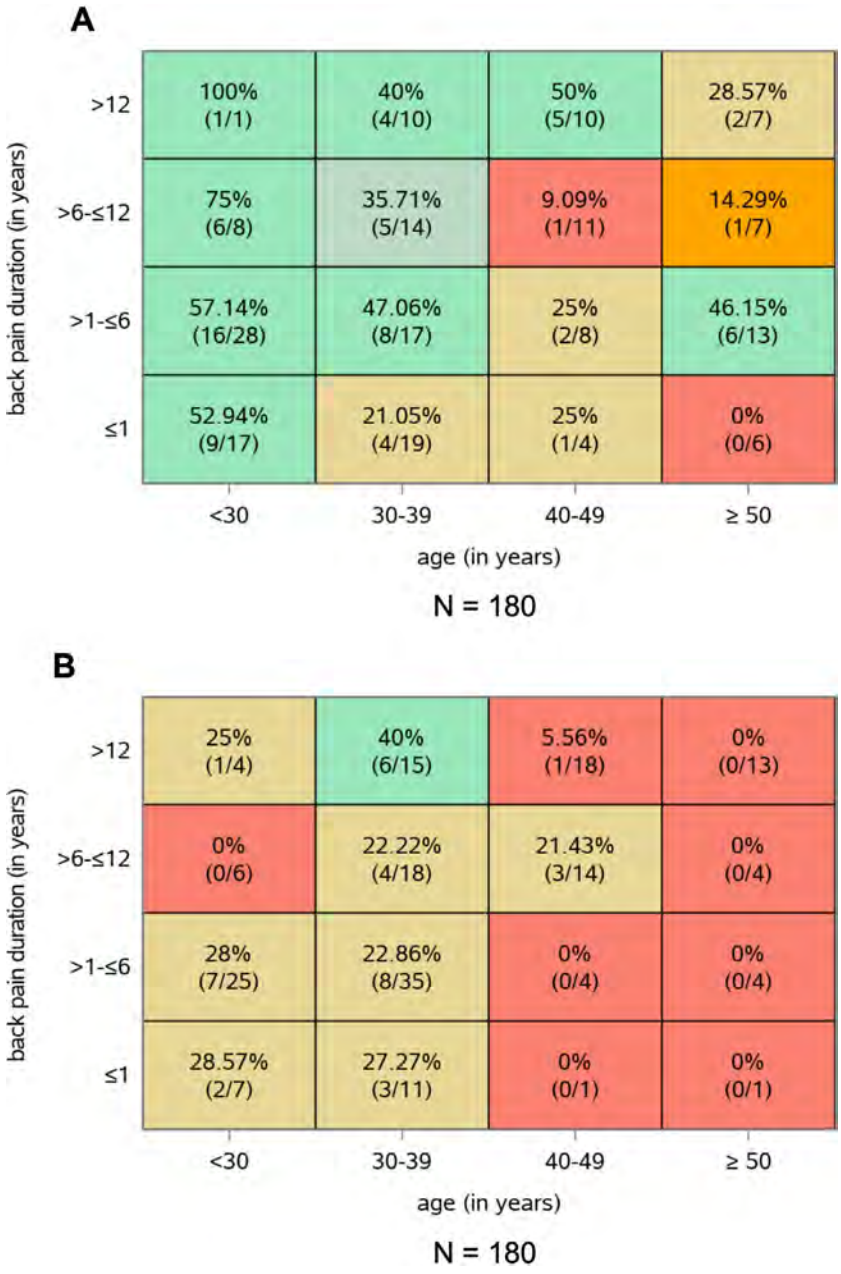

Figure 1. Heatmaps depicting the proportions of patients diagnosed with axSpA in relation to age and symptom duration in the physician-based (A) and OSR (B) groups.

Results: A total of 360 patients (180 presented via the OSR and 180 referred by the physician based referral strategy) were included in this analysis. Patient's characteristics are shown in Table 1. A total of 71 patients (39.4%) in the physician-based group and 35 patients (19.4%) in the OSR group were finally diagnosed with axSpA. The heatmaps depicting the relationship between the proportions of patients diagnosed with axSpA and age plus symptom duration (Figure 1) showed a clear decline of the axSpA probability with increasing age. In the physician-referred group, however, axSpA was diagnosed even in patients who were above 50 years at the timepoint of the examination, while there were only few patients with axSpA in the self-referred group aged 40-49 years, and none in the age group ≥50 years. Interestingly, there was no clear relationship between symptom duration and probability of the diagnosis: axSpA was diagnosed in a substantial proportion of patients even with a long history of back pain (>12 years) in both subgroups.

Conclusion: The probability of axSpA is high in patients suffering from back pain and aged < 40 years with a substantial decline thereafter. Therefore, a referral strategy based on self-evaluation of symptoms should be more focused on a younger patient population, while physician-based strategies do not require such a restriction.

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Spondyloarthritis Including PsA – Diagnosis, Manifestations, & Outcomes Poster I: Clinical Aspects of Axial Spondyloarthritis (0357–0386)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Current knowledge on the health status of patients (pts.) with axial spondyloarthritis (axSpA) mainly focusses on physical function and disease activity. Using a generic measure for physical- or mental health (SF36), a hierarchical relationship between disease activity, spinal damage, spinal mobility, physical function and overall health has been demonstrated in pts. with radiographic axSpA (r-axSpA) [1]. Disease-specific global functioning and health can be assessed in pts. with axSpA using the ASAS Health Index (ASAS HI), which encompasses physical function, as well as aspects of emotional and social functioning and aspects of activity and participation. To build a structural model that visualizes interrelationships of different patient- and disease characteristics with global functioning and health in pts. with early axSpA.

Table 1. Patient and disease characteristics at month 72

	N = 398
Gender (male), N (%)	181 (45%)
Age (years)	40.7 (8.7)
Symptom duration (years)	7.5 (0.9)
BMI (kg/m²)	25.0 (4.6)
ASDAS	2.0 (1.0)
BASFI (0–10)	2.3 (2.1)
BASMI (0–10)	2.5 (1.0)
mSASSS (0-72)	1.0 (3.6)
ASAS HI (0-17)	5.7 (3.9)
good global functioning: ASAS HI ≤5, N (%)	201 (51%)
moderate global functioning: 5< ASAS HI <12, N (%)	160 (40%)
bad global functioning: ASAS HI ≥12, N (%)	37 (9%)
Comorbidity count	1.4 (0.7)

Methods: Data of pts. with axSpA from the DESIR cohort was analyzed, which included information on socio-demographics (age, BMI), disease activity (ASDAS), physical function (BASFI), spinal mobility (BASMI), structural damage (mSASSS), disease-specific global functioning (ASAS HI), and comorbidity count. Information on patient- and disease characteristics was retrieved from the visit performed 72 months after inclusion, which was the first time point of ASAS HI collection. A Bayesian network (BN) was used to obtain insight of the underlying structural model. BNs are probabilistic graphical models consisting of "nodes" (representing specific variables) joined by "edges" (lines

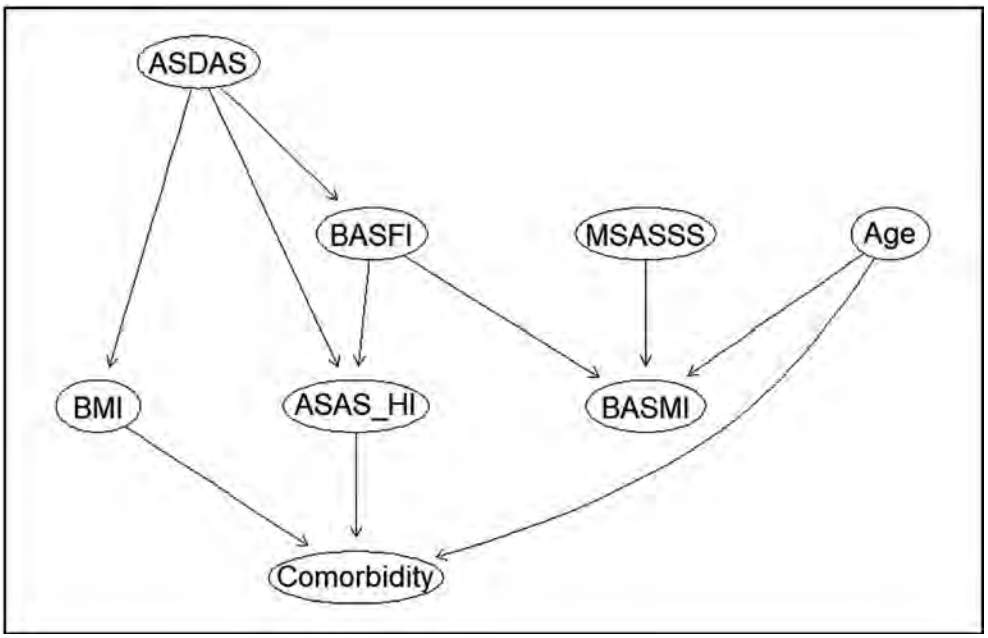

Figure 1. Structural model on interrelationships of different patient- and disease characteristics with global functioning and health (ASAS HI) in patients with early axSpA.

representing directions of effects). They are capable of capturing complex relationships between variables and allow the incorporation of existing (prior) knowledge from previous studies.

Results: The DESIR cohort contained data from 582 pts. at month 72, of whom 398 had data for ASAS HI. Descriptive information of these pts. is shown in Table 1. The mean ASAS HI was 5.7 (range: 0 - 16). Applying existing cut-offs for ASAS HI, 51% had 'good' global functioning (ASAS HI ≥5), 40% had 'moderate' global functioning (5< ASAS HI < 12) and 9% had 'bad' global functioning (ASAS HI ≥12). The structural model that was constructed from combining data and prior expert knowledge is visualized in Figure 1. It suggests that ASDAS and BASFI have a direct effect on ASAS HI as well that ASDAS has an indirect effect via BASFI. Moreover, the model suggests that BMI is also determined by ASDAS, and that BASFI determines BASMI, which is in turn also influenced by age and mSASSS. In addition, it suggests a direct effect of age, BMI and ASAS HI on the comorbidity count. The model denies a relationship between BASMI or mSASSS and ASAS HI.

Conclusion: The BN-analysis approach, that combines prior knowledge and measured data, serves to better understand the construct of global functioning and health in pts. with early axSpA. Our model shows that global functioning (ASAS-HI) is determined both by patient reported physical function (BASFI) and by disease activity (ASDAS), which confirms the hierarchical model once proposed by Machado et al. The observed directional relationship between ASAS HI and comorbidity count is counterintuitive and requires further investigation.

Abstract Number: 0377

The Prevalence of Inflammatory Back Pain and HLA-B27 in a Large Population-Based Cohort in the Netherlands

Stan Kieskamp, Suzanne Arends, Elisabeth Brouwer, Hendrika Bootsma, Ilja Nolte and Anneke Spoorenberg, University Medical Center Groningen, Groningen, Netherlands

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Spondyloarthritis Including PsA – Diagnosis, Manifestations, & Outcomes Poster I: Clinical Aspects of Axial Spondyloarthritis (0357–0386)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Chronic low back pain (CLBP; back pain >3 months) with onset at age < 45 and inflammatory back pain (IBP) are regarded as early presenting and key features of axial spondyloarthritis (axSpA), and HLA-B27 as its most important genetic risk factor. Despite increasing familiarity with non-radiographic axSpA and the advent of Magnetic Resonance Imaging in demonstrating sacroiliitis, the long delay in axSpA diagnosis has not improved. The objective of this study was to explore the prevalence of CLBP and IBP in combination with HLA-B27 in the general population.

Methods: Participants of the Lifelines cohort, a large population-based cohort of the northern region of the Netherlands, filled out a questionnaire on chronic low back pain and IBP. Chronic low back pain was defined as an affirmative answer to the question 'Did you suffer from low back pain for ≥3 months?'. IBP was questioned based on the validated European Spondyloarthropathy Study Group (ESSG) IBP criteria and was confirmed if at least 4 out of the following 5 criteria were present: (a) onset before age 45, (b) insidious onset, (c) improvement with exercise, (d) associated with morning stiffness, (e) at least 3 months duration. Participants reporting to have been diagnosed with axSpA were identified using variations of the search terms "Bechterew", "spondyloarthritis" and "ankylosing spondylitis". The Illumina global screening array (GSA) beadchip-24 v1.0 was used to genotype genome-wide SNPs in a subset of Lifelines participants. HLA-B haplotypes were imputed using neighboring SNPs with HIBAG, which is an R-package, using published parameter estimates. The predicted HLA-B haplotype was considered valid if the posterior probability was >80%.

Results: 94.277 participants answered the question about CLBP, of which 22.804 (24.2%) participants reported CLBP. CLBP before the age of 45 could be identified in 17.481 (18.6%) participants. Of the 93.665 participants with ESSG questionnaire data available, 13.514 (14.4%) fulfilled the IBP criteria. HLA-B haplotype was determined with high prediction accuracy (posterior probability >0.8) in 29.399 Lifelines participants of which 2.279 (7.8%) were HLA-B27+. In the group of HLA-B27+ participants with CLBP (n=373; 23.2%), 238 (14.8%) also fulfilled the ESSG IBP criteria. Only 11 (4.6%) of these participants reported a previous axSpA diagnosis.

Conclusion: In this large Dutch population-based cohort, 7.8% were HLA-B27 positive, similar to earlier studies. Considerable underdiagnosis of axSpA may be expected since only a minor proportion of HLA-B27+ participants with CLBP fulfilling the ESSG IBP criteria reported to have been diagnosed with axSpA.

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Spondyloarthritis Including PsA – Diagnosis, Manifestations, & Outcomes Poster I: Clinical Aspects of Axial Spondyloarthritis (0357–0386)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: The co-existence rate of Familial Mediterranean Fever (FMF) and axial spondyloarthritis (axSpA) in adults is ranging from 0.5% to 7.5%. Clinical implications of this association in the course of FMF is still a research question. Compared to axSpA, FMF+axSpA tends to have more peripheral joint involvement and start at an earlier age, but may have similar prevalence of psoriasis and inflammatory bowel disease. The aim of this study was to compare of demographic, clinic and radiological features of patients with axSpA and FMF+axSpA.

Methods: A total of 9630 FMF patients was detected according to the ICD-10 code (E85.0) of FMF in Hacettepe University Hospital database. 241 of these patients also had axSpA according to the ICD-10 code (M45). FMF diagnosis was confirmed by Tel- Hashomer criteria. AxSpA diagnosis was confirmed by either presence of sacroiliitis on sacroiliac radiography according to the Modified New York (mNY) Criteria or presence of active sacroiliitis according to ASAS criteria on magnetic resonance imaging. 136 patients were confirmed according to these criterias as having FMF+axSpA. 107 of these patients were previously treated with any biological drugs. As a control group, 102 consequent axSpA patients without FMF previously treated with any biological drugs recorded on the TReasure database, age and sex matched with other group and followed up at our center were included in the analysis. Demographic, clinic and radiological features of those patients in both groups were compared. $p < 0.05$ was considered as statistically significant, correction for multiple comparisons was not performed.

Results: 107 patients (54 (50.5%) female) were included in FMF+axSpA group and 102 patients (50 (49.0%) female) were included in axSpA group. Age at axSpA symptom onset and diagnosis were earlier, disease durations were longer in FMF+axSpA group in our study cohort (Table 1). Frequency of axSpA signs and symptoms were comparable. Amyloidosis was more prevalent in FMF+axSpA group (7.5% vs. 1%, p=0.04). 94 (87.9%) patients in FMF+axSpA group and 98 (96.1%) patients in axSpA group had radiographic sacroiliitis according to mNY criteria (p=0.03). Lumbar mSASSS score was higher and lumbar syndesmophyte frequency were higher in FMF+axSpA group. Severe spinal involvement (BASRI≥4 and total ankylosis) is similar in both groups. Radiologically documented moderate to severe hip disease and total hip replacement were more prevalent in FMF+axSpA group (respectively; 23.4% vs. 4.7%, p< 0.001; 11.2% vs. 2.8%, p=0.016).

Conclusion: Co-existence of FMF and axSpA significantly brought the age of axSpA onset earlier. Radiographic characteristics in FMF+axSpA were found to point a more advanced disease, however a possible bias related to high disease duration of FMF+axSpA. As expected, rate of amyloidosis and hip involvement were higher in FMF+axSpA group.

Table 1. Comparison of demographic, clinic and radiological features of two groups

Demographic, Clinic and Radiological Features	FMF+axSpA (n=107)	axSpA (n=102)	p value
Age [year, median (25-75)]	38 (32-48)	39 (32-48)	0.98

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Spondyloarthritis Including PsA – Diagnosis, Manifestations, & Outcomes Poster I: Clinical Aspects of Axial Spondyloarthritis (0357–0386)

Session Type: Poster Session A

Session Time: 8:30AM–10:30AM

Background/Purpose: Chronic widespread pain (CWP) is common in axial spondyloarthritis (axSpA). For ankylosing spondylitis (AS) and non-radiographic axSpA (nr-axSpA) patients, no differences were found in pain measures, including algometry-assessed pain sensitivity (1), while comparisons versus controls and regarding sex were not reported. The current study aimed to assess differences in pain sensitivity in patients and controls, women and men, and between patients with and without CWP, using different CWP definitions.

Methods: We studied 172 patients with AS/radiographic axSpA and 84 patients with nr-axSpA (modified New York/ASAS criteria) from a well-characterized cohort (2), and 44 controls, frequency-matched for age and sex. All subjects were assessed for pain sensitivity (pain threshold, pain tolerance and temporal summation of pain) by computerized cuff pressure algometry (3), and reported pain intensity, duration, and distribution. The participants were categorized by a mannequin (18 pain sites) (4) into CWP, chronic regional pain or no chronic pain according to the CWP assessment of the 1990 fibromyalgia criteria (CWP1990) and with the novel 2019 CWP criteria (CWP2019) mannequin adopted to 15 pain sites by excluding the chest and adding knees to upper legs (5). Comparisons between patients and controls, women and men, and pain groups defined by CWP1990 and CWP2019 using Student's t-test/Chi-square test, as appropriate.

Results: Characteristics for patients and controls are presented in the Table. Comparisons between patients and controls showed no differences in pain sensitivity measures except a trend ($p=0.056$) towards lower pain threshold for axSpA patients. The patients reported significantly higher pain intensity and more painful sites than controls (≤ 0.001).

Women with axSpA, reported lower pain threshold and tolerance, higher pain intensity, and more painful sites than men (all $p \leq 0.01$). More women also reported CWP than men (CWP1990; 52% vs. 29%/CWP2019; 31% vs. 15%) (Figure 1), but with no difference in pain sensitivity for men and women who reported CWP, irrespective of CWP definition.

A larger group of the axSpA patients reported CWP according to CWP1990 than controls (40% vs. 5%) while 22% of the axSpA patients and none of the controls reported CWP according to CWP2019 (Figure 1). Patients with CWP2019

Table; Characteristics of the study population

Mean (S.D.) if not otherwise stated. Missing data, n (%): Symptom duration 1 (0.4%); ASDAS-CRP 10 (4%); BASDAI 11 (4%), BASFI 13 (5%); BASMI 2 (0.8%); NRS Global 6 (2%); NRS Fatigue 6 (2%); NRS pain 6 (2%); Painsites 3 (1%); Paingroup 1990 3 (1%). Paingroup 2019 3 (1%); LegPDT 50 (17%); Leg PTT 50 (17%); TSI 55 (18%). Patients on anticoagulant therapy did not perform the algometry pain sensitivity assessment. AxSpA, axial spondyloarthritis; ASDAS-CRP, ankylosing spondylitis disease activity score using CRP; BASDAI, Bath ankylosing spondylitis disease activity index; BASFI, Bath ankylosing spondylitis functional index; BASMI, Bath ankylosing spondylitis metrology index; EQ-5D, EuroQol 5-Dimensions (British preference set); NRS, Numeric rating scale; Paingroup 1, no chronic pain; Paingroup 2, chronic regional pain; Paingroup 3, chronic widespread pain; CWP, Chronic widespread pain; PDT, pain threshold; PTT, pain tolerance; TSI, temporal summation index; csDMARD, conventional synthetic disease-modifying anti-rheumatic drug; bDMARD biologic disease-modifying anti-rheumatic drug; tsDMARD, targeted synthetic disease-modifying anti-rheumatic drug.

had lower pain threshold and tolerance, while patients with CWP1990 only had lower pain tolerance than patients without chronic pain (Figure 2). For temporal summation no differences between any of the groups were found.

Conclusion: Chronic widespread pain is more common in axSpA patients than controls and in women compared to men, irrespective of CWP definition. Despite this, men and women with axSpA and concomitant CWP express similar levels of pain sensitivity. The CWP2019 definition identified a smaller group of patients with high pain sensitivity than CWP1990. CWP2019 may therefore be more accurate in identifying patients with more severe chronic pain.

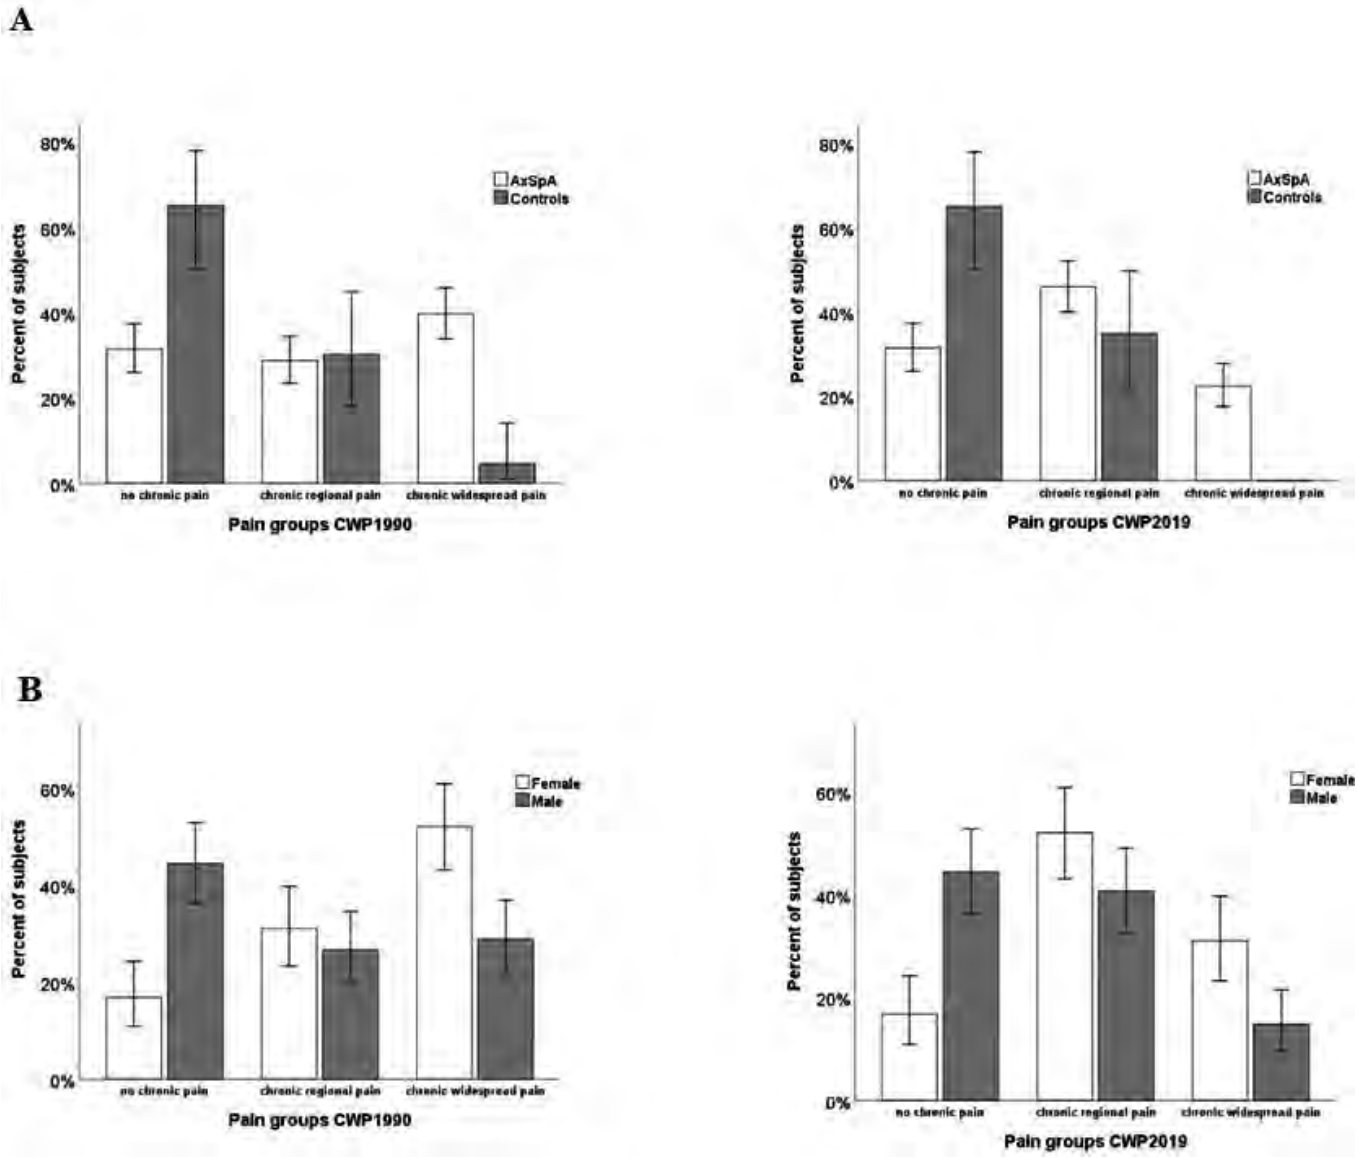

Figure 1. Bar charts showing the distribution in pain groups according to CWP1990 and CWP2019 for A) axSpA patients (AS/radiographic and nr-axSpA combined) and controls, and B) for men and women with axSpA. Error bars with 95% CI (all p≤0.001).

SL=Sick Leave; [1]Censored due to unemployment/ retirement/ housework; [2]Censored due to work disability.

Background/Purpose: Sick leave (SL) represents an often poorly studied adverse work outcome especially in early axSpA, with speculation around the potential role of clinical and socioeconomic (SE) factors.

Methods: Patients with a clinical diagnosis of axSpA from the DESIR cohort with work-related data and up to five-year follow-up were studied. Incidence, time to first SL and potential baseline and time-varying predictors were analysed, with a focus on socioeconomic variables (age, gender, ethnicity, education, job-type, marital and parental status). Univariable analyses, followed by collinearity and interaction tests, guided subsequent multivariable time-varying Cox survival model building.

Results: In total, 704 axSpA patients were included (mean (SD) age 33.8 (8.6); 46% male). At baseline, 80% of patients were employed; of these, 5.7% reported being on SL. The distribution of first and recurrent SL episodes over time is shown in Figure 1. The incidence of SL amongst those at risk during the study-period (n=620, 88%) was 0.05 (95% CI 0.03-0.06) per 1000 days of follow-up. Mean (SD) time to first SL was 806 (595) days (range:175-2021 days). In multivariable models, male gender (HR 0.41 (95%CI 0.20-0.86)) and higher education (HR 0.48 (95%CI 0.24-0.95)) were associated with lower hazard of SL, while higher disease activity (HR 1.49 (95%CI 1.04-2.13)), older age, smoking and use of TNFi were associated with higher hazard of SL.

Conclusion: In this early axSpA cohort of young, working-age individuals, male gender and higher education were independently associated with a lower hazard of SL, whereas older age and higher disease activity were associated with higher hazard of SL. The findings suggest a role of socioeconomic factors in adverse work outcomes, alongside active disease.

How Do Clinical and Socioeconomic Factors Impact on Work Disability in Early Axial Spondyloarthritis? Five-year Data from the DESIR Cohort

Elena Nikiphorou[1], Annelies Boonen[2], Bruno Fautrel[3], Pascal Richette[4], Robert Landewé[5], Désirée van der Heijde[6] and Sofia Ramiro[1], [1]Leiden University Medical Center, Leiden, Netherlands, [2]Department of Internal Medicine, Division of Rheumatology, Maastricht University Medical Centre+ (MUMC+), Maastricht, Limburg, Netherlands, [3]Pitié Salpêtrière Hospital, APHP, Sorbonne Université, Paris, France, [4]Lariboisiere Hospital, Paris, France, [5]Amsterdam Rheumatology & Clinical Immunology Center, Amsterdam, Netherlands; Zuyderland MC, Heerlen, Netherlands, [6]Department of Rheumatology, Leiden University Medical Center, Meerssen, Netherlands

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Spondyloarthritis Including PsA – Diagnosis, Manifestations, & Outcomes Poster I: Clinical Aspects of Axial Spondyloarthritis (0357–0386)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: There remains substantial unmet need to study work disability (WD) in early axSpA. Previous studies suggest that treatment interventions alone do not improve work outcomes and that socioeconomic (SE) as well as clinical factors may play an important role.

Methods: Patients from the DESIR cohort with a clinical diagnosis of axSpA were studied over 5 years. Time to WD and potential baseline and time-varying predictors were explored, with a focus on socioeconomic (including ethnicity, education, job-type, marital/parental status) and clinical (including disease activity, function, mobility) factors. Univariable analyses, collinearity, and interaction tests guided subsequent multivariable time-varying Cox survival analyses.

Results: From 704 patients eligible for this study, the estimated incidence of WD amongst those identified at-risk (n=663, 94%) and across the five-years of DESIR, was 0.05 (95% CI 0.03-0.06) per 1000 days. Significant differences in baseline socioeconomic factors, including lower educational status and clinical measures, including worse disease activity, were seen in patients developing WD over follow-up, compared to those who never did. In the main multivariable model, educational status was no longer predictive of WD, whereas the Ankylosing Spondylitis (AS) disease activity score (ASDAS) and the Bath AS functional index (BASFI) were significantly and independently associated with a higher hazard of WD (HR[95%CI] 1.79[1.27-2.54] and 1.42[1.22-1.65], respectively).

Conclusion: WD was an infrequent event in this early axSpA cohort. Nevertheless, clinical factors were amongst the strongest predictors of WD, over socioeconomic factors, with worse disease activity and function independently associated with a higher hazard of WD. Disease severity remains a strong predictor of adverse work outcome even in early disease, despite substantial advances in therapeutic strategies in axSpA.

Session Date: Saturday, November 6, 2021

Session Title: Spondyloarthritis Including PsA – Diagnosis, Manifestations, & Outcomes Poster I: Clinical Aspects of Axial Spondyloarthritis (0357–0386)

Session Type: Poster Session A

Session Time: 8:30AM–10:30AM

Background/Purpose: Esperanza was a multicenter national health program developed to facilitate an early diagnosis of patients with Spondyloarthritis (SpA) in Spain. The main objective of this study is to compare the clinical evolution of patients with axial SpA (axSpA) and peripheral SpA (pSpA) included in this program.

Methods: Patients from the Esperanza cohort fulfilling ASAS criteria for axSpA or pSpA and completed the 6-year follow-up were included. Patients were classified a cording to the predominant symptom. In case of having axSpA and pSpA, they were classified as axSpA. Clinical features, disease activity and treatment aspects at baseline and 6-year visit were evaluated.

Results: Six-year follow-up data from 178 (83.5%) fulfilling ASAS criteria at the final visit were available: 133 (74.7%) for axSpA and 45 for pSpA (25.3%). 118 (66.3%) were males (50.6% with axSpA and 62.2%, pSpA, p=0.4). Patients with axSpA had more frequently positive HLA-B27 (90.5%) vs. (9.5%), p< 0.001. Follow-up clinical features are shown in table 1. At the final visit, both axSpA and pSpA presented an improvement in clinical symptoms, disease activity (CRP, BASDAI, BASDAS and VAS-pt) and quality of life (ASQoL). A worsening of mobility (BASMI) was observed in both groups. The prevalence of uveitis, psoriasis and inflammatory bowel disease (IBD) at baseline was 10.7%, 18% and 5.6%, respectively. At the 6-year visit, the cumulative prevalence (CP) was 14% for uveitis (16.5% in axSpA and 6.7% in pSpA), 22.5% for psoriasis (12.8% in axSpA and 51.1% in pSpA) and 7.9% for IBD (5.3% in axSpA and 15.6% in pSpA). Most of the patients were prescribed NSAIDS at baseline and more patients maintained this treatment at the 6-year visit in axSpA compared with pSpA (96.9% vs 87.5%, p=0.02). At the final visit, a higher percentage with pSpA received csDMARDs in comparison with axSpA (81% vs. 35.7%, p< 0.001). Sixty (44.4%) patients received biologic therapy at the final visit and no differences were observed in their prescription: 43% in axSpA and 48.6% in pSpA(p=0.6).

	Baseline visit			Six-year visit

BASDAI (0-10), mean ± SD	4 ± 2.2	4.2 ±2.4	0.59	2.4 ± 2.1	2.3 ± 2.1	0.67	<0.001	0.001
BASFI (0-10), mean ± SD	2.4 ± 2.2	2.4 ± 2.4	0.94	2.1 ± 2.2	1.6 ± 1.9	0.2	0.17	0.289
BASDAS, mean ± SD	2.3 ± 1.1	2.5 ± 1.3	0.264	1.6 ± 1.4	1.6 ± 0.9	0.690	<0.001	0.001
BASMI, mean ± SD	1.4 ± 1.3	1.2 ± 0.9	0.43	1.9 ± 1	1.6 ± 0.7	0.19	<0.001	0.002
VAS (0-10) physician, mean ± SD	3.1 ± 2.4	2.9 ± 2.4	0.61	1.8 ± 1.8	1.8 ± 1.6	0.92	<0.001	0.04
VAS (0-10) patient, mean ± SD	4.1 ± 2.7	4.8 ± 3	0.23	2.8 ± 2.3	2.4 ± 2.2	0.32	<0.001	0.03
ASQoL, mean ± SD	5.9 ± 4.7	6.4 ± 5.6	0.6	2.9 ± 3.8	3.9 ± 4.9	0.38	<0.001	0.006

Conclusion: The early diagnosis of recent-onset SpA achieves a significant improvement in clinical features, disease activity and quality of life in patients with axSpA and pSpA after 6 years of follow-up. Although previous publications revealed a low radiographic progression in this cohort[1], the worsening of BASMI must aware clinicians of possible evolutive structural damage.

Differences Between Male vs. Female Presenting with Back Pain in an Integrated Delivery System

Aniket Kawatkar[1], Esther Yi[2], Erika Estrada[1], Jose Pio[1], Cecilia Portugal[1], David Yi[1] and Steve Lee[3], [1]Kaiser Permanente Southern California, Pasadena, CA, [2]Novartis Pharmaceuticals Corporation, Weehawken, NJ, [3]Southern California Permanente Medical Group, Fontana, CA

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Spondyloarthritis Including PsA – Diagnosis, Manifestations, & Outcomes Poster I: Clinical Aspects of Axial Spondyloarthritis (0357–0386)

Session Type: Poster Session A

Session Time: 8:30AM–10:30AM

Background/Purpose: Back pain exerts significant economic burden and in its inflammatory form is the main clinical symptom of axial spondylarthritis. We evaluated differences in patient history between males and females presenting with back pain. We also evaluated the association between sex and axial spondylarthritis (axSpA).

Methods: A retrospective study was conducted in adult (age 21 & up) members belonging to Kaiser Permanente Southern California health plan. Between 01/2009-12/2013, we included patients who presented with either a diagnosis or chief compliant of back pain during a face-to-face encounter with a provider. Patients were followed until 12/2020 to see if they subsequently developed axSpA. We evaluated differences between male and female patient's history (in the 3 years prior to back-pain diagnosis) of: pain medication use (non-steroidal anti-inflammatory drugs (NSAIDs), opioid drugs, non-opioid drugs, corticosteroids, biologic and synthetic disease-modifying antirheumatic drugs (DMARDs)); imaging tests (X-ray, computed tomography, magnetic resonance imaging, ultrasound etc.); and laboratory tests for inflammation (erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP)). Differences between sex in patient history were evaluated by multivariable logistic regression model adjusting for socio-demographic factors (age, race, ethnicity, insurance type, education, and income), modifiable risk factors (smoking status and obesity) and prevalence of Elixhauser comorbidity conditions. A proportional hazards model adjusting for socio-demographic factors, modifiable risk factors and comorbid conditions was used to evaluate the association between sex and axSpA. Loss to follow-up due to death or health plan disenrollment was right censored in the proportional hazards model.

Results: The sample (N= 107,598) was predominantly made up of females (52%). The majority (36%) age category was 21-45 years, while the majority (45%) of patients had 2 or more Elixhauser comorbidity conditions. Female sex was associated with significantly (all $P< 0.001$) higher odds of history of pain medication use [NSAIDs (odds ratio (OR) 1.40 (95% CI 1.36-1.44)), opioids (OR 1.25 (1.22-1.29)), non-opioids (OR 1.49 (1.38-1.60)), corticosteroids (OR 1.11 (1.07-1.15)) and synthetic DMARDs (OR 1.65 (1.48-1.83))]. Female sex was also associated with nearly 4-fold higher odds of history of imaging test orders (OR 3.81 (3.68-3.93)) and 38% higher odds of history of inflammation detection laboratory test orders (OR 1.38 (1.34-1.42)). Lastly, female sex was associated with 36% higher hazard of future axSpA diagnosis (hazard ratio 1.36 (1.20 -1.54))).

Conclusion: In this retrospective study, female sex was found to be disproportionately associated with higher odds of pain medication use, history of imaging tests and laboratory tests for inflammation, observed prior to back pain. We also observed higher hazard of future axSpA diagnosis in females presenting with back pain. More studies are needed to better understand the natural history of back pain and if it predominantly relates to non-radiographic axSpA in females.

A Tough Cell: The Argument for a Biomarker of Clinical and Imaging Outcomes in Spondyloarthritis: The Neutrophil Lymphocyte Ratio and the Platelet Lymphocyte Ratio

Rouhin Sen[1], Emmeline Kim[2], Elizabeth Cheng[3], Kavya Ganuthula[4], Meika Fang[5], Gail Kerr[6], Jessica Walsh[7], Elizabeth Chang[8], Siba Raychaudhuri[9], Andreas Reimold[10] and Liron Caplan[11], [1]University of Colorado School of Medicine/Rocky Mountain Regional Veterans Affairs Medical Center (VAMC), Denver, CO, [2]University of Colorado School of Medicine, Aurora, CO, [3]Rocky Mountain Regional VAMC, Aurora, CO, [4]Rocky Mountain Regional VAMC/University of Colorado School of Medicine, Aurora, CO, [5]David Geffen School of Medicine at UCLA/West Los Angeles Veterans Affairs Medical Center (VAMC), Los Angeles, CA, [6]Washington D.C., Veterans Affairs Medical Center (VAMC)/Georgetown and Howard Universities, Washington, DC, [7]Salt Lake City Veteran Affairs Medical Center (VAMC)/University of Utah Hospital, Salt Lake City, UT, [8]Phoenix Veterans Affairs Medical Center (VAMC), Phoenix, AZ, [9]Sacramento Veterans Affairs Medical Center (VAMC)/University of California-Davis Health, Davis, CA, [10]University of Texas – Southwestern Medical Center/Dallas Veterans Affairs Medical Center (VAMC), Dallas, TX, [11]Rocky Mountain Regional Veterans Affairs Medical Center (VAMC)/University of Colorado School of Medicine, Aurora, CO

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Spondyloarthritis Including PsA – Diagnosis, Manifestations, & Outcomes Poster I: Clinical Aspects of Axial Spondyloarthritis (0357–0386)

Session Type: Poster Session A

Session Time: 8:30AM–10:30AM

Background/Purpose: Biomarkers of disease activity/severity and imaging outcomes in axial spondyloarthritis (axSpA) remain a challenge. The most common relevant biomarker is the C-Reactive Protein (CRP), but it is elevated in only 60% of clinically active axSpA patients and demonstrates low specificity. Several epidemiologic studies have identified the neutrophil lymphocyte ratio (NLR) and platelet lymphocyte ratio (PLR) as useful tools in the characterization of inflammatory disease. In this study, we explored the utility of the NLR and PLR in axSpA and their associations with patient reported outcomes (PROs), CRP and the erythrocyte sedimentation ratio (ESR), and sacroiliac joint (SIJ) radiograph damage scores.

Methods: The study population consisted of US veterans with a clinical diagnosis of axSpA enrolled in the Program to Understand Long-term Outcomes of Spondylarthritis (PULSAR) registry. Included data were sociodemographics, PROs, and pharmacologic variables. Absolute neutrophil, platelet, and lymphocyte counts were extracted from the VA Corporate Data Warehouse (CDW). To moderate the effect of medications on lab values, analyses were restricted to encounters in which patients were not taking disease modifying anti-rheumatic drugs. SIJ 3-view radiographs (Ferguson and obliques) were evaluated by three blinded readers using the scoring from the modified New York (mNY) criteria. Associations between NLR and PLR and the CRP, PROs (BASDAI and BASFI), and radiograph scores were calculated using linear regression and plotted with a superimposed regression line (including 95% CIs). Cell count data were used only if they were same day as clinical data (apart from radiographs within 90 days of labs). Statistical analysis was performed using STATA/MP v15 software.

Results: In the PULSAR registry, a majority were white males, HLAB27 positive, and reported current or former tobacco use (Table 1). Of 254 patients with a diagnosis of axSpA, the NLR and PLR were both associated the CRP with $p < 0.001$ (Figure 1). The CRP however, was not significantly associated with BASDAI or BASFI. In contrast, the ESR

Figure 1. Linear regression of NLR and CRP (*left*) and PLR and CRP (*right*) in patients with axSpA

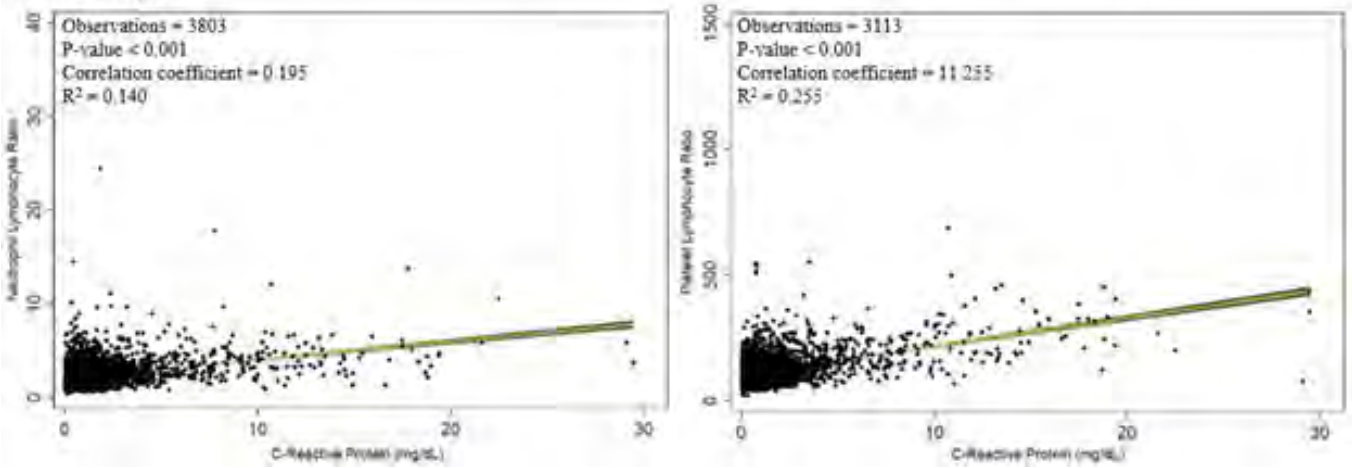

Table 2. Correlation of selected lab data (CRP, ESR, NLR, PLR) and PROs in patients with axSpA

Lab	PRO	Observations	*p*-value	Correlation Coefficient (95% CI)	R^2
CRP	BASDAI	275	0.102	0.037 (-0.007 – 0.082)	0.0098
	BASFI	237	0.211	0.034 (-0.096 – 0.089)	0.0067
ESR	BASDAI	155	0.026	0.013 (0.002 – 0.023)	0.0322
	BASFI	120	<0.001	0.031 (0.018 – 0.045)	0.1506
NLR	BASDAI	194	0.628	0.056 (-0.172 – 0.285)	0.0012
	BASFI	157	0.038	0.292 (0.016 – 0.567)	0.0274
PLR	BASDAI	141	0.028	0.006 (0.001 – 0.011)	0.0343
	BASFI	105	0.128	0.006 (-0.002 – 0.015)	0.0224

was the only inflammatory marker with significant associations to both BASDAI ($p = 0.026$) and BASFI ($p < 0.001$). The NLR had statistically significant correlation with BASFI ($p = 0.038$) while the PLR had statistically significant correlation with BASDAI ($p = 0.028$) (Table 2). There was no significant correlation between radiographic scores by mNY criteria and CRP, ESR, NLR, or PLR.

Conclusion: In our cohort, axSpA patients were found to have specific correlations between the NLR, PLR and PROs, suggesting additional parameters for disease assessment in clinical practice. Radiographs however did not correlate with selected laboratory data, perhaps reflecting poor correlation of accumulative damage with the transient nature of inflammatory, NLR and PLR indices. Additional variables in larger numbers of axSpA patients may provide further guidance of the utility of these biomarkers.

Abstract Number: 0385

The Diagnostic Utility of Serum interleukin-22 in Patients with Suspected Axial Spondyloarthritis

Michal Sagiv[1], Abid Awisat[2], Aniela Shouval[2], Regina Peri[3], Mohammad Adawi[4], Firas Sabbah[4], Itzhak Rosner[2], Aharon Kessel[3] and Gleb Slobodin[2], [1]Faculty of Medicine, Bar Ilan University, Tel Aviv, Israel, [2]Rheumatology Unit, Bnai Zion Medical Center, Haifa, Israel, [3]Clinical Immunology and Allergy Division, Bnai Zion Medical Center, Haifa, Israel, [4]Puria Medical Center, Tiberias, Israel

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Spondyloarthritis Including PsA – Diagnosis, Manifestations, & Outcomes Poster I: Clinical Aspects of Axial Spondyloarthritis (0357–0386)

Session Type: Poster Session A

Session Time: 8:30AM–10:30AM

Background/Purpose: There is an unmet need for a reliable biomarker for the diagnosis and differentiation of AxSpA from its multiple mimickers. Serum levels of IL-22, which is tightly involved in the pathogenesis of AxSpA, have been previously found significantly elevated in patients with AxSpA, when compared to healthy individuals or persons with osteoarthritis.

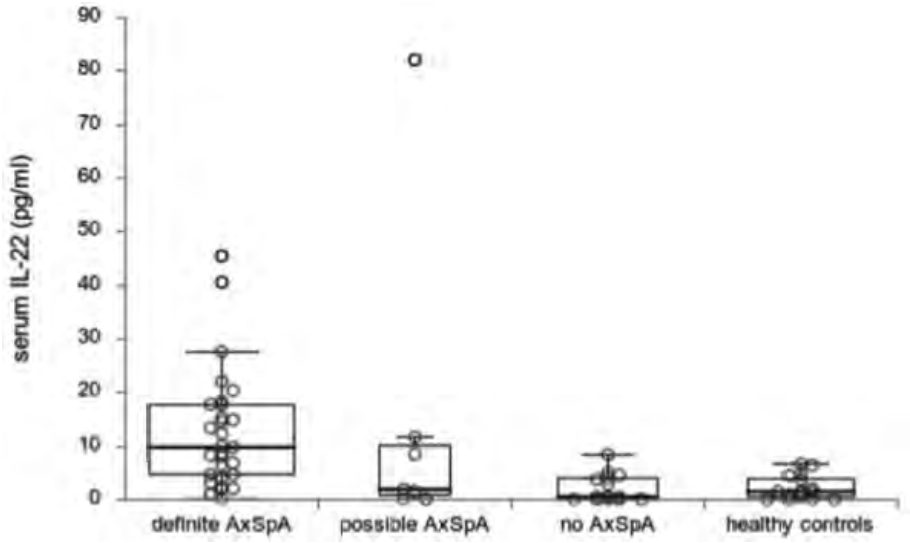

Figure 1. Serum levels of IL-22 in study participants.

Methods: Consecutive patients with established or suspected AxSpA, followed in the outpatient clinic of Bnai Zion Medical Center, Haifa, were enrolled. The demographic and anamnestic data, as well as results of laboratory and imaging studies and estimates of disease activity were acquired from patients' charts. The final diagnosis of definite or probable SpA, or alternative diagnoses, based on the existing medical data, was determined by the joint opinion of the treating rheumatologist and a senior author (GS), blinded to the estimates of the serum IL-22, which were examined by Quantikine ELISA Human IL-22 Immunoassay.

Results: Serum levels of IL-22 were significantly higher in patients with definite AxSpA (29 patients) compared to patients with alternative diagnoses (14 patients) and healthy volunteers (16 individuals) ($p< 0.001$ for both comparisons). Patients with possible AxSpA (7 patients) had a wide range of data distribution, probably reflecting its heterogeneity. The sensitivity and specificity of the serum levels of IL-22 for the AxSpA diagnosis were 0.68 (95% CI 0.49-0.84) and 0.86 (95% CI 0.68-0.95), respectively, for the cut-off of 5 pg/ml, and 0.48 (95% CI 0.29-0.67) and 1 (95% CI 0.85-1) for the cut-off of 10 pg/ml. In patients with AxSpA, serum IL-22 levels did not correlate with mSASSS, BASDAI, ASDAS indices or serum CRP levels, with all results far away from the level of statistical significance.

Conclusion: Serum IL-22 leves are elevated in patients with AxSpA and can serve as an independent biomarker for the differentiation of AxSpA from its non-inflammatory mimickers.

Delay to Diagnosis in Axial Spondyloarthritis: The Gap Is Closing, but Persistent Association with Severe Disease

Maria McWalter[1], Conall MacGearailt[1], Sinead Maguire[2], Finbar (Barry) O'Shea[2] and Gillian Fitzgerald[3], [1]Galway University Hospitals, Galway, Ireland, [2]St James's Hospital, Dublin, Ireland, [3]Galway University Hospital, Galway, Ireland

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Spondyloarthritis Including PsA – Diagnosis, Manifestations, & Outcomes Poster I: Clinical Aspects of Axial Spondyloarthritis (0357–0386)

Session Type: Poster Session A

Session Time: 8:30AM–10:30AM

Background/Purpose: Diagnostic delay in axial spondyloarthritis (axSpA) presents a challenge in the management of the condition, despite increased awareness. Reducing the gap between symptom onset and time of diagnosis is needed to limit associated morbidity and mortality. We aimed to examine delay to diagnosis in a large cohort of well characterised individuals with axSpA, with the specific objectives of:

1. Assessing if delay to diagnosis has reduced in individuals with more recent onset of disease

2. Identifying clinical and demographic characteristics associated with delayed diagnosis

3. Determining whether sex has an impact on delay to diagnosis

4. Assessing the association between delay to diagnosis and disease severity.

Methods: The Ankylosing Spondylitis Registry of Ireland (ASRI) provided the cohort for this study. The objectives of ASRI are to provide descriptive epidemiological data on the Irish axSpA population. A standardised clinical assessment is performed on each patient. Structured interviews provide patient-reported data. Delay to diagnosis was calculated as age at diagnosis minus age at symptom onset. Validated outcome measures were collected: Bath Ankylosing Spondylitis Disease Activity Index (BASDAI), Bath AS Functional Index (BASFI), Health Assessment Questionnaire (HAQ), AS Quality of Life (ASQoL), and Bath AS Metrology Index (BASMI).

Results: Eight hundred and eighty-six patients were included, 644 of whom were male (73%), mean age 46 years (SD 13) and 76% (n=667) fulfilled modified New York (mNY) criteria. Detailed baseline clinical and demographic characteristics are outlined in Table 1.

Table 1. Baseline demographic and clinical characteristics

Variable	
Age, mean (SD)	45.9 (12.6)
Female, n (%)	232 (26.2)
Smoker, n (%)	503 (56.8)
HLA-B27 positive, n (%)	602 (67.9)
Disease duration, median (25^{th},75^{th})	17.1 (9.5, 27.8)
Delay to diagnosis, median (25^{th},75^{th})	5 (2.0, 11.0)
• 0-5 years, n (%)	• 444 (50.1)
• 5-10 years, n (%)	• 192 (21.7)
• >10 years, n (%)	• 232 (26.2)
AAU, n (%)	297 (33.5)
PsO, n (%)	144 (16.3)
IBD, n (%)	91 (10.3)
BASMI, mean (SD)	4.0 (2.1)
BASFI, mean (SD)	3.7 (2.9)
BASDAI, mean (SD)	4.0 (2.4)
HAQ, median (25^{th}, 75^{th})	0.38 (0.0, 0.8)
ASQoL, mean (SD)	6.5 (5.5)

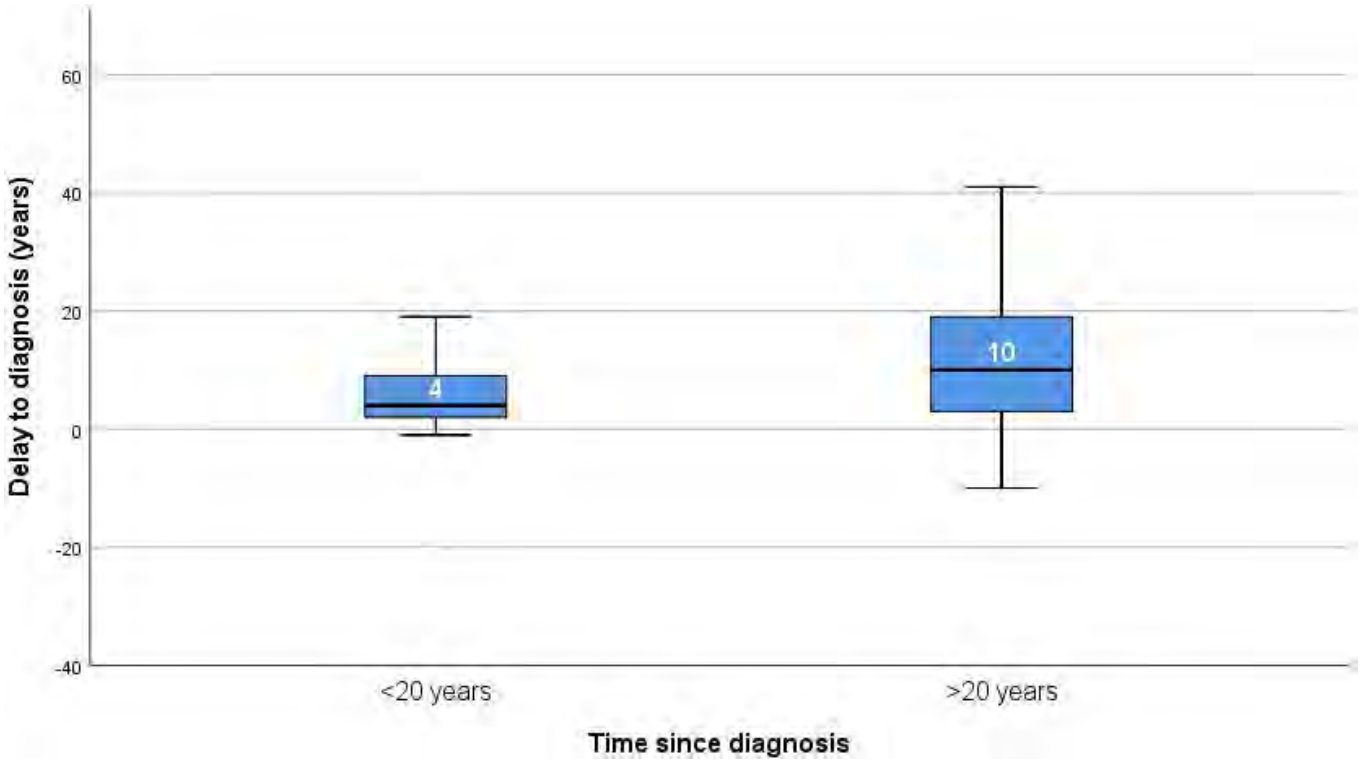

Figure 1. Boxplot demonstrating median delay to diagnosis according to time since diagnosis.

The mean (SD) disease duration was 19 (12) years, with 27% having a duration of less than 10 years, 32% having duration of 10-20 years and 42% with a duration of >20 years. The median delay to diagnosis in the whole cohort was 5 years (2, 11), with 51% (n=444) of the cohort diagnosed within 5 years, 22% (n=192) diagnosed between 5-10 years and 27% (n=232) diagnosed more than ten years from symptom onset. The median delay to diagnosis has reduced significantly (< 0.01) in recent years (see Figure 1).

Factors associated with a shorter delay to diagnosis include smoking (6.7 vs 8.9 years, p< 0.01), peripheral arthritis (7.0 vs 8.4 years, p=0.02) and absence of sacroiliitis on x-rays (6.5 vs 8.4 years, p=0.03). HLA-B27 status had no impact on delay to diagnosis and there was no difference between sexes. The presence of EAM did not influence the delay to diagnosis.

When compared to a delay of < 5 years, individuals with a delay to diagnosis > 10 years had significantly higher BASMI (4.7 vs 4.0, p=0.01) and BASFI (4.8 vs 3.8, p=0.02) scores, with no difference in BASDAI (4.1 vs 3.9, p=0.6).

Conclusion: Although still present, delay to diagnosis has reduced in individuals with a more recent diagnosis of axSpA, with no sex effect seen. Longer delays to diagnosis are associated with more severe disease in this cohort, indicating a significant unmet need in the management of axSpA.

Predictors for Progressive Fibrosis in Patients with Connective Tissue Disease Associated Interstitial Lung Diseases

Yu-Hsiang Chiu[1], Julia Spierings[2], Pim de Jong[1], Firdaus Mohamed Hoesein[1], Jan Grutters[3], Jacob van Laar[1] and Mareye Voortman[1], [1]University Medical Centre Utrecht, Utrecht, Netherlands, [2]University Medical Center Utrecht, Utrecht, Netherlands, [3]St. Antonius Hospital, Nieuwegein, Netherlands

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Systemic Sclerosis & Related Disorders – Clinical Poster I (0387–0413)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Connective tissue disease associated interstitial lung disease (CTD-ILD) is associated with decreased quality of life and high mortality risk. Outcome and treatment response is unpredictable. This study aimed to identify clinical predictors for CTD-ILD with poor outcome.

Methods: We performed a retrospective single center cohort study in outpatients with CTD-ILD seen between 2004 and 2018. Clinical, biochemical data as well as pulmonary function test (PFT) and high-resolution computed tomography (HRCT) results were recorded. The ILD patterns were classified according to the classification for idiopathic interstitial pneumonia and categorised into fibrotic or inflammatory. Overall survival and progressive fibrosing ILD (PF-ILD, defined as ≥ 10% decline in FVC, ≥ 15% decline in DLCO, or progression of the fibrosis on HRCT within two years) were assessed.

Results: In total, 150 patients with CTD-ILD were included. Table 1 shows the baseline patient characteristics. Thirty (20%) deaths occurred during a median follow-up of 40 months (IQR 27.3–60.8), which were attributed to pulmonary infection in six (4%), respiratory failure due to PF-ILD in ten (7%) and due to other causes in fourteen patients. PF-ILD occurred in 74 (49.3%) patients and was associated with poor overall survival. (Figure 1) Age, smoking, C-reactive protein, and steroid-use were independently associated with increased mortality risk as well. (Table 2) Furthermore, patients with diabetes mellitus (adjusted OR 4.2, 95%CI 1.05–16.78), steroid-use (adjusted OR 2.38, 95%CI 1.09–5.18), and a fibrotic HRCT pattern at baseline (adjusted OR 3.02, 95%CI 1.11–8.24) had a higher risk of PF-ILD.

Conclusion: PF-ILD is associated with increased mortality in patients with CTD-ILD. Patients with a fibrotic HRCT pattern at baseline, diabetes mellitus and steroid-use have a higher risk of developing PF-ILD.

Prediction Tool for Damage Accrual Trajectory in Incident Systemic Sclerosis

Ariane Barbacki[1], Ada Man[2], Mianbo Wang[3], Dylan Johnson[4], Yuqing Zhang[5], Mandana Nikpour[6] and Murray Baron[7], [1]McGill University, Montral, Montréal, QC, Canada, [2]University of Manitoba, Winnipeg, MB, Canada, [3]Lady Davis institute for Medical Research, Montréal, QC, Canada, [4]University of Alberta, Edmonton, AB, Canada, [5]Massachusetts General Hospital, Quincy, MA, [6]University of Melbourne at St Vincent's Hospital, Melbourne, Australia, [7]Jewish General Hospital, Montréal, QC, Canada

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Systemic Sclerosis & Related Disorders – Clinical Poster I (0387–0413)

Session Type: Poster Session A

Session Time: 8:30AM–10:30AM

Background/Purpose: Systemic sclerosis (SSc) is a systemic autoimmune disease associated with the accrual of organ damage over time, which can be measured using the Scleroderma Clinical Trials Consortium Damage Index (SCTC-DI). The natural history of SSc is heterogenous ranging from benign to severe with the latter associated with high mortality. The aim of this study was to build a prediction model that could identify newly diagnosed SSc patients at higher risk of accruing damage quickly.

Methods: Incident adult SSc cases (disease duration < 2 years) were identified in the Australian Scleroderma Interest Group (ASIG) and Canadian Scleroderma Research Group (CSRG) registries. Patients meeting 2013 ACR-EULAR Scleroderma classification criteria were included. Using a combination of group-based trajectory modelling and substantive knowledge, we identified two trajectories of damage accrual (fast, slow) for each of diffuse and limited patients. Baseline variables associated with trajectory membership were entered into logistic regression models. Using backward selection, prediction models for the two cutaneous SSc subset groups were built independently since the actual DI trajectories for the two subsets were very different from one another. ROC curves were analyzed to

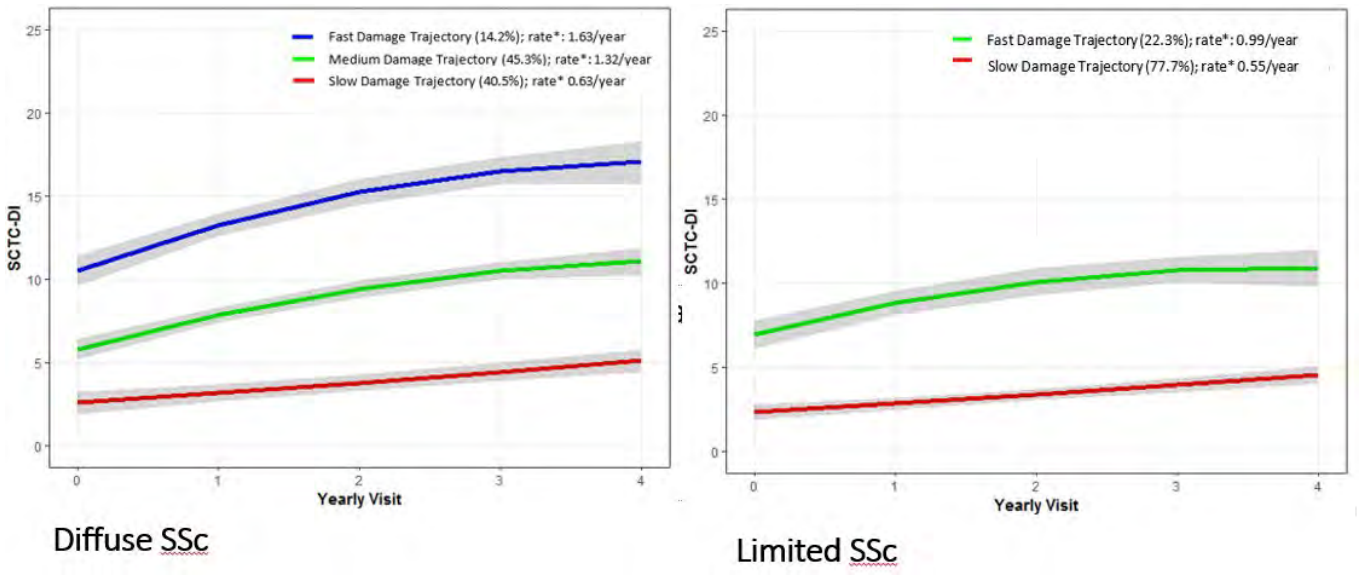

Figure 1. Incident Systemic Sclerosis Damage Trajectories.

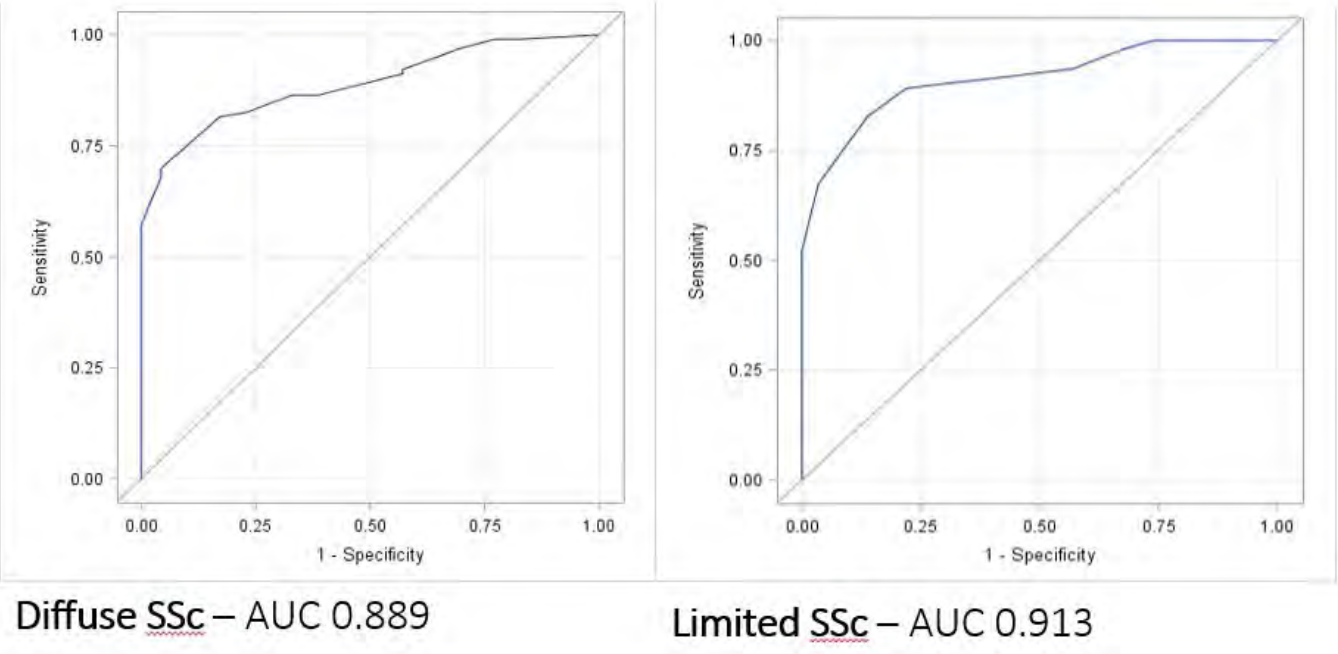

Figure 2. ROC Curves for the Prediction Models

Table 1. Variable Selection for Final Prediction Models

	Diffuse (n=192)				Limited (n=210)			
	Full model		Selected model		Full model		Selected model	
	OR (95% CI)	P values	OR (95% CI)	P values	OR (95% CI)	P values	OR (95% CI)	P values
Age	1.02 (0.98, 1.06)	0.377			1.03 (0.99, 1.07)	0.115		
Male	3.23 (1.02, 10.21)	0.046	3.29 (1.17, 9.25)	0.024	0.73 (0.15, 3.52)	0.699		
Caucasian	0.46 (0.10, 2.07)	0.312						
CRP (log)	1.18 (0.82, 1.69)	0.364			0.96 (0.68, 1.35)	0.806		
ESR (log)	0.90 (0.58, 1.39)	0.629			1.37 (0.86, 2.19)	0.181		
TFRs	1.18 (0.38, 3.72)	0.776						
Baseline SCTC-DI	2.05 (1.61, 2.63)	<.001	2.07 (1.65, 2.58)	<.001	3.09 (2.09, 4.57)	<.001	2.79 (2.02, 3.84)	<.001

determine the optimal cut-offs for the predictive variables. The Hosmer–Lemeshow Goodness-of-Fit test was used to determine prediction accuracy.

Results: 402 patients were included. The mean age was 53 years, 20% were men, 85% were Caucasian, and 47% had diffuse disease. For the diffuse subset, the mean length of follow up was 3.0 years (SD ± 1.2) and 60% were in the fast trajectory, whereas the mean length of follow up was 3.1 years (SD ± 1.1) and 23% were in the fast trajectory in the limited subset (Figure 1). The final prediction model included male sex and baseline SCTC-DI for the diffuse subset, and only baseline SCTC-DI for limited (Table 1). The ROC curves for the limited and diffuse prediction models showed good discriminative abilities (AUC 0.91 and 0.89, respectively) (Figure 2). In limited patients, a baseline DI ≥ 5 predicts a fast damage trajectory with a sensitivity of 0.70 and specificity of 0.96. In diffuse patients, a baseline DI ≥ 4 in men and ≥ 6 in women, predicts a fast damage trajectory with a sensitivity of 0.83 and specificity of 0.86. The

Hosmer-Lemeshow Goodness-of-Fit test confirmed the prediction accuracy of both models (p = 0.77 for diffuse and p = 0.33 for limited).

Conclusion: Baseline disease damage as gauged by the SCTC-DI, and sex can be used as predictors of future damage trajectories. These prediction models may be useful in the clinical or trial design setting.

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Systemic Sclerosis & Related Disorders – Clinical Poster I (0387–0413)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Interstitial lung disease (ILD) affects 40-60% of adults with systemic sclerosis (SSc) and is the leading cause of death in this population. Nintedanib, a tyrosine kinase inhibitor, was the first medication to receive Food & Drug Administration approval for the treatment of SSc-ILD, in September 2019, based on the results of the SENSCIS trial. The most common adverse event (AE) associated with nintedanib is gastrointestinal distress. Of the 288 participants who received nintedanib in the SENSCIS trial, 75.7% experienced diarrhea, 31.6% nausea, and 24.7% vomiting. Moreover, 16% of participants discontinued nintedanib due to an AE.[1] It is unknown how nintedanib is being used in clinical practice. The aims of this study were to describe the nintedanib prescribing practices at expert SSc centers in the US.

Methods: We performed a prospective cohort study of patients enrolled in the Collaborative National Quality and Efficacy Registry (CONQUER) at 13 sites in the US between June 6, 2018, and March 1, 2021. CONQUER is a US-based, prospective, multicenter cohort of adults with SSc who met 2013 ACR/EULAR Classification Criteria and had a disease duration ≤ 5 years from the 1st non-Raynaud's symptom at enrollment. We compared baseline characteristics between participants with SSc-ILD who did and did not receive nintedanib. Descriptive data are presented due to the small sample size of subjects who received nintedanib.

Results: 459 SSc patients were enrolled in CONQUER, of whom 202 (44%) had ILD. Of the 202 participants with SSc-ILD, 14 (6.9%) had taken nintedanib at some point during their SSc-ILD disease course. Among those who received nintedanib compared to those who did not, a greater proportion were male (42.9% vs. 19.1%), Hispan-

Table 1. Baseline Characteristics by Nintedanib Status

	Overall (N = 202)	Ever on Nintedanib: Yes (N = 14)	Ever on Nintedanib: No (N = 188)

Missing	33 (16.3%)	3 (21.4%)	30 (16.0%)

Continuous variables are summarized using median (interquartile range) and categorical variables are summarized using counts (percentages).
FEV1/FVC had 21 missing values

the “moderate” range for those who received nintedanib and in the “none-to-mild” range for those who did not. SSc patients who received nintedanib had lower baseline forced vital capacity, total lung capacity, and diffusion capacity for carbon monoxide than those who did not (Table 2). Of the 14 patients who received nintedanib, 10 (71.4%) have remained on it, 2 (14.3%) stopped and then restarted it, and 2 (14.3%) discontinued it. Twelve of the 14 (85.7%) patients who received nintedanib were concurrently receiving mycophenolate mofetil (MMF).

Conclusion: A relatively small percentage of patients with SSc-ILD enrolled in CONQUER have received nintedanib. The majority of patients who received nintedanib did so in combination with MMF. Most patients who received nintedanib were able to remain on this therapy. Future research should explore the tolerability of nintedanib in clinical practice, including reasons for discontinuation. Longitudinal registries such as CONQUER are critical for understanding SSc care in the US.

Session Title: Systemic Sclerosis & Related Disorders – Clinical Poster I (0387–0413)

Session Type: Poster Session A

Session Time: 8:30AM–10:30AM

Background/Purpose: COVID-19 vaccination is recommended for individuals with rheumatic diseases, yet data are limited regarding vaccine safety in this population, particularly among those with rare autoimmune conditions such as systemic sclerosis (SSc; scleroderma). The purpose of this cross-sectional, observational study was to evaluate the self-reported experiences of individuals with SSc who have received at least one dose of a COVID-19 vaccine.

Methods: Participants were adults with physician-verified SSc enrolled in the Scleroderma Patient-centered Intervention Network (SPIN) Cohort. SPIN includes 47 international centers and has approximately 1600 active participants. From April 9 to May 15, 2021, participants from the SPIN Cohort were invited by email and popups during regular SPIN Cohort assessments to participate in a COVID-19 vaccine survey, which was conducted in English and French. The survey inquired about whether participants had received the COVID-19 vaccine and their experience with vaccination. Frequencies and means (standard deviation (SD)) are reported. Characteristics are compared between

Table 1. Characteristics of responders within the Scleroderma Patient-centered Intervention Network (SPIN) Cohort who have received at least one dose of a COVID-19 vaccine

Clinical Variable	Total Vaccinated (N=699)
Age, years, mean (SD)	62 (11)

History of COVID-19 infection, n (%)	48 (7%)

Legend: ILD=interstitial lung disease; PH=pulmonary hypertension; *Time since first non-Raynaud's Phenomenon symptom; +Includes all listed except hydroxychloroquine; [a]N=690; [b]N=678; [c]N=671

those with and without self-reported adverse reactions using chi-square or t-test. Logistic regression was used to compare likelihood of self-reported adverse reactions by vaccine type.

Results: Among 932 responders, 699 (75%) had received at least one dose of a COVID-19 vaccine, and 358 (51%) had also received a second dose. The majority of participants received the Pfizer vaccine (63%). Demographic data are presented in Table 1. Most responders did not make changes to their SSc medications for the first (94%) or second (92%) vaccine dose. Adverse reactions were self-reported in 270 individuals (39%) after the first vaccine dose and 209 individuals (58%) after the second vaccine dose (Table 2). The three most common symptoms after the first and second vaccine dose were sore arm (30% and 45%, respectively), fatigue (23% and 40%, respectively), and muscle aches (9% and 22%, respectively). No serious allergic reactions were reported. Self-reported flares of SSc symptoms were rare after the first (6%) and second vaccine dose (10%), and most common symptoms were fatigue and muscle weakness (Table 2). Those with (vs. without) self-reported adverse reactions (any) to the COVID-19

Table 2. Patient-reported adverse reactions following COVID-19 vaccination among individuals with systemic sclerosis (N=699)		
Post-vaccine outcome reported, n (%)	**First vaccine (N=699)**	**Second vaccine (N=358)**
No symptoms	429 (61%)	149 (42%)

vaccine were younger (60 vs. 63, p=0.001), more often female (94% vs. 84%, p< 0.001), and more often had a prior history of COVID-19 (10% vs. 5%, p=0.009) (Table 3). Compared to those who received the Pfizer vaccine, the odds of a self-reported adverse reaction were higher for those who received Moderna (OR 1.77, 95% CI 1.20, 2.60) or AstraZeneca (OR 2.20, 95% CI 1.43, 3.39) vaccines.

Conclusion: The rate and types of self-reported adverse reactions to the COVID-19 vaccine among individuals with SSc were similar to those observed in the general population. Few individuals altered their medication regimen for the vaccine, and self-reported worsening of SSc symptoms was rare.

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Systemic Sclerosis & Related Disorders – Clinical Poster I (0387–0413)

Session Type: Poster Session A

Session Time: 8:30AM–10:30AM

Background/Purpose: There are currently no validated objective measures of systemic sclerosis (SSc)-related skin thickening and this hampers clinical trials of potential new treatments. The modified Rodnan skin score (mRSS, the current gold standard) has limitations including concerns about inter-rater reliability. The aim of this study was to test the hypothesis that high frequency ultrasound (HFUS), which measures skin thickness is (a) sensitive to change and (b) correlates with local 'skin score' (criterion validity), both OMERACT criteria for validation.

Methods: In this prospective study, patients with early diffuse cutaneous SSc (dcSSc; duration of first non-Raynaud's clinical manifestation < 5 years) underwent HFUS at each visit. Imaging was carried out at nine sites (most corresponding to sites assessed for mRSS; non-dominant ring finger, dorsum of hand, forearm, upper arm, forehead, anterior chest, abdomen, leg and dorsum of foot. Local skin score (0-3; 0 normal, 3 unable to move) was also assessed at each site. Images were assessed by one observer; skin thickness was measured as the distance from the surface of the skin to the base of the dermis (i.e. epidermis and dermis). The average thickness was taken of 3 measures made on each image at the left, centre and right in order to take into account any differences in thickness across the image (Figure 1). Longitudinal data underwent linear mixed effects modelling; a random intercept model with a Holm- Bonferroni correction applied.

Table 1. Imaging site, local skin (palpation) score co-efficient indicative of relationship between local palpation and HFUS (increase in coefficient indicative of positive relationship), confidence intervals and adjusted p value (p'); *p'<0.05

Site	Local palpation score co-eff	Confidence intervals	p'
Non-dominant ring finger	0.029	(-0.169 to 0.227)	0.464
Dorsum of hand	0.303	(0.119 to 0.488)	0.024*
Forearm	0.296	(0.127 to 0.465)	0.014*
Upper arm	0.134	(-0.010 to 0.278)	0.464
Forehead	0.035	(-0.167 to 0.237)	0.464
Chest	0.241	(0.102 to 0.379)	0.014*
Abdomen	0.125	(-0.038 to 0.287)	0.261
Leg	0.346	(0.197 to 0.495)	0.044*
Dorsum of the foot	0.134	(-0.007 to 0.276)	0.210

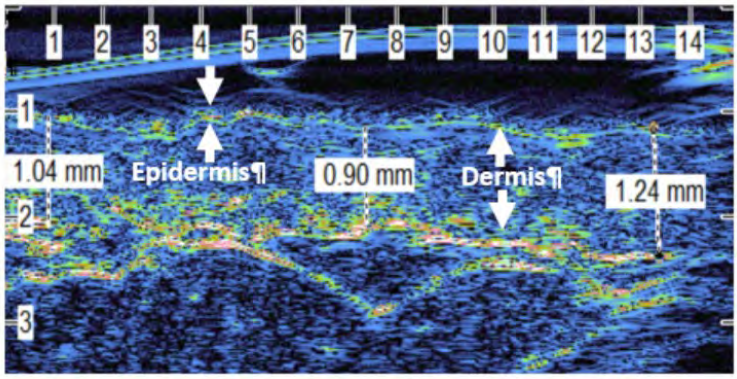

Figure 1. Example of an HFUS image of the chest showing mark-ups on the left, centre and right. Numbers in white boxes along the top and side of the image represent mm.

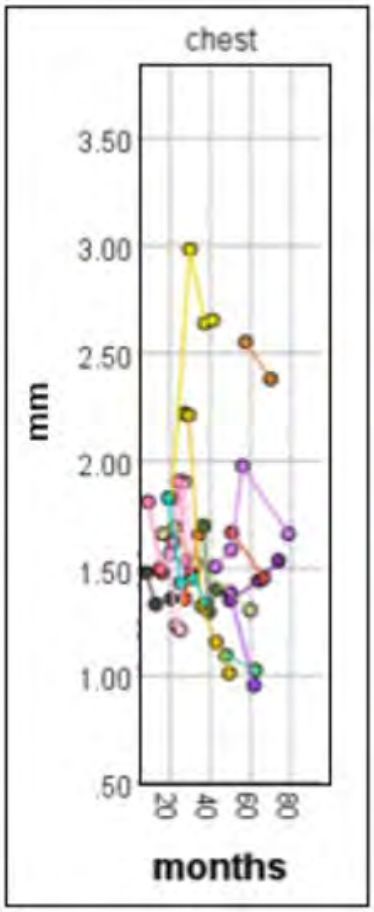

Graph of skin thickness (mm) as measured by HFUS with time (months); each colour represents a patient.

Results: Seventeen patients with dcSSc were recruited (10 F:7M), median age 54 (range 42 to 61) years, median duration of Raynaud's 2 (IQR 2- 5) years and duration of first non-Raynaud's clinical manifestation 2 (1- 4) years. Three patients had 5 sets of measures, four had 4, four had 3, six had 2; median duration of follow-up of 16 months (range 7-43 months). Although patients did not follow a set pattern of change (i.e. skin thickness increased for some patients and sites and decreased for others) HFUS was sensitive to changes in thickness (example in Figure 2). Modelling indicated that changes in local skin score tracked well with changes in HFUS thickness measures at the dorsum of the hand, forearm, chest and leg (indicated by the local skin score coefficent in Table 1, p'< 0.05).

Conclusion: Conclusions

In patients with early dcSSc HFUS was able to determine differences in skin thickness with time, indicative of sensitivity to change.

Changes in skin thickness as measured by HFUS mirrored changes assessed by local palpation scores at several sites.

Patients at first visit had different levels of skin thickening due to the different durations and

severities of disease, this heterogeneity makes identifying patterns of change over time in patients difficult.

These findings support the hypothesis that HFUS is sensitive to change and shows criterion validity, showing promise for future validation of HFUS as an outcome measure in clinical trials.

Faecal Incontinence in Scleroderma: Prevalence, Impact and Response to Sacral Neuromodulation in an Single Centre Observational Cohort

Nikhil Suresh[1], Ranjitha Karanth[1], David Jayne[2], Giuseppina Abignano[3] and Francesco Del Galdo[3], [1]LIRMM, Leeds, United Kingdom, [2]Colorectal Surgery / St James University Hospital, Leeds, United Kingdom, [3]University of Leeds, Leeds, United Kingdom

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Systemic Sclerosis & Related Disorders – Clinical Poster I (0387–0413)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Scleroderma (SSc) is a chronic autoimmune disorder involving multiple organs, the gastrointestinal system (GI) commonly involved in up to 90% of the sufferers. Faecal incontinence (FI) is frequent manifestation of SSc but data on prevalence of FI are lacking. Treatment options are limited. This study aims to estimate the prevalence of FI in patients with SSc managed at a tertiary referral centre and to determine the efficacy of sacral neuromodulation (SNS) in cases of failed medical management.

Methods: Data was extracted from the STRIKE observational cohort database (Stratification for risk of progression in scleroderma) between 2015 and 2020. Collected data included Patient Reported Outcomes included gastrointestinal VAS scores. Data were categorised into 2 groups based on GI involvement using descriptive statistics, including uni- and multii-variate analysis were applicable. SHAQ-DI indices were calculated for the 2 groups. Faecal incontinence was defined as the inability to control bowel movements causing passive leakage of faeces from the rectum. Prevalence of FI was estimated in this cohort. Anorectal involvement was identified using anorectal manometry and endoanal ultrasound. A positive response to SNS was defined as a >50% improvement in continence score leading

to insertion of a permanent SNS implant. Improvements were measured based on improvements FIQL scores and reduction in the frequencies of bowel movements on follow up.

Results: 539 patients were available in the dataset of which 300 had all follow up information available to be included in the study. Among the 300 patients analysed 26 patients had FI (8.66%). 25 were females (96%). Mean age was 62.4 years, 17 (65.38%) patients had limited SSc and 4 (15.38%) with diffuse SSc. Mean disease duration of 14 years. 70.2% were ANA positive, 50% were ACA, and 19.23% were SCL70 positive. Median (IQR) GI VAS for patients with FI was 60 (40-85) as compared to 10 (0-50) for patients without FI. Median HAQ-DI for FI was 2.75 (0-5.25) as compared to 3.06 (0.6-5.65) for patients without FI. In patients with FI, internal anal sphincter (IAS) atrophy was found in 42.23%, anterior sphincter defect was seen 23.07%. Pudendal neuropathy was observed in 21.73% patients with FI. Anorectal intussusception with perianal descent was seen in 15.38% patients with FI. Pelvic physiotherapy did not benefit any patients. 34.61% patients received a permanent SNS of which 88.5% had a good treatment effect.

Conclusion: The prevalence of FI in our cohort of patients with SSc was 8.6% but is probably underestimated given the reservations that patients feel in declaring FI as a symptom. Patients with FI had higher GI VAS whereas higher overall HAQ scores in non FI patients. FI does affects the quality of life considerably. The finding of sphincter atrophy and pudendal neuropathy warrant further investigation and comparison with non SSc FI cohorts. Despite the need of large controlled studies, the high response to SNS supports its potential role for treating FI in SSc patients. However, reasons for failure of SNS need to be investigated further.

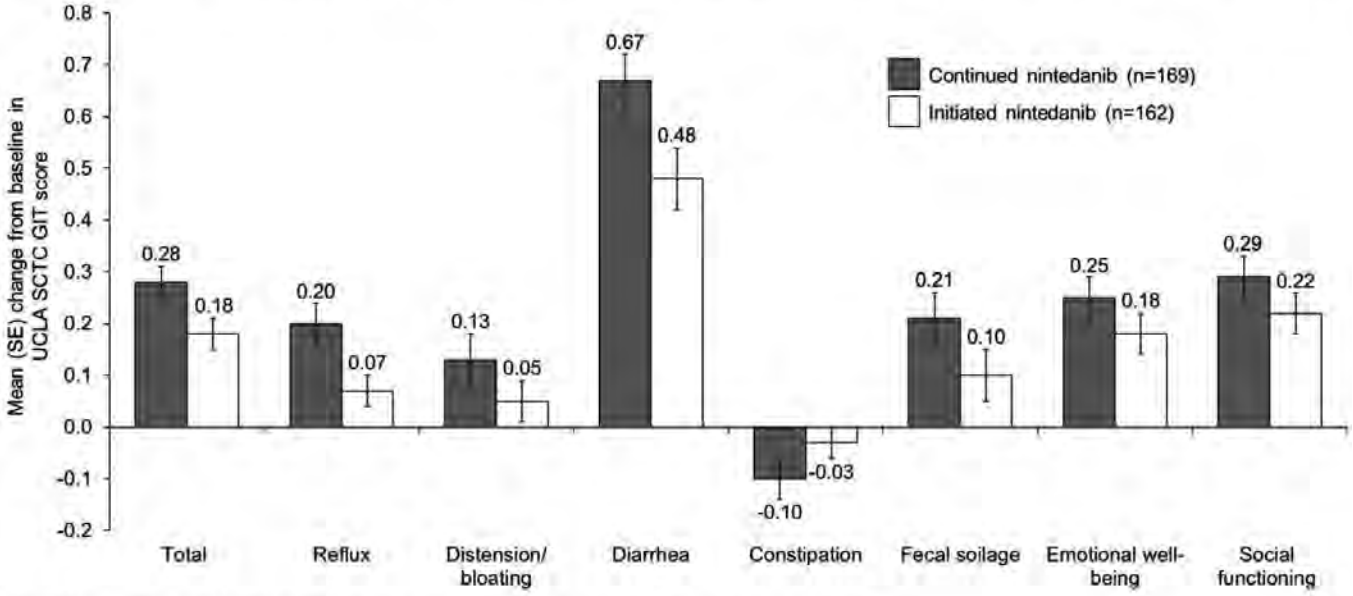
Session Title: Systemic Sclerosis & Related Disorders – Clinical Poster I (0387–0413)

Session Type: Poster Session A

Session Time: 8:30AM–10:30AM

Background/Purpose: Gastrointestinal (GI) involvement is a common manifestation of systemic sclerosis (SSc) and a frequent side-effect of drugs used to treat SSc. In the SENSCIS trial, nintedanib reduced the rate of decline in forced vital capacity (FVC) in patients with SSc-associated interstitial lung disease (SSc-ILD), with an adverse

Figure. Changes in UCLA SCTC GIT scores from baseline to week 52 of SENSCIS-ON



n=168 for changes in UCLA SCTC GIT total score and diarrhea scale score in the continued nintedanib group.

	Total	125 (63.5)	47 (23.9)	6 (3.0)	19 (9.6)	197 (100)
	Initiated nintedanib					
	None or mild	31 (12.6)	15 (6.1)	2 (0.8)	3 (1.2)	51 (20.6)
	Moderate	39 (15.8)	22 (8.9)	3 (1.2)	3 (1.2)	67 (27.1)
	Severe or very severe	23 (9.3)	21 (8.5)	6 (2.4)	2 (0.8)	52 (21.1)
	Missing	32 (13.0)	19 (7.7)	5 (2.0)	21 (8.5)	77 (31.2)
	Total	125 (50.6)	77 (31.2)	16 (6.5)	29 (11.7)	247 (100)

Data are n (%) of patients. None or mild=scores of 0 to 0.49; moderate=scores of 0.5 to 1; severe or very severe=scores of 1.01 to 2.

Methods: Patients with SSc-ILD who completed the SENSCIS trial or a drug–drug interaction (DDI) study of nintedanib and oral contraceptive were eligible to enter SENSCIS-ON. Patients who received nintedanib in SENSCIS (up to 100 weeks) and continued nintedanib in SENSCIS-ON comprised the "continued nintedanib" group. Patients who received placebo in SENSCIS and initiated nintedanib in SENSCIS-ON, or who received nintedanib for a short time in the DDI study, comprised the "initiated nintedanib" group. There was a maximum interruption of 12 weeks between the last dose of nintedanib in SENSCIS and the first dose in SENSCIS-ON. We assessed changes in scores on the UCLA Scleroderma Clinical Trial Consortium Gastrointestinal Tract (UCLA SCTC GIT) questionnaire v2.0 from baseline to week 52. This questionnaire comprises 7 scales measuring the severity and impact of GI symptoms: reflux, distension or bloating, fecal soilage, diarrhea, constipation, emotional well-being, social functioning. Each scale is scored from 0 to 3 except for the diarrhea scale (0 to 2) and constipation scale (0 to 2.5). The total score, derived as the mean of the scores for the scales except constipation, ranges from 0 to 2.83, with higher scores indicating worse symptoms.

Results: The "continued nintedanib" group comprised 197 patients and the "initiated nintedanib" group comprised 247 patients (231 from SENSCIS). Of these, 178 and 218 patients, respectively, provided a total UCLA SCTC GIT score at baseline. At baseline, mean (SD) total scores were 0.33 (0.33) and 0.33 (0.34) in the continued nintedanib and initiated nintedanib groups, respectively. Mean (SD) scores on the 7 scales ranged from 0.16 (0.52) to 0.70 (0.73) in the continued nintedanib group and from 0.13 (0.43) to 0.64 (0.68) in the initiated nintedanib group. Increases (worsening) in scores were observed in both groups from baseline to week 52, except for on the constipation scale (Figure). Based on the total score, between baseline and week 52, the proportion of patients with moderate or severe

or very severe GI symptoms increased, but 45.7% and 39.7% of patients in the continued nintedanib and initiated nintedanib groups, respectively, had no or mild GI symptoms at week 52 (Table 1). Changes in the diarrhea scale score are shown in Table 2.

Conclusion: In the SENSCIS-ON trial, the majority of patients with SSc-ILD treated with nintedanib had no or mild GI symptoms at baseline. A small worsening in GI symptoms was observed over 52 weeks. Diarrhea had the greatest impact, reflecting the adverse event profile of nintedanib. Recommendations for the management of diarrhea in patients treated with nintedanib should be implemented in clinical practice.

Hyperspectral Imaging in Systemic Sclerosis-Raynaud Phenomenon

Akash Gupta[1], Shannon Teaw[2], Alyssa Williams[2], F. Perry Wilson[3], Brandon Sumpio[4], Bauer Sumpio[4] and Monique Hinchcliff[5], [1]Department of Medicine, Yale University School of Medicine, New Haven, CT, [2]Section of Rheumatology, Allergy & Immunology, Department of Medicine, Yale School of Medicine, New Haven, CT, [3]Section of Nephrology, Department of Medicine, Yale School of Medicine, New Haven, CT; Department of Medicine Clinical and Translational Research Accelerator Yale School of Medicine, New Haven, CT, [4]Division of Vascular Surgery, Department of Surgery, Yale School of Medicine, New Haven, CT, [5]Yale School of Medicine, Westport, CT

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Systemic Sclerosis & Related Disorders – Clinical Poster I (0387–0413)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Raynaud phenomenon (RP), a microcirculatory, vasospastic disorder, may be primary or secondary to an autoimmune disease [e.g., an early indicator of systemic sclerosis (SSc)]. Raynaud phenomenon clinical trials have been hampered by the lack of a robust, feasible, and quantitative methodology for assessing change over time. Hyperspectral imaging (HSI) noninvasively measures oxygenated hemoglobin (oxyHb) and deoxygenated he-

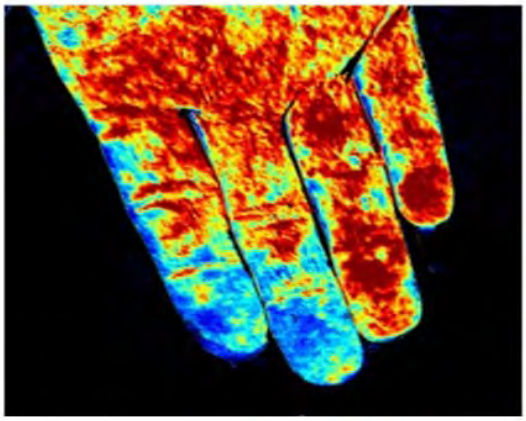

Figure 1. Hyperspectral Imaging Heatmap. A representative HSI OxyHb image. Red: higher OxyHb [arbitrary units (AU)]; Blue: lower OxyHb (AU). In this patient, only the left two fingers demonstrated RP color changes.

moglobin (deoxyHb) concentrations, and oxygen saturation (O2 sat) in the skin microcirculation by visible spectroscopy (a spectrometer quantifies hemoglobin light absorption). Data are depicted as an oxygenation heatmap (Fig. 1). The study goal is to explore the potential role of HSI in quantifying SSc-RP hand microcirculation.

Methods: The Yale University Human Investigation Committee approved this prospective study (HIC# 2000026608) of Yale Scleroderma Program patients and healthy control participants (HC). Patients with SSc completed two patient-reported outcome (PRO) instruments: the Raynaud Condition Score (RCS) and the Cochin Hand Function Scale (CHFS) to assess symptom burden. Then, bilateral palmar HSI (HyperMed™, Waltham, MA) was obtained in a temperature-controlled room (22°C). OxyHb, deoxyHb and O2 sat values were calculated using a default region of interest (ROI) measuring 78 mm^2 on the palmar side of the fingertips and palm (for normalization) (Fig. 2). Subjects then underwent a cold provocation challenge whereby hands were submerged in 15°C for one minute, and HSI was subsequently repeated at 0, 10, and 20 minutes (min.). Statistical analysis was performed using the mixed effects model (Stata, College Station, TX).

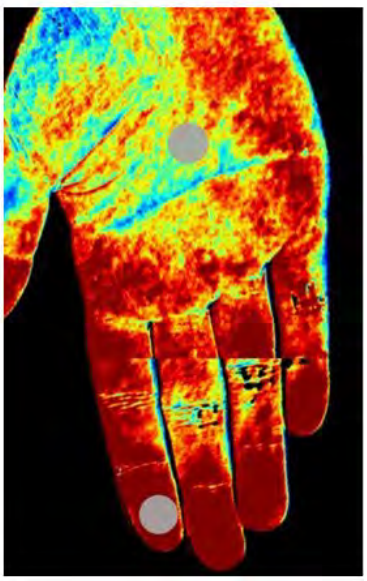

Figure 2. Region of interest (ROI) on the palmar side of palm (used for normalization) and fingertips.

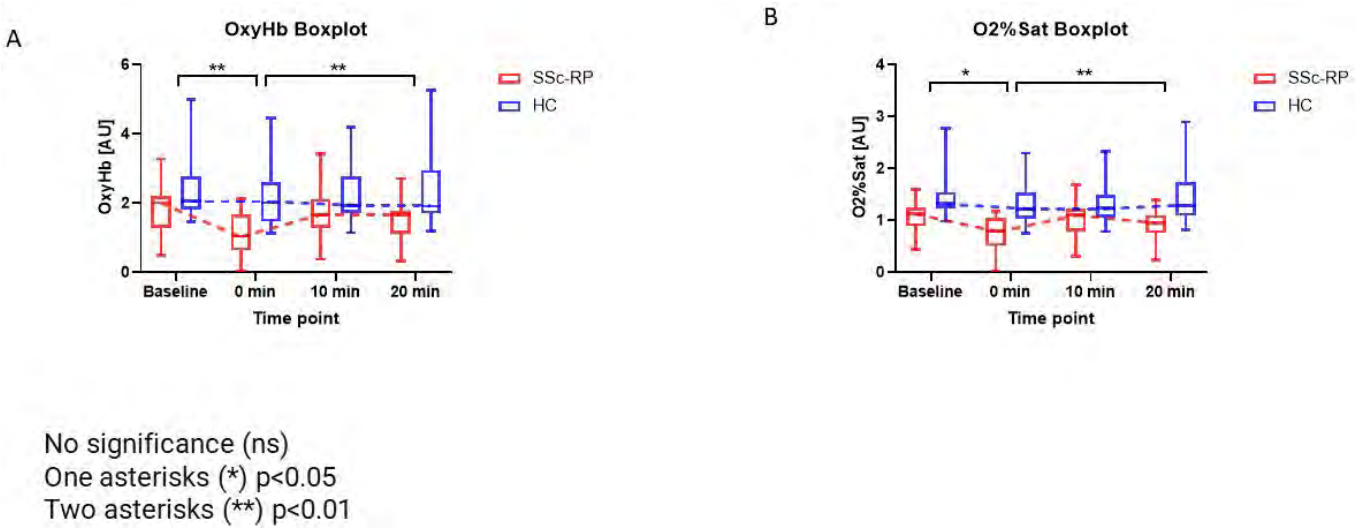

Figure 3. A. Box plot of oxyHb over time in systemic sclerosis (SSc) and healthy control participants (HC) between baseline and during cold provocation challenge and B. Box plot of O2 sat over time in systemic sclerosis (SSc) and healthy control participants (HC) between baseline and during cold provocation challenge.

Results: The mean and standard deviation (SD) age and % female for SSc (n=13) and HC (n=13) participants were 49±22 and 40±13 years (y), and 92% and 94% female, respectively. The mean (SD) SSc duration was 10.9 ± 10.4 y with 69% having limited cutaneous SSc. Thirty eight percent of SSc subjects had prior digital ulcers; none were current. Sixty-two% and 38% of SSc patients were prescribed a calcium channel blocker and statin, respectively. Baseline oxyHb, deoxyHb and O2 sat maps did not significantly differ between SSc and HC participants. However, after cold provocation, images from baseline to 0 min revealed significant reductions in mean slopes of oxyHb and O2 sat for SSc (-0.71, -0.33) compared to HC (-0.22, -0.11; p=0.005, 0.014, respectively). There were no differences in deoxyHb maps between SSc patients and HC immediately post cold challenge. From 0 to 20 min, SSc subjects had more change in oxyHb (p=0.001), deoxyHb (p=0.003), and O2 sat (p< 0.001) compared to HC (Fig. 3).

Conclusion: We showed that HSI is a feasible approach for microcirculation measurement in the hands of SSc patients and HC participants. SSc subjects had a greater decline in oxyHb and O2 sat images from baseline to time 0 (after cold provocation) with significant change in oxyHb, O2 sat, and deoxyHb compared to HC subjects thereafter. These data suggest that HSI technology to assess RP vascular dysfunction is a potential quantitative measure for SSc-RP severity and activity in clinical trials.

P for trend					0.0023	0.0028

*Potential confounders: age, gender, tobacco use, malignancy, other connective tissue disease, renal crisis, nailfold capillary changes, ANA pattern, +anti-centromere antibody, +anti-Scl-70 antibody

Background/Purpose: Raynaud phenomenon is often the initial manifestation in systemic sclerosis (SSc) and can precede other SSc symptoms by years (1). Several SSc-specific autoantibodies are useful to identify patients with isolated Raynaud phenomenon (RP) at risk of progression to SSc (2). Anti-RNA polymerase III (anti-RNAP III) is associated with diffuse skin thickening, risk for renal crisis, and malignancy (3,4). The level of anti-RNAP III in patients with RP and the risk of progression to SSc has not previously been evaluated. We examined the relationship between anti-RNAP III levels and SSc risk among patients with RP.

Methods: We performed a retrospective cohort analysis of anti-RNAP III positive patients with RP seen at a US tertiary hospital system between January 1, 2010 and December 31, 2020. SSc diagnosis was determined through medical record review utilizing the 2013 ACR-EULAR classification criteria. Anti-RNAP III levels were classified into three categories: weak (20-39 units), moderate (40-80 units), and strong positive (> 80 units). We estimated the rate of developing SSc for each anti-RNAP III category and examined their relation using a cause-specific Cox-proportional hazard model accounting for competing risk of death. In the multivariable regression model, we adjusted for socio-demographic and lifestyle factors, family history of rheumatic disease, comorbidities, and several laboratory results.

Results: We identified 118 patients with anti-RNAP III and RP. Patients with strong positive anti-RNAP III levels were more likely to be older, have negative centromere antibodies, a smoking history, a malignancy history, puffy hands, and skin thickening (Table 1). During 604 person-years of follow up, 79 patients developed SSc. The rate of SSc development was 9.3, 8.6, and 18.3 per 100-person-years among patients with weak, moderate, and strong positive anti-RNAP III levels, respectively (Table 2). Compared with those with weak anti-RNAP III levels, adjusted hazard ratios for patients with moderate and strong positive anti-RNAP III levels were 1.49 (95% CI: 0.74-3.01) and 2.88 (95% CI: 1.53-5.41), respectively (P for trend < 0.003).

Conclusion: Patients with high levels of anti-RNAP III had a much higher risk of progression to SSc than those with moderate and weak levels. Our findings suggest the level of anti-RNAP III is a strong predictor for the risk of SSc among patients with RP and those with high levels of anti-RNAP III should be closely monitored for development of SSc.

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Systemic Sclerosis & Related Disorders – Clinical Poster I (0387–0413)

Session Type: Poster Session A

Session Time: 8:30AM–10:30AM

Background/Purpose: Upper gastrointestinal involvement such as esophageal dilation is frequently observed in patients with SSc-ILD and may be associated with the presence or severity of SSc-ILD. We assessed the characteristics of patients with SSc-ILD based on the presence of esophageal distension and gastroesophageal reflux disease (GERD), and based on widest esophageal diameter, using data from the SENSCIS trial.

Table 1. Characteristics of patients with esophageal distension with and without GERD* at baseline in the HRCT sub-study of the SENSCIS trial

	Esophageal distension and GERD (n=85)	Esophageal distension and no GERD (n=25)
Female	65.9	76.0
Age, years	53.7 (12.5)	58.2 (11.8)
Race		
White	69.4	44.0
Asian	20.0	56.0
Black or African-American	8.2	0
Other	1.2	0
Body mass index, kg/m^2	26.0 (4.8)	25.7 (4.5)
Time since onset of first non-Raynaud symptom, years	3.2 (1.5)	2.3 (1.2)
Diffuse cutaneous SSc	47.1	24.0
mRSS	9.0 (8.0)	7.1 (5.3)
Extent of fibrotic ILD on HRCT, %†	36.9 (19.4)	34.8 (24.0)
FVC % predicted	73.9 (16.0)	80.6 (16.5)
DLco % predicted	51.2 (13.7)	59.3 (17.4)
SGRQ total score	39.0 (20.6)	29.3 (17.0)

Data are mean (SD) or % of patients. Seven patients had GERD and no esophageal distension.

*Presence of GERD was based on "esophageal (dysphagia, reflux)" reported as SSc-related medical history.

†Assessed visually in the whole lung to the nearest 5%. Pure (non-fibrotic) ground-glass opacity was not included.

Table 2. Characteristics of patients by widest esophageal diameter at baseline in the HRCT sub-study of the SENSCIS trial

	Widest esophageal diameter at baseline ≤15mm (n=41)	Widest esophageal diameter at baseline >15mm (n=75)
Female	82.9	60.0
Age, years	56.3 (11.6)	54.0 (12.8)
Race		
White	65.9	64.0
Asian	26.8	26.7
Black or African-American	4.9	6.7
Other	0	1.3
Body mass index, kg/m^2	26.9 (5.9)	25.8 (4.3)
Time since onset of first non-Raynaud symptom, years	2.9 (1.4)	3.1 (1.5)
Diffuse cutaneous SSc	22.0	52.0
mRSS	6.1 (6.9)	9.6 (7.6)
GERD*	68.3	84.0
Extent of fibrotic ILD on HRCT, %†	29.1 (18.5)	39.1 (20.7)
FVC % predicted	78.0 (15.6)	73.7 (16.5)
DLco % predicted	56.0 (17.3)	51.7 (13.7)
SGRQ total score	33.7 (20.4)	39.0 (19.7)

Data are mean (SD) or % of patients. *Presence of GERD was based on "esophageal (dysphagia, reflux)" reported as SSc-related medical history. †Assessed visually in the whole lung to the nearest 5%. Pure (non-fibrotic) ground-glass opacity was not included.

Methods: Patients in the SENSCIS trial had SSc with first non-Raynaud symptom ≤7 years before screening and an extent of fibrotic ILD on HRCT (based on visual assessment of the whole lung) ≥10%. In a sub-study, the presence of esophageal distension and the widest esophageal diameter (i.e. the largest distance between internal esophageal mucosal limits for three diameter measurements) were assessed at baseline using high-resolution computed tomography (HRCT). In descriptive analyses, we assessed the characteristics of patients in subgroups by the presence (yes/no) of esophageal distension and GERD, and by widest esophageal diameter ≤15mm vs >15mm at baseline.

Results: Of 576 patients in the SENSCIS trial, 150 participated in the HRCT sub-study, of whom 117 had data available on esophageal distension at baseline. Of these, 85 (72.6%) had both esophageal distension and GERD, 25 (21.4%) had esophageal distension and no GERD, and 7 (6.0%) had GERD and no esophageal distension. Compared with patients with esophageal distension but no GERD, the subgroup of patients with both esophageal distension and GERD had a greater proportion of patients with diffuse cutaneous SSc, worse modified Rodnan skin scores, greater extent of fibrotic ILD on HRCT, worse lung function, and worse quality of life based on the St George's Respiratory Questionnaire (SGRQ) total score (Table 1). Of 116 patients with data available on esophageal diameter at baseline, 75 (64.7%) had a widest esophageal diameter >15mm. Compared with patients with a smaller esophageal diameter, the subgroup of patients with a widest esophageal diameter >15mm had a greater proportion of patients with GERD, greater proportion of patients with diffuse cutaneous SSc, worse modified Rodnan skin scores, greater extent of fibrotic ILD on HRCT, worse lung function, and worse quality of life based on the SGRQ total score (Table 2).

Conclusion: Exploratory analyses of data from a sub-study of the SENSCIS trial suggest that the combination of esophageal involvement and GERD, and a widest esophageal diameter >15 mm, were associated with worse disease severity in patients with SSc-ILD.

Safety and Persistence of Monthly Intravenous Iloprost in Systemic Sclerosis

Patrícia Martins[1], Eduardo Dourado[1], João Eurico Fonseca[1], Vasco C Romão[1] and Catarina Resende[2], [1]Rheumatology Department, Hospital de Santa Maria, Centro Hospitalar Universitário Lisboa Norte, Lisbon Academic Medical Centre and European Reference Network on Rare Connective Tissue and Musculoskeletal Diseases Network (ERN-ReCONNET); Rheumatology Research Unit, Instituto de Medicina Molecular João Lobo Antunes, Faculdade de Medicina, Universidade de Lisboa, Lisbon, Portugal, [2]Centro Hospitalar Universitário Lisboa Norte, Rheumatology Department, Lisbon, Portugal

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Systemic Sclerosis & Related Disorders – Clinical Poster I (0387–0413)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Vasculopathy is a crucial feature of systemic sclerosis (SSc). Raynaud's phenomenon (RP) and digital ulcers (DU) greatly impact the patients' quality of life. Intravenous (IV) iloprost is broadly used to treat RP and DU secondary to SSc. However, no internationally accepted standardised protocol on iloprost use is currently available.

Methods: We reviewed the clinical records of patients with SSc-related DU and/or moderate-to-severe RP (more than two attacks/day with at least moderate pain) not responsive to calcium channel blockers (CCB), receiving or that have received IV iloprost infusions from January 1st 2011 to March 31st 2021. There were no restrictions concerning combination treatments or comorbidities. Our protocol for IV iloprost consists of an initial ten-hour infusion of iloprost 200ng/mL (0.05 mg in 250 ml of 0.9% saline solution) on five consecutive days, followed by a single-day infusion every month. Over the ten hours of infusion, there is a progressive increase of the dose, up to the patient's maximum tolerated dose, ranging from 0.5 to 1.5 ng/kg/min. The infusion rate starts at 4 ml/h and is increased according to the following scheme: 4 mL/h (1st hour), 8 mL/h (2nd hour), 12 mL/h (3rdhour), and then 16 mL/h if tolerated by the patient, until the end of the infusion. Adverse events were assessed by consulting clinical records.

Demographic data	
Female, n (%)	47 (95.9)
Mean age, years ± SD	56.7 ± 18.1
Mean age at diagnosis, years ± SD	47.9 ± 18

ILD, n (%)	18 (36.7)
PAH, n (%)	3 (6.1)
Arthritis/arthralgia, n (%)	18 (36.7)
Concomitant treatment for RP/DU	
Nifedipine/amlodipine, n (%)	45 (91.8)
Bosentan, n (%)	14 (28.6)
Sildenafil, n (%)	5 (10.2)

Table 1. Demographic and clinical data of SSc patients. ACA – anticentromere antibodies; *dcSSc* - diffuse cutaneous systemic sclerosis; DU - digital ulcers; ILD – interstitial lung disease; lcSSc. - limited cutaneous SSc; PAH – pulmonary arterial hypertension; RP - Raynaud's phenomenon; SD - standard deviation; VEDOSS - very early diagnosis of systemic sclerosis.

Results: Forty-nine patients with SSc have been treated with IV iloprost according to our treatment protocol. Patients' characteristics and clinical features are presented in Table 1. Thirty patients initiated iloprost to treat DUs, 14 to treat RP and 5 to treat both. Sixty per cent of patients in the DU group resolved the DUs within the first month of therapy. RP significantly improved in 64% of patients in the RP group within a month. In the RP+DU group, 60% of patients resolved the DUs and significantly improved RP after three months. Currently, 36 patients are actively undergoing treatment. The reasons for discontinuation in the remaining 13 patients included clinical improvement (N=5), switch to treatment with ambulatory elastomeric pump (N=4), death (N=3) or change of follow-up to another hospital (N=1). Iloprost persistence at two and five years after treatment onset was 95.9% and 83.7% (Figure 1), respectively. Nine adverse events were recorded (18.4% of patients): headache was reported in four patients, hypotension in three patients, tachycardia in one patient and generalised erythroderma in one patient.

Conclusion: SSc patients achieved clinical improvement with a good tolerability profile, leading to a high drug persistence rate. Side effects were managed by adapting the infusion rate. Our data support that monthly single iloprostinfusions can be effective, safely administered and adjusted according to the drug tolerance.

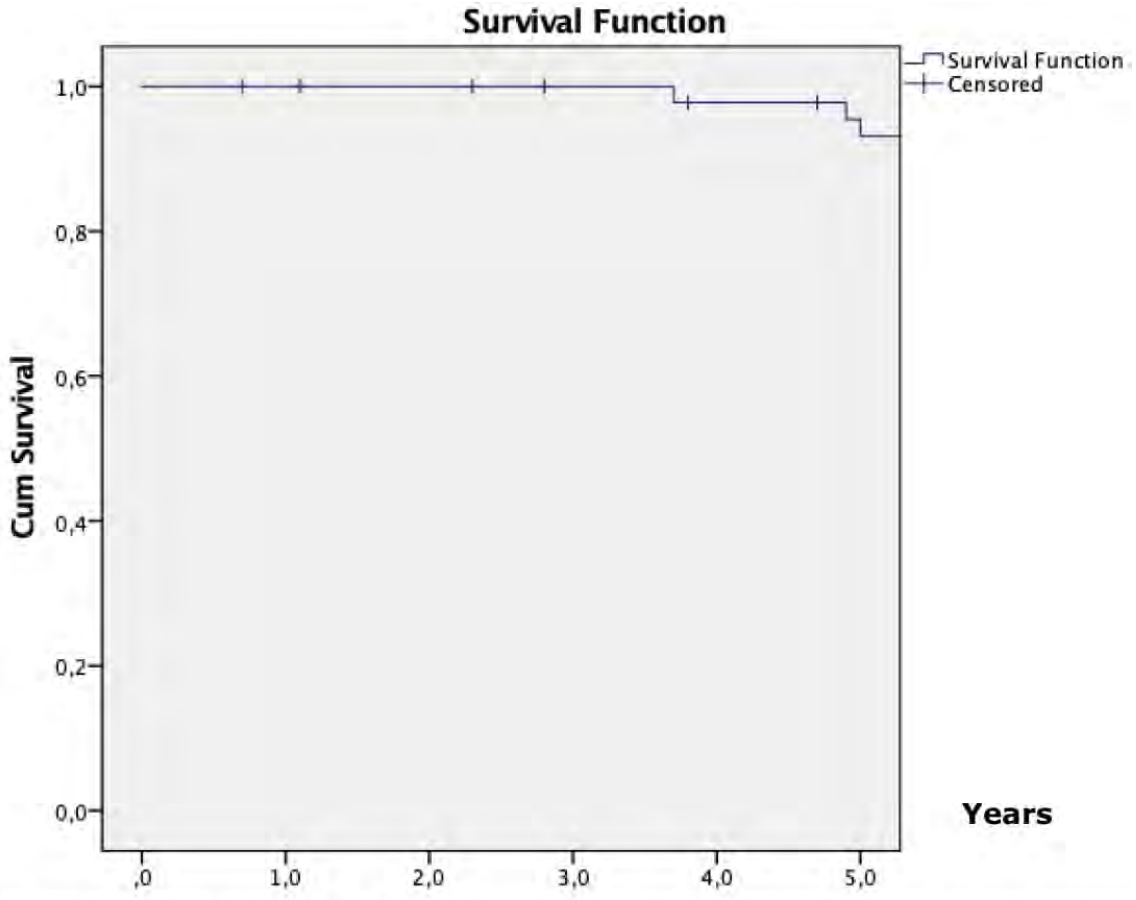

Fig. 1 Kaplan-Meier analysis of the treatment persistence of Iloprost up to five years after treatment onset.

Performance of ACR CRISS Score and Revised ACR CRISS Response in a Phase 3 Trial of Lenabasum in Diffuse Cutaneous Systemic Sclerosis (dcSSc) in Which Background Immunosuppressive Therapies (bIST) Were Allowed

Dinesh Khanna[1], Robert Spiera[2] and Barbara White[3], [1]University of Michigan, Ann Arbor, MI, [2]Hospital for Special Surgery, New York, NY, [3]Corbus Pharmaceuticals, Norwood, MA

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Systemic Sclerosis & Related Disorders – Clinical Poster I (0387–0413)

Session Type: Poster Session A

Session Time: 8:30AM–10:30AM

Background/Purpose: ACR CRISS score is the probability of improvement from baseline in each participant (pt) ranging from 0 to 1 (no to high probability), based change in 5 core items: mRSS, FVC%, PtGA, MDGA, and HAQ-DI. Development of this score was done by experts who assessed profiles of dcSSc pts who were recruited in clinical practice on bIST, so its performance and reflection of pt opinion of improvement is unknown in clinical trials in which

Table 1. ACR CRISS Scores by Background Immunosuppressive Therapies and Participant-reported Category of Improvement, at 1 Year

Background immunosuppressive therapies (bIST)	n, % N = 325	ACR CRISS score, median, by participant-reported category of improvement from baseline, range 0 – 1		
		All	Moderate	Major
MMF	171 (53%)	0.937	0.954	0.990
Non-MMF bIST	105 (32%)	0.810	0.962	0.981
All treatments	325 (100%)	0.853	0.951	0.983

Table 2. Revised ACR CRISS Responses, by Background Immunosuppressive Therapies and Participant-reported Category of Improvement, at 1 Year

Background immunosuppressive therapies (bIST)	rCRISS response	% participants achieving rCRISS responses, by participant-reported category of improvement at 1 year		
		All	Moderate	Major
MMF All, n = 171 Moderate improvement, n = 45 Major improvement n = 37	20/5	56%	67%	65%
	25/5	49%	60%	57%
	30/5	42%	**47%**	**54%**
	35/5	36%	**38%**	**51%**
	40/5	33%	**33%**	**46%**
Non-MMF bIST All, n = 105 Moderate improvement, n = 26 Major improvement n = 9	20/5	40%	50%	67%
	25/5	35%	42%	67%
	30/5	28%	**35%**	**56%**
	35/5	20%	**19%**	**44%**
	40/5	20%	**19%**	**44%**
All treatments All, n = 325 Moderate improvement, n = 83 Major improvement n = 48	20/5	47%	57%	63%
	25/5	41%	51%	56%
	30/5	34%	**41%**	**52%**
	35/5	27%	**29%**	**48%**
	40/5	25%	**27%**	**44%**

bIST such as mycophenolate (MMF) are widely used. Revised ACR CRISS (rCRISS) responses are the proportion of pts who improve in ≥ 3/5 core items by certain percentages, for example, 30% (except ≥ 5% in FVC%). Performances were assessed of ACR CRISS score (prospectively as primary endpoint) and rCRISS responses (retrospectively) in a Phase 3 trial in which bIST were allowed.

Methods: Data were analyzed from a 1-year Phase 3 double-blind, placebo-controlled study of lenabasum in pts with dcSSc ≤ 6 years duration, with stable doses of bIST allowed. Pts completed a Patient Global Assessment of Change to categorize their improvement as None, Slight, Moderate, or Major. All cohorts were combined for analyses as the primary endpoint was not meet. Pre-specified analyses had identified a statistically significant effect of MMF on ACR CRISS score in this study, so analyses were done first in pts on MMF, then results validated in other patients.

Results: 276/325 (85%) pts were on bIST. Among 171 pts on MMF, 65% of pts reported improvement at 1 year, which was moderate or major in 48%. ACR CRISS score had a ceiling effect (median = 0.937), with similar scores in pts reporting moderate and major improvement (Table 1). rCRISS responses were examined for potential to distinguish between higher levels of treatment effect, reported by pt opinion. Pts on MMF who reported moderate or major improvement had ~3 core items that improved by ≥ 20% vs. ~2 core items in pts reporting no improvement, supporting requirement for ≥ 3 core items to improve when defining rCRISS responses. rCRISS responses of at

least 30/5 (≥ 3 core items improved by ≥ 30%, except ≥ 5% for FVC%) were numerically greater in pts on MMF who reported major vs. moderate improvement (Table 2), with greater discrimination using 35/5 and 40/5 than 30/5 responses. The rCRISS 30/5, 35/5, and 40/5 responses were 52%, 48%, and 44%, respectively, in pts reporting major improvement on background MMF (Table 2). All these findings were directionally confirmed in pts on non-MMF bIST.

Conclusion: In this Phase 3 trial, bIST provided treatment effect, with about half the pts on background MMF reporting moderate or major improvement at 1 year. Use of the ACR CRISS score to prove efficacy on top of bIST was constrained by its ceiling effect. rCRISS 30/5 or greater responses may help distinguish high level treatment effects on top of bIST. rCRISS responses may be ~ 50% in pts given placebo on top of bIST, setting a high bar for proving additional treatment effect. Use of rCRISS responses to improve the ACR CRISS score may decrease the ceiling effect, provide an equal weight for 5 core items, and improve the interpretation of data (similar to ACR 20% response in RA). These findings should be confirmed in other trials in which pts receive current standard treatment with bIST.

Abstract Number: 0399

Nailfold Videocapillaroscopy Findings and Associations with Organ Involvement in Mixed Connective Tissue Disease

Camille Kasser, Gonçalo Boleto, Yannick Allanore and Jerome Avouac, Université de Paris, Service de Rhumatologie, Hôpital Cochin, AP-HP.CUP, Paris, France

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Systemic Sclerosis & Related Disorders – Clinical Poster I (0387–0413)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Mixed connective tissue disease (MCTD) is a rare autoimmune condition characterized by Raynaud's phenomenon, positivity of antibodies targeting the U1 small nuclear ribonucleoprotein particle (U1 snRNP), various clinical features and potential risk of severe cardio-pulmonary involvement (interstitial lung disease, ILD, and pulmonary hypertension, PH).

Nailfold videocapillaroscopy (NVC) is a simple, non-invasive and inexpensive imaging technique that allows a detailed assessment of skin microcirculation. NVC abnormalities have been barely described in MCTD and associations between NVC features and MCTD disease characteristics have only been partially investigated. Our objective was to describe the NVC patterns observed in MCTD and assess their potential association with disease characteristics.

Figure 1. Representative nailfold videocapillaroscopy (NVC) patterns; A, normal NVC pattern; B, non-specific organic microangiopathy; C, Scleroderma pattern.

Methods: Cross-sectional study based on the retrospective analysis of patients hospitalized in the department of Rheumatology, Cochin Hospital, Paris France. To be included, patients were required to fulfill at least one classification criteria used in MCTD. The following data were collected: demographics, clinical features, para-clinical and laboratory data, treatment, and NVC findings.

Results: 51 patients met the inclusion criteria. Mean age was 51±12 years, 44 (86%) were women, mean disease duration was 13.8±11.1 years and 16 patients (31%) had ILD. Three different NVC patterns have been identified in our cohort: a) normal findings in 6 patients (11,7 %) (Figure 1A); b) non-specific organic microangiopathy in 16 patients (31,4%) (Figure 1B) and c) scleroderma pattern in 18 patients (35.3%) (Figure 1C), defined by the presence of at least 3 of the 4 following features: at least 1 giant capillary, decreased capillary density (< 7/mm), avascular areas and disorganization of capillary bed architecture (4). Scleroderma pattern was associated with clinical features of systemic sclerosis: skin sclerosis (9/18 vs. 5/33; p=0.008) and digital ulcers (6/18 vs. 2/31; p=0.017). Conversely, no association was observed between the normal or the non-specific NVC pattern and disease specific characteristics. Interestingly, we observed a significant reduction in the number of capillaries in patients with ILD (4.80±1.87 vs. 6.03±1.47; p=0.039), and patients with severe reduction of capillary density (≤4/mm) were more likely to have ILD (5/7 vs. 5/33; p=0.002). Neoangiogenesis was also more frequent in patients with ILD (6/13 vs. 4/27; p=0.034). Multivariate logistic regression analysis showed that the association between severe reduction of capillary density and ILD was observed independently of the presence of a scleroderma NVC pattern and skin fibrosis.

Conclusion: We identified three main NVC patterns in MCTD patients. The scleroderma NVC pattern was associated with clinical scleroderma characteristics whereas non-specific microangiopathy and normal NVC were not associated with a specific phenotype. Moreover, severe capillary loss was independently associated with the presence of ILD. These data suggest that NVC may be helpful for disease risk stratification in MCTD, and that NVC findings, and particularly severe capillary loss, may be a warning for the presence of ILD.

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Systemic Sclerosis & Related Disorders – Clinical Poster I (0387–0413)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: The episodic and uniquely personalised nature of Raynaud's phenomenon (RP) has led to reliance upon self-report to capture how patients 'feel' and 'function'. Existing diary-based patient-reported outcome (PRO) instruments have not supported marketing authorisation of promising therapeutic interventions for RP in patients with systemic sclerosis (SSc). We report item development for the novel Assessment of Systemic sclerosis-associated RAynaud's Phenomenon (ASRAP) questionnaire.

Methods: The conceptual framework for the ASRAP questionnaire was to devise a novel PRO instrument that captured the severity and impact of SSc-RP. A provisional item bank was developed with input from patient insight partners with candidate items grounded in the themes and sub-themes identified in an earlier international multicentre qualitative research study of SSc-RP (Figure 1). Iterative modification of the items was undertaken with input from 4 SSc experts and a patient research partner to ensure item wording, recall period and response options were simple, understandable, relevant to specific domain concepts and conformed to internationally agreed standards. Linguistic evaluation was assessed using the Simple Measure of Gobbledygook (SMOG) with modification to achieve a readability age of < 14 years. Cognitive de-briefing interviews were held with English-speaking

Figure 1. Conceptual map of the patient experience of Systemic sclerosis-associated Raynaud's phenomenon

#25. Raynaud's symptoms have interfered with my home/family life	SMOG index: 16.2 Total words: 8 Polysyllabic words: 2	#25. Raynaud's symptoms have had an effect on my home / family life	SMOG index: 13.8 Total words: 12 Polysyllabic words: 1
#26. Raynaud's symptoms have interfered with personal relationships	SMOG index: 18 Total words: 7 Polysyllabic words: 3	#26. Raynaud's symptoms have had an effect on my personal / private life	SMOG index: 13.8 Total words: 12 Polysyllabic words: 1
#28. Visiting a grocery store /supermarket has caused Raynaud's symptoms	SMOG index: 18 Total words: 9 Polysyllabic words: 3	#28. Going inside a grocery store / supermarket has caused Raynaud's symptoms	SMOG index: 13.8 Total words: 12 Polysyllabic words: 1
#35. I have limited my activities (going outside/doing things I enjoy) to avoid worsening Raynaud's symptoms	SMOG index: 19.6 Total words: 15 Polysyllabic words: 4	#35. I have avoided doing things (e.g. going outside / doing things I enjoy) to avoid making my Raynaud's symptoms worse	SMOG index: 11.4 Total words: 21 Polysyllabic words: 1

patients at US and UK sites. An item tracking matrix was devised to document modifications throughout the item development process.

Results: A provisional item-bank of 37 candidate items was devised to capture the patient experience of SSc-RP with respect to physical symptoms (n=10), emotional distress (n=7), impact on daily life (n=6), exacerbating factors (n=6), self-management (n=4), adaptation (n=3) and uncertainty (n=2). An additional 2 items were proposed following expert review. Item recall period and response options were optimised for item response theory. Modification to 11 items to improve readability ensure a SMOG index < 14.0 for all items (Figure 2). Cognitive de-briefing interviews were held with 7 patients and led to modification to 11 items, alongside changes to format and structure of the ASRAP questionnaire (Figure 3). No new items were proposed during cognitive de-briefing.

Conclusion: The ASRAP questionnaire item bank has been devised and tested with direct input from an international consortium of SSc experts and patients. The items have been tested to ensure they reflect the intended conceptual framework and fully capture the lived experience of SSc-RP in wording that is comprehensible, minimizes ambiguity

Figure 3. Item Tracking Matrix detailing changes to format and item wording following cognitive de-briefing interviews

Item number or general change	Original item wording/formatting	New item wording/format change
Strengthen focus on 7-day recall period	Considering your Raynaud's attacks over the last 7 days [presented in lower case bold)	In the **PAST 7 DAYS**... [shortened with 'past 7 days' presented in capital letters, in bold and underlined using largest font possible]
9	How often have you experienced attacks of Raynaud's symptoms?	On average, how often have you experienced attacks of Raynaud's symptoms?
10	On average, how much total time have you spent each day experiencing attacks of Raynaud's symptoms?	On average, how much total time per day have you experienced attacks of Raynaud's symptoms?
11	Response option 4: '10-20 minutes' Response option 5: 'Over 30 minutes'	Change response option 4 to '10-25 minutes' Change response option 5 to 'over 25 minutes'
12	Raynaud's symptoms have made me upset/tearful	Raynaud's symptoms have made me tearful
14	Raynaud's symptoms have made me Annoyed/frustrated	Raynaud's symptoms have made me frustrated
18	Raynaud's symptoms have caused low mood / made me depressed	Raynaud's symptoms have made me sad/depressed
23	Raynaud's symptoms have made social events / doing sport difficult	Raynaud's symptoms have made social events / doing exercise difficult
27	I have been able to reduce (control) the intensity my Raynaud's symptoms?	I have been able to reduce (control) the intensity of my Raynaud's symptoms?
28-32	'This activity not undertaken' currently on far left of response options	Move 'This activity not undertaken' response option column to the far right
28	Going inside a grocery store / super-market has caused Raynaud's symptoms	Being inside a grocery store / super-market has caused Raynaud's symptoms
31 and 32	Inadvertent consideration of being indoors by one subject	Switch positions of items 31 and 32
34	I have used hand warmers/put my hands in warm water to control/ manage Raynaud's symptoms	I have used techniques (e.g. hand warmers/putting hands in warm water/sitting on hands) to control/ manage Raynaud's symptoms'
39	Changes to my normal routine have caused me to worry about possible worsening of Raynaud's symptoms	A change in my normal routine has caused me to worry about possible worsening of my Raynaud's symptoms

and meets accepted criteria for optimal translatability into non-English languages. The provisional 39-item ASRAP questionnaire shall progress to formal validation.

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Systemic Sclerosis & Related Disorders – Clinical Poster I (0387–0413)

Session Type: Poster Session A

Session Time: 8:30AM–10:30AM

Background/Purpose: The Assessment of Systemic sclerosis-associated RAynaud's Phenomenon (ASRAP) questionnaire is a novel patient-reported outcome (PRO) instrument devised to assess the severity and impact of SSc-RP. We report a data driven approach to item reduction of the preliminary 39-item questionnaire.

Methods: The international multicentre ASRAP validation study enrolled SSc patients with RP from English speaking UK (n=3) and US (n=4) SSc centres during 2 consecutive winters (2019-2021). All participants completed a 39-item ASRAP questionnaire. Pooled data was used to assess dimensionality, before splitting the cohort to facilitate exploratory and confirmatory factor analyses (CFA). Items with low factor loadings < 0.5 and/or low item discrimination parameter estimates (α< 1.5) were considered for removal. Local dependency (LD) marginal Chi square analyses identified redundant items. Goodness-of-fitness testing examined the extent to which observed data fitted the item response model. Finally, differential item functioning (DIF) explored extent to which each item may measuredifferent concepts according to geographic enrolment (UK versus US sites). At each step, items were retained if content validity considered them essential.

Results: A total of 438 SSc subjects were enrolled at UK (n=238) and US (n=200) sites, with adequate data for analysis on 421 subjects. Eigenvalues for uni- and bi-dimensional options were 21.577 and 3.08 respectively. A single

Figure 1. Example Item Discrimination Parameter estimates for ASRAP Items 1 & 2 (α values >1.0 satisfactory)

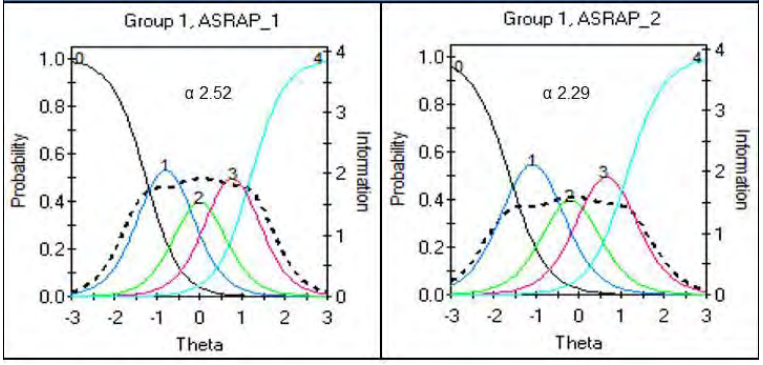

Figure 2. Local Dependency Marginal Chi Square analysis for redundancy (LD Chi Square values <10 desirable and higher values indicate greater redundancy)

Item Pairing		LD Chi-Square	Decision
ASRAP_1	ASRAP_2	12.3	Remove item 2
ASRAP_1	ASRAP_3	10.3	
ASRAP_2	ASRAP_3	26.9	
ASRAP_3	ASRAP_5	12.6	Remove item 5
ASRAP_3	ASRAP_6	10.2	
ASRAP_4	ASRAP_5	11.7	
ASRAP_6	ASRAP_7	19.8	Retain both
ASRAP_9	ASRAP_10	27.4	Remove item 10 Retain item 9
ASRAP_9	ASRAP_11	12.1	
ASRAP_10	ASRAP_11	39.6	
ASRAP_25	ASRAP_26	25.7	Remove item 25
ASRAP_28	ASRAP_29	17.3	Remove item 29
ASRAP_33	ASRAP_37	11.1	Retain both
ASRAP_35	ASRAP_38	19.3	Remove item 38

Figure 3. Summary of item reduction for ASRAP questionnaire

Item	Factor Analysis		IRT Analysis				Content Review
	Exploratory	Confirmatory	*a* parameter	Local Dependency	Model Fit	DIF-Location	
Item 1							
Item 2				X		X	REMOVE
Item 3							
Item 4							
Item 5				X		X	REMOVE

Item 34			X				REMOVE
Item 35						X	REMOVE
Item 36-37							
Item 38				X	X		REMOVE
Item 39							

factor solution provided the best-fitting model with factor loadings for the majority of factors ~0.8. Three items were removed owing to lower factor loadings (0.415-0.443). CFA revealed a Root Mean Square Error of Approximation of 0.114, a Standardized Root Mean Square Residual of 0.083 and a Confirmatory Factor Index of 0.917; each indicating excellent fit. Four low scoring Item Discrimination Parameter estimates (Figure 1) were identified (alpha scores of 1.04-1.25), leading to removal of one item (the remainder having already been removed). Only 14 potentially redundant pairings were identified using LD marginal chi square (>10 indicates redundancy), which led to the removal of a further 6 items (Figure 2). Model fit analyses identified 3 problematic items; one of which was removed, one retained due to content validity and the other already removed). Finally, DIF identified 3 items which differed due to geographic location (2 already removed) and led to removal of an item (Figure 3).

Conclusion: We report a data driven approach (focussed on item response theory) to removing problematic or redundant items from the provisional ASRAP item bank. This has facilitated item reduction to a 27-item PRO instrument that will undergo psychometric testing and other tests of reliability and construct validity.

What Is the Patient's Perspective on Symptoms Experience in Limited Cutaneous Systemic Sclerosis?

Alain Lescoat[1], Susan Murphy[2], Yen Chen[3], Nadia Vann[1], David Cella[4] and Dinesh Khanna[3], [1]Michigan Scleroderma Program, University of Michigan, Ann Arbor, MI, [2]University of Michigan, Grosse Ile, MI, [3]University of Michigan, Ann Arbor, MI, [4]Department of Medical Social Sciences, Northwestern University Feinberg School of Medicine, Chicago, IL

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Systemic Sclerosis & Related Disorders – Clinical Poster I (0387–0413)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Limited cutaneous SSc (lcSSc) affects approximately 60-70% of SSc patients but drug development and therapeutic research has largely focused on the more severe diffuse SSc. As a result, lcSSc has been rather neglected with respect to development of relevant outcome measures. To identify relevant candidate items (outcome measures) to include in a future combined response index for clinical trial assessment of lcSSc patients (the CRISTAL index: Combined Response Index for Scleroderma Trials Assessing Limited SSc), this qualitative study aimed to identify the most salient domains affecting everyday life from the patients' perspective and to capture the overall symptom experience of lcSSc.

Table 1: Domains and outcomes reported as bothersome or impacting by patients with lcSSc

Domains mentioned (22) *=mentioned in all focus groups	Symptoms and/or outcomes mentioned (93)	
Fatigue*	-Tiredness -Exhaustion / Lack of endurance	-Mental fatigue -Running out of energy
Cognition	-Brain fog / memory loss	
Digital Ulcers*	-Sores / open digital wounds -Foot hole / digital ulcers on the toes -New DU onset -Number of DUs / recurrent DUs -DU healing-time /time to heal	-DU-related pain -DU-related Neuropathic pain -Auto-amputation / Acro-osteolysis -Surgical amputation -infected DU
Gastro-Intestinal*	-GERD -Heartburns -Dysphagia -Throwing up -Failed swallowing -cough -Sore Throat	-Odynophagia -gastroparesis -early satiety -stomach pain -Diarrhea -Weight loss -malabsorption
Raynaud's*	-Attacks or episodes -Lack of circulation -Finger pain / Fingertip pain -Numbness/loss of feeling -Ischemia-reperfusion	-Finger/hand stiffness -Color change -Acrocyanosis -Chilblains -cold extremities
Calcinosis	-Onset of calcinosis -Calcinosis-related pain -pseudo-tumoral calcinosis	-affecting different body parts -flares/episodes of calcinosis
Pulmonary*	-Dyspnea / shortness of breath -Evolution of PFT parameters	-CT scan evolution / Lung fibrosis
Sicca syndrome	-dry eyes -dry mouse	-Tongue burn / sensitive oral mucosa
Musculoskeletal*	-joint pain -synovitis / tenosynovitis -morning stiffness -Joint tenderness	-Diminished range of motion -Muscle pain -Strength loss -cramps
Pain	-Neuropathic pain -Soft tissue pain	-Indescribable pain -Fibromyalgia-like or fibromyalgia-related pain
Skin*	-Hand/finger/feet puffiness or swelling -Itching/pruritus -skin thickening -skin tightening -hypertrophic cuticles / cuticles splitting	-extent of skin involvement / mRSS -skin cracks -Aspect/appearance of the hands / Overall skin appearance -Finger and hand deformity
Vasculopathy other than DU and/or Raynaud	-Widespread vasculopathy -telangiectasia	-obliterative vascular disease
Cardiac*	-Shortness of breath -Left ventricular heart failure -Right heart catheterization parameters	-PH/PAH -Diastolic dysfunction / Myocardial fibrosis
Sleep	-difficulties in staying asleep/night awakenings	-difficulties in falling asleep
Sexual Health	-Dyspareunia	-Erectile dysfunction
Renal	-Renal insufficiency / need for dialysis	
Dental Health	-Teeth loss / Tooth decay	
Mental Health	- Low moral/ Negative ideas	-Depression
Global Health	-General looking -General shape	-General feeling
Quality of Life	-Altered quality of life	
Survival	-Shorter life expectancy	
Biomarkers	-Acute phase reactants	

Methods: A participatory action research approach facilitated collaboration between patients and researchers in the identification of domains and candidate items that lcSSc patients consider most important (i.e., symptoms that are most bothersome and affect daily life). Focus groups with lcSSc were conducted using a predefined guide with 10 open-ended questions. The number of focus groups was determined by data saturation. Focus groups were

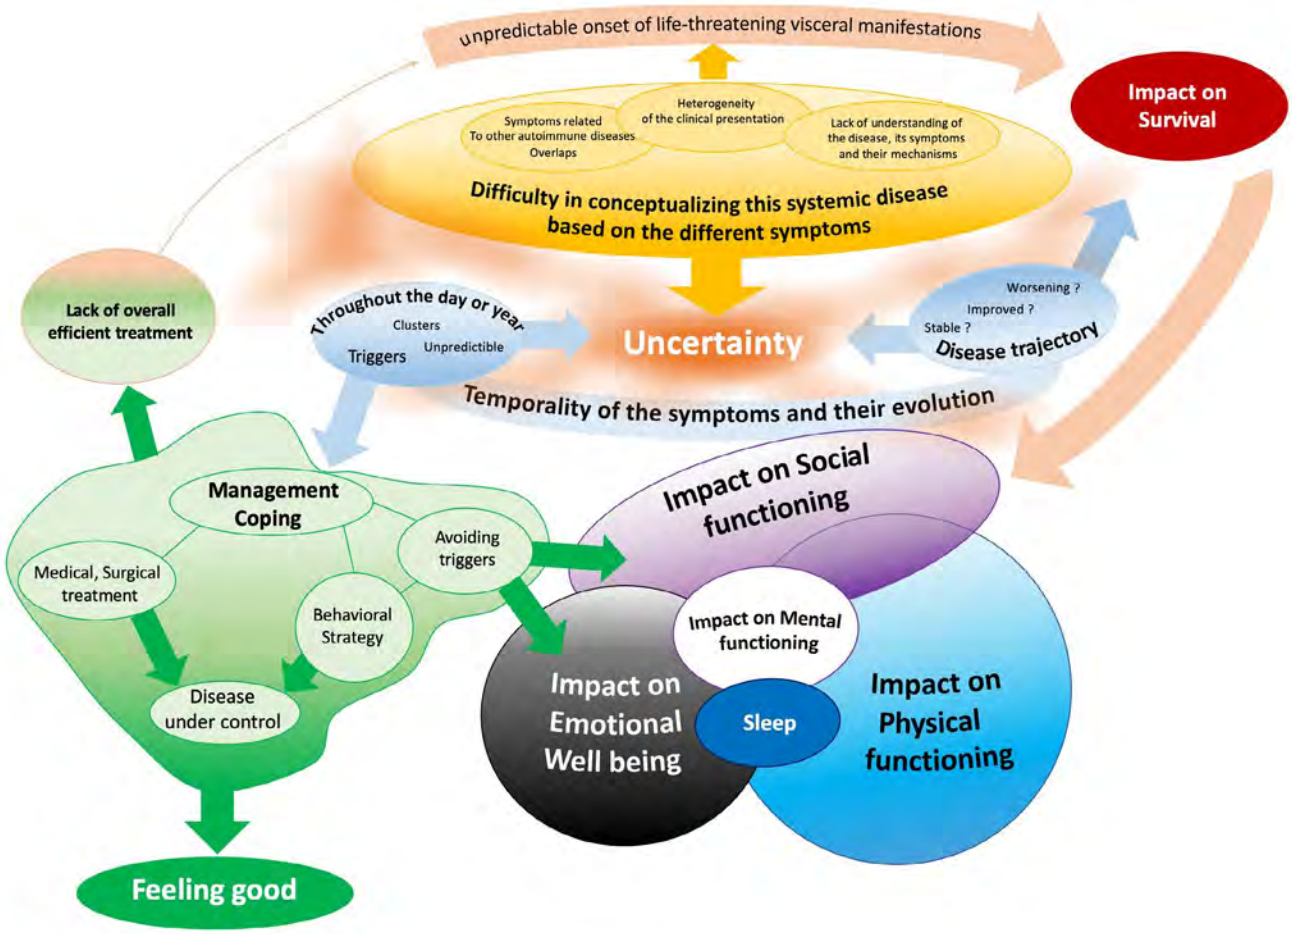

Figure 1 : Preliminary conceptual model of symptom experience in patients with lcSSc

recorded, transcribed verbatim, and de-identified. A hierarchical taxonomy of domains/outcomes and experience-related themes was developed using an iterative, deductive and inductive approach with two independent coders. Throughout the coding process, the codebook was revised and edited in a collaborative process that included a patient partner as co-investigator.

Results: Twenty-six patients with lcSSc (median age 56 yo (25-77yo); 42% with early disease< 5 years, 15.4% >20 years) from the University of Michigan were included in 4 focus groups lasting 2-hours each. One group included only men; two were only women; and one was with both sexes. Twenty-two domains were identified, comprising 93 symptoms and/or outcomes. Eight domains were reported in all four focus groups: fatigue, digital ulcers, gastro-intestinal involvement, Raynaud's phenomenon, pulmonary involvement, cardiac involvement, musculoskeletal manifestations and skin involvement (**Table 1**). The 14 remaining domains notably included calcinosis, sicca syndrome, sexual health and survival. In terms of symptom experience, 6 themes were identified: difficulty in conceptualizing the disease, experiencing the temporality of SSc-related symptoms, uncertainty, need for coping and better management, impact of the symptoms on functioning (comprising social, mental and physical functioning) and impact of the symptoms on emotional well-being. The connections between these themes are represented in a preliminary conceptual map (**Figure 1**).

Conclusion: This qualitative study based on a participatory action research approach allowed a comprehensive identification of key domains and related-outcomes in lcSSc and provide in depth analysis on symptoms experience

in this neglected but frequent subset of the disease. These results paved the way for the selection of candidate items (outcome measures) to include in a future patient-centered, combined response index for clinical trial assessment of lcSSc.

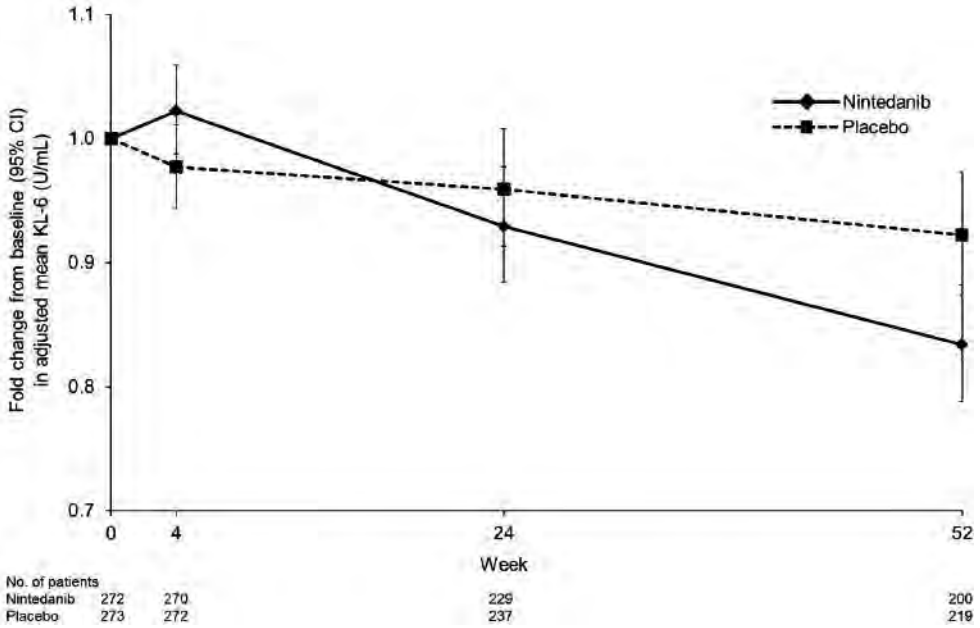
SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Systemic Sclerosis & Related Disorders – Clinical Poster I (0387–0413)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Krebs von den Lungen-6 (KL-6), a marker of lung epithelial and endothelial injury, has been associated with progression of interstitial lung disease associated with systemic sclerosis (SSc-ILD). In the SENSCIS trial, nintedanib, an intracellular inhibitor of tyrosine kinases, slowed the rate of decline in forced vital capacity (FVC) in patients with SSc-ILD compared with placebo. We assessed the associations between levels of KL-6 and clinical variables, and the effect of nintedanib on changes in KL-6 in the SENSCIS trial.

Methods: Patients in the SENSCIS trial had SSc with first non-Raynaud symptom ≤7 years before screening and an extent of fibrotic ILD on HRCT ≥10%. Blood samples for biomarker analysis were taken at baseline and at weeks 4, 24 and 52. Absolute changes from baseline in KL-6 over 52 weeks were analyzed using a mixed model for repeated measures and restricted maximum likelihood approach. Data were $\log_{10}$ transformed prior to analysis and estimates of change from baseline were back-transformed to provide fold changes. Associations between KL-6 levels and age, FVC, DLco, SpO_2, modified Rodnan skin score, St George's Respiratory Questionnaire total score, and digital ulcer net burden at baseline, and between changes from baseline in KL-6 and each clinical variable over 52 weeks, were assessed using Spearman's correlation coefficients (rho). Correlations with a coefficient ≥0.25 and a p-value < 0.05 were considered notable.

Results: Of 576 treated patients, 559 (97.0%) had data on KL-6 levels at baseline. At baseline, there was a weak negative correlation between KL-6 levels and DLco % predicted (rho: –0.38 [95% CI: –0.45, –0.31]; nominal p< 0.0001).

Figure. Fold changes from baseline in KL-6 over 52 weeks based on a mixed model for repeated measures with fixed categorical effects of treatment at each visit, anti-topoisomerase I antibody status, sex, SSc subtype (limited cutaneous SSc or diffuse cutaneous SSc), mycophenolate use at baseline, methotrexate use at baseline, and fixed continuous effects of baseline KL-6 value at each visit, body mass index and age.



No notable correlations were observed between KL-6 and other clinical variables at baseline. No notable correlations were observed between changes in KL-6 and changes in other clinical variables over 52 weeks. Fold changes from baseline in adjusted mean KL-6 at week 52 were 0.83 (95% CI: 0.79, 0.88) in the nintedanib group and 0.92 (95% CI: 0.87, 0.97) in the placebo group (ratio of 0.91 [95% CI: 0.84, 0.98]; nominal p=0.01) (Figure). Mean (SE) absolute changes from baseline in KL-6 at week 52 were –202.2 (47.5) U/mL in the nintedanib group and –124.5 (54.8) U/mL in the placebo group. There was no significant difference between the nintedanib and placebo groups in fold change from baseline in adjusted mean KL-6 at week 24.

Conclusion: In the SENSCIS trial in patients with SSc-ILD, higher KL-6 levels at baseline were associated with lower DLco % predicted. KL-6 levels decreased over 52 weeks both in the nintedanib and placebo group, with a larger decrease in the nintedanib group. These data suggest that KL-6 demonstrates a pharmacodynamic response to nintedanib in patients with SSc-ILD over 52 weeks of treatment.

Perifollicular Hypopigmentation in Systemic Sclerosis: Associations with Clinical Features and Internal Organ Involvement

Melody Chung[1], Jamie Perin[1], Carrie Richardson[2], Christopher Mecoli[3], Fred Wigley[1] and Zsuzsanna McMahan[4], [1]Johns Hopkins University, Baltimore, MD, [2]Rush University Medical Center, Chicago, IL, [3]Johns Hopkins University School of Medicine, Baltimore, MD, [4]Johns Hopkins Rheumatology, Baltimore, MD

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Systemic Sclerosis & Related Disorders – Clinical Poster I (0387–0413)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Among the autoimmune rheumatic diseases, there is precedent for utilizing cutaneous manifestations of systemic disease as clues to clinical phenotype and disease prognosis. Though skin thickening affects >90% of patients with SSc, perifollicular hypopigmentation is observed less frequently. We sought to determine whether perifollicular hypopigmentation is associated with demographics, clinical features, and autoantibody profiles.

Methods: Data from SSc patients were prospectively collected from a single tertiary academic medical center. Patients were consecutively recruited, with additional targeted recruitment to enrich for patients with hypopigmentation. A standardized data collection form was completed on each patient including anatomic distribution of hypopigmentation. Autoantibody screens were performed using the commercially available Euroline immunoblot assay [Scleroderma Nucleoli Profile Uroline (IgG); Euroimmun, Lubeck, Germany]. Associations between perifollicular hypopigmentation and distinct features of SSc were assessed using logistic regression.

Results: Of the 179 adult SSc patients enrolled (Table 1), 36 (20%) SSc patients had perifollicular hypopigmentation. Among patients with perifollicular hypopigmentation, 94% (n=34) were female and 33% (n=12) had limited cutaneous SSc. Significant heterogeneity in the distribution of perifollicular hypopigmentation was observed, with dominant patterns involving the face/scalp (n=19), posterior neck (n=14), chest/back/leg (n=12/region), and dorsum hand (n=11) (Table 1). In univariable logistic regression analyses, black race (OR 15.63, 95% CI 6.6-37.20, p< 0.001), diffuse cutaneous disease (OR 4.62, 95% CI 2.11-10.09, p< 0.001), a higher maximum MRSS (OR 1.05, 95% CI 1.02-1.08, p=0.003), myopathy (OR 3.92, 95% CI 1.80-8.57, p< 0.001), a lower minimum FVC % predicted (OR 0.96, 95% CI 0.94-0.99, p=0.001), and a lower minimum DLCO % predicted (OR 0.97, 95% CI 0.95-0.99, p=0.009) were associated with perifollicular hypopigmentation (Table 2). An association with severe GI involvement (OR 2.77, 95% CI 0.85-9.07, p=0.09) trended towards significance. Anti-centromere antibodies inversely associated with perifollicular hypopigmentation (OR 0.24, 95% CI 0.07-0.86, p=0.028). In multivariable logistic regression analyses, diffuse cutaneous subtype (OR 4.28, 95% CI 1.46-12.53, p=0.008) was significantly associated with perifollicular hypopigmentation, even after adjusting for age, race, and disease duration. An association between perifollicular hypopigmentation and the presence of myopathy trended towards significance (OR 2.30, 95% CI 0.87-6.10, p=0.09).

Conclusion: Perifollicular hypopigmentation is observed in a subset of patients with SSc, and associates with diffuse cutaneous disease, black race, and myopathy. The distribution of perifollicular hypopigmentation is variable, with distinct patterns observed across patients. Larger longitudinal studies exploring whether specific patterns of perifollicular hypopigmentation associate with the development of internal organ complications may provide insight into patient risk stratification.

Table 1. Characteristics of the SSc patients with and without perifollicular hypopigmentation in the Scleroderma Center cohort

Clinical and demographic features	Hypopigmentation (n=36)	No hypopigmentation (n=143)	p-value
Age at first symptom, mean (SD)	57 (14)	60 (13)	0.230

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Systemic Sclerosis & Related Disorders – Clinical Poster I (0387–0413)

Session Type: Poster Session A

Session Time: 8:30AM–10:30AM

Background/Purpose: Cardiac involvement is a leading cause of death in systemic sclerosis (SSc). Cardiac MRI (CMR) is useful in the early assessment of cardiac disease. Our aim was to describe the characteristics of patients with inflammatory and/or fibrotic abnormalities on CMR and their clinical outcomes in a large retrospective SSc cohort.

Methods: We identified SSc patients with CMR done from 2010 to 2020 by searching the electronic database of a tertiary-care university center. CMR abnormalities of interest were edema (T2 hyperintensity) and fibrosis (late gadolinium enhancement, LGE). Outcomes included heart failure, atrial and ventricular arrhythmias, need for pacemaker or defibrillator and cardiac death (not attributable to other causes). Student's, Mann-Whitney U and chi-square tests were used to compare patient characteristics.

Results: A total of 114 CMRs performed in 99 patients were identified (95% met ACR-EULAR criteria). Mean (SD) age was 57.8 (11.7) years and median (IQR) disease duration was 5.9 (2.6-12.8) years. Patients were mostly female (80%) and white (92%). Half of CMRs were performed as screening tests (asymptomatic), 25% were done to investigate cardiac symptoms and 25% were done following abnormal cardiac investigations.

After excluding two patients with coronary artery disease-related changes, 12 (12%) patients had inflammatory and/or fibrotic CMR abnormalities (LGE, n=11; T2 hyperintensity, n=5), of whom 4 were asymptomatic. LGE was most often described as heterogeneous, linear or focal/nodular areas of enhancement affecting the left ventricular mid-wall and/or subendocardial layers of the basal and/or mid-cavity segments, in non-ischemic distributions involving the antero-septal (n=5), inferior (n=5), infero-lateral (n=5), anterior (n=3), antero-lateral (n=3) and/or infero-septal (n=2) segments.

Baseline characteristics are presented in Table 1. Patients with abnormal CMR more often had cardiac symptoms/signs or abnormal investigations (80% vs 44%, p=0.02), lower left ventricular ejection fractions (p=0.007) and higher troponin levels (p=0.013). They were also numerically more often males (40% vs 18%) with hypertension (50% vs

Table 1. Baseline characteristics, stratified by the presence of CMR abnormalities

	No CMR abnormalities (n=97)	CMR abnormalities (n=15)	P-values
Age at time of CMR, years (mean, SD)	57.4 (11.4)	60.2 (15.7)	0.478

Smoking (ever)	30 (38%)	3 (33%)	1.000
Hypertension	23 (27%)	5 (50%)	0.255
Diabetes mellitus II	8 (9%)	0 (0%)	0.680
Obesity (BMI >30)	15 (18%)	1 (10%)	0.869
Disease duration at time of CMR, years (median, IQR)	5.9 [2.7, 13.1]	6.8 [1.7, 12.5]	0.674
Diffuse subtype	35 (40%)	4 (40%)	1.000
Anti-centromere	20 (25%)	3 (33%)	0.872
Anti-topoisomerase I	15 (18%)	3 (30%)	0.632
Myositis	9 (11%)	2 (20%)	0.731
Arthritis	24 (28%)	1 (10%)	0.390
Digital ulcers/scars	28 (34%)	5 (50%)	0.506
Interstitial lung disease	46 (54%)	8 (80%)	0.207
Pulmonary arterial hypertension	26 (31%)	3 (30%)	1.000
Cardiac symptoms/signs or abnormal investigations at time of CMR	43 (44%)	12 (80%)	0.022
Left ventricular ejection fraction, % (median, IQR)	60 [57, 64]	56 [46, 58]	0.007
Troponin, ng/L (median, IQR)	7 [5, 14]	20 [10, 32]	0.013
NT-proBNP, ng/L (median, IQR)	40 [19, 67]	52 [23, 60]	0.702
Follow-up time, years (mean, SD)	4.4 (2.9)	3.6 (3.4)	0.457

CMR= Cardiac Magnetic Resonance Imaging

27%), myositis (20% vs 11%), digital ulcers/scars (50% vs 34%), interstitial lung disease (80% vs 54%) and anti-topoisomerase I antibodies (30% vs 18%).

Over a mean (SD) follow-up of 4.3 (2.9) years, no patient developed new-onset heart failure. One patient with normal CMR developed syncope with frequent premature ventricular contractions (6% of QRS complexes) on Holter and inflammation/fibrosis on follow-up CMR, leading to implantable defibrillator placement 3 years after the initial CMR. Two patients with symptomatic myocarditis died from sudden death within one year of the initial abnormal CMR. None of the four asymptomatic patients with CMR abnormalities developed clinically apparent cardiac complications.

Conclusion: In this real-world SSc cohort, CMR abnormalities were found in 12% of patients, most of whom had clinically apparent cardiac disease. Abnormalities in asymptomatic patients were infrequent. Further study is required to determine the value of CMR screening in asymptomatic SSc patients.

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Systemic Sclerosis & Related Disorders – Clinical Poster I (0387–0413)

Session Type: Poster Session A

Session Time: 8:30AM–10:30AM

Background/Purpose: Systemic sclerosis (SSc) is a rare connective tissue disease of unknown etiology, with a broad spectrum of clinical and laboratory features. Evidence for the role of sex in the clinical manifestations of SSc patients is emerging. Some multicenter cohorts have shown that male SSc patients have more severe disease [Freire M, et al. Clin Exp Rheumatol 2017; Peoples C, et al. J Scleroderma Relat Disord 2016].

Our objective was to assess the clinical manifestations and survival in the cohort of Portuguese SSc patients according to gender.

Methods: Data from adult SSc patients included in Reuma.pt database was analyzed. Demographic features, SSc subsets, main clinical and immunological features, treatments used and survival data were evaluated and compared between genders. Survival was calculated for patients included in Reuma.pt within the first two years of diagnosis. Of the 1054 patients included, 716 (68%) fulfilled ACR/EULAR 2013 criteria.

Results: In total, 1054 adult patients with SSc were included, 132 (12.5%) males. No differences in demographic features and comorbidities were found between women and men, except for a higher rate of smokers among men (64.5% vs 19.2%; p< 0.01). Diffuse cutaneous SSc subtype and anti-topoisomerase antibodies were more prevalent in males (Table 1). Raynaud's phenomenon (RP) and skin thickening were the most frequently observed clinical manifestations, RP being more prevalent in females (84.1% vs 94%, p=0.04) and skin thickening proximal to metacarpophalangeal and metatarsophalangeal joints in males (83.2% vs 75%, p=0.03). Additionally, male patients presented significantly more myositis (13.3% vs 4.6%, p< 0.01), interstitial lung disease (38.9% vs 27.1%, p=0.03) and gastric involvement (20.4% vs 11.3%, p< 0.01). One-third of patients were treated with immunomodulators, with

Table 1. Cumulative clinical and immunologic features and treatments used. MCF - metacarpophalageal joints; MTF – metatarsophalangeal joints. Pulmonary arterial hypertension confirmed by right heart catheterization. Immunomodulators include Methotrexate, Leflunomide, Hydroxychloroquine; Immunosuppressants include Azathioprine, Mycophenolate Mofetil and Cyclophosphamide. P-value comparing female and male

PPIs/Ranitidine/Prokinetics – N(%)	353 (33.5)	309 (33.5)	44 (33.3)	0.97

no differences in the pattern of drugs used between genders. During follow-up, more deaths were reported in men (12.1% vs 7.3%, p=0.04). However, the overall 1-, 3- and 5-year survival was not significantly different between men and women (96.4% vs 98.2%, 93% vs 95.9% and 83.4% vs 93.2%, p=0.08, Figure 1).

Conclusion: This study confirms the existence of gender differences in clinical and immunologic features of SSc patients. Although SSc is less common in men, they have a more severe expression of internal organ involvement. Nevertheless, no statistically significant differences were found in survival rates.

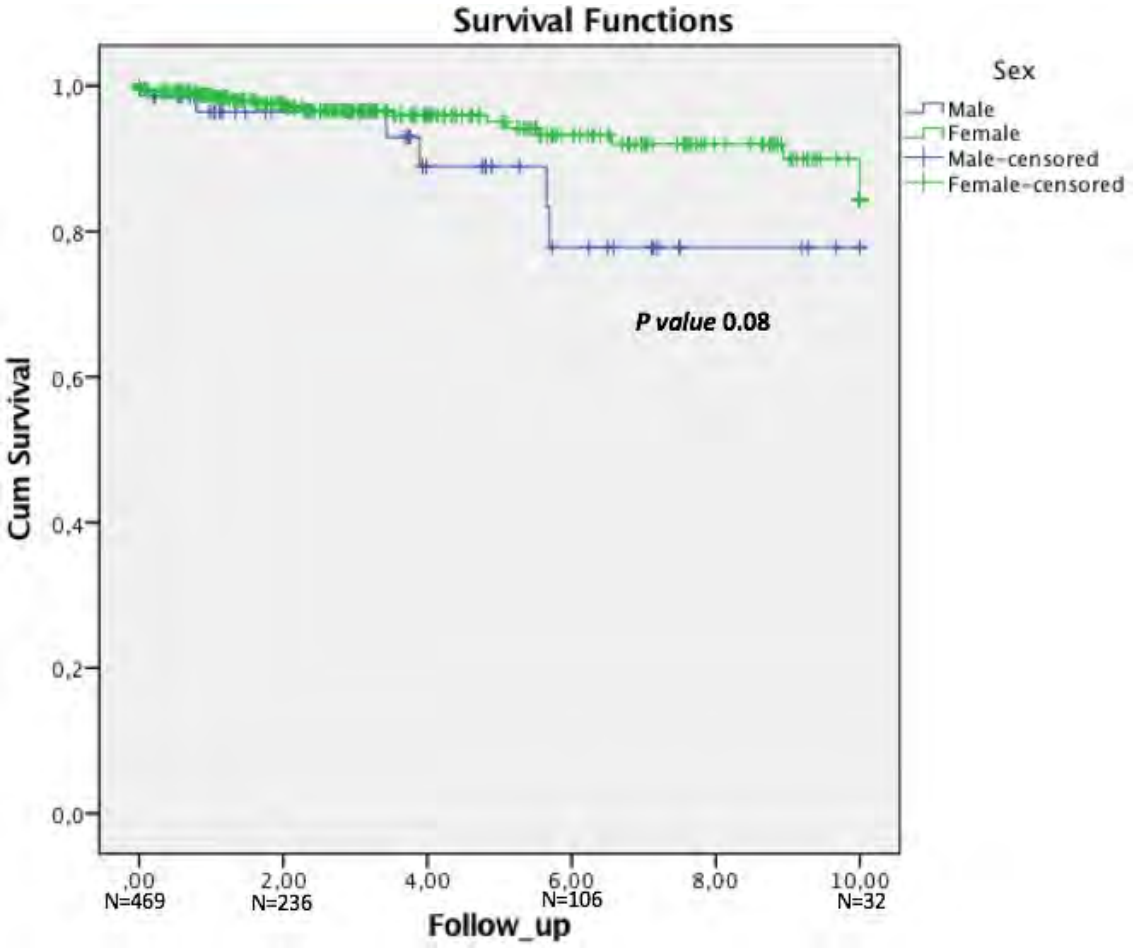

Figure 1. Survival from diagnosis of patients with SSc included in the cohort in the first two years of disease (N=469). The X and Y axes represent follow-up time in years and the proportion of patients still on follow-up, respectively.

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Systemic Sclerosis & Related Disorders – Clinical Poster I (0387–0413)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Systemic sclerosis (SSc) is characterized by skin and internal organs tissue fibrosis including the myocardium. Cardiovascular magnetic resonance (CMR) parametric mapping is a promising modality to detect diffuse myocardial fibrosis.

The study aims to detect early-stage cardiac involvement in SSc using CMR parametric mapping and evaluate the associations with clinical and laboratory findings.

Methods: 24 controls (12 female, 58.0±18.9 years) and 57 SSc patients (51 female, 59.4±12.9 years) underwent CMR at 3.0T and analyzed myocardial damage using parametric mapping and compared with clinical data.

Results: The mean disease duration in the SSc group was 3.9±7.4 years, and four patients had pulmonary hypertension. The mean left ventricular (LV) ejection fraction was 58.3±8.1 in the SSc group and 56.9±7.0 in the control group. LV global longitudinal and circumferential strain evaluated by CMR feature tracking showed no significant differences between the two groups. Focal fibrosis on late gadolinium enhancement was found in 9 SSc patients (15.7%) but none of the controls. Mid-ventricular native T1 and extracellular volume fraction were significantly higher in SSc patients compared with the control group (1331.2±65.4mesc vs. 1253.6±44.1msec, p< 0.0001 and 32.4±4.1% vs. 28.3±3.3%, p< 0.0001, respectively). There was a significant correlation between native T1 and BNP levels (r=0.353,

Puffy fingers, n (%)	23 (41.0%)	11 (57.8%)	0.757

Results: Baseline characteristics of patients with SSc

p=0.008) in the SSc group. SSc patients were divided into two groups, low and medium native T1 group (n=37) and high native T1 group (n=19). Cutaneous vascular symptoms including digital ulcer and telangiectasia were significantly higher in the high native T1 SSc group compared with the low and medium native T1 SSc group (6 (31.5%) vs. 1 (2.7%), p=0.005 and 7 (36.8%) vs. 4 (10.8%), p=0.027). There were no differences in biventricular volume and contraction, but the left and right atrial volume index were significantly larger in the high native T1 SSc group than the low and medium native T1 SSc group (all p< 0.05). In univariate logistic regression analysis revealed that diffuse cutaneous SSc, the coexistence of digital ulcer, telangiectasia, albumin, hemoglobin, and erythrocyte sedimentation rate were independent predictors of mid-ventricular high native T1 values. In multivariate logistic regression analysis, the coexistence of digital ulcers was the only independent predictor of mid-ventricular high native T1 values in the SSc group (p=0.013 odds ratio=12, CI 1.1-138.9).

Results: Univariate and multivariate logistic regression analysis for predicting mid-ventricular septum high native T1

Predictors of high native T1	Univariate logistic regression analysis			Multivariate logistic regression analysis		
	Odds ratio	95% CI	p value	Odds ratio	95% CI	p value
Age	0.993	0.951-1.036	0.743			
Disease duration	1.000	1.000-1.000	0.433			
Diffuse cutaneous SSc	3.560	1.101-11.509	0.034	2.636	0.466-14.896	0.273
Digital ulcer	16.615	1.823-151.454	0.013	12.393	1.105-138.967	0.041
Telangiectasia	4.812	1.193-19.416	0.027	1.760	0.223-13.865	0.591
Interstitial lung disease	3.300	0.941-11.575	0.062			
Brain natriuretic peptide	1.006	1.000-1.013	0.069			
Albumin	0.187	0.049-0.723	0.015	2.089	0.211-20.678	0.529
Hemoglobin	0.543	0.339-0.868	0.011	0.664	0.349-1.265	0.213
Erythrocyte sedimentation rate	1.042	1.005-1.079	0.024	1.030	0.985-1.078	0.199

Results: Univariate and multivariate logistic regression analysis for predicting mid-ventricular septum high native T1

Conclusion: Native T1 mapping is a useful method to detect early myocardial damage in SSc patients. The clinician should take notice of cardiac involvement in SSc patients with progressed skin lesions even without cardiac symptoms.

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Systemic Sclerosis & Related Disorders – Clinical Poster I (0387–0413)

Session Type: Poster Session A

Session Time: 8:30AM–10:30AM

Background/Purpose: High resolution computed tomography (conventional CT) represents the diagnostic gold standard for systemic sclerosis-related interstitial lung disease (SSc-ILD). A low-dose 9-slices (reduced) CT protocol was previously shown to be a highly sensitive tool to screen for ILD and to classify it into limited or extensive according to the Goh et al visual staging system (1). Histogram-based densitometry analysis is an automated quantitative evaluation of SSc-ILD, with mean lung attenuation, skewness, and kurtosis as main variables, recently merged into a Computerized Integrated Index (CII) (2). CII has shown good discrimination of SSc-ILD presence and association with the Goh et al staging on conventional CT. We aimed at testing the CII in reduced CT, in comparison to conventional CT, in discriminating for the presence and severity of SSc-ILD.

Methods: We analyzed prospectively collected conventional and reduced CT images of SSc patients followed at our tertiary referral center. The Goh et al staging (limited vs extensive ILD) was applied by an experienced radiologist. Conventional and reduced CT images were analyzed using the free-source software Horos to obtain the CII, named conventional and reduced CII respectively. We measured the association between CIIs and categories using generalized estimating equations (GEE). The predictive ability of CIIs was assessed in a ROC analysis.

Results: We enrolled 468 SSc patients, further described in the table 1: 427 had undergone at least one conventional CT (total 719 CTs), 345 at least one reduced CT (total 814 reduced CTs). Both CT and reduced CT images were available at the same visits for 243 patients (total 294 conventional + reduced CTs). The three groups were comparable

Table 1. Characteristics of the study population

Parameters	Distribution among the whole cohort (n=468)
Age [years, mean ± SD]	57 ± 14
Disease duration [years, mean ± SD]	9 ± 11
Female sex [n (%)]	381 (81.4)
Diffuse cutaneous subset [n (%)]	112 (24)
Anti-Centromere antibody positive [n (%)]	212 (45)
Anti-Topoisomerase I antibody positive [n (%)]	126 (27)
Anti-RNA polymerase III antibody positive [n (%)]	50 (11)
Anti-PM/Scl antibody positive [n (%)]	55 (12)
Digital ulcers [ever, n (%)]	98 (21)
Arthritis [ever, n (%)]	83 (18)
Pulmonary arterial hypertension [n (%)]	21 (4)
Scleroderma Renal Crisis [n (%)]	9 (2)
Interstitial lung disease on HRCT [n (%)]	212 (45)
Extensive ILD on HRCT [n (% of ILD positive patients)]	54 (26)
FVC% [mean ± SD]	96 ± 20
DLCO% [mean ± SD]	75 ± 22
NYHA functional class ≥ 2 [n (%)]	177 (38)
Ongoing immunosuppressive medication [n (%)]	93 (20)

in terms of ILD prevalence and extensive ILD (48% vs 45% vs 48% and 25% vs 21% vs 20%, in conventional CT, reduced CT and conventional + reduced CTs groups, respectively).

Both conventional and reduced CII significantly differentiated ILD vs non-ILD (mean conventional CII-0.46±0.15vs 0.67±0.09, p< 0.001 and mean reduced CII -0.50±0.17 vs 0.48±0.11, p< 0.001, respectively). Similarly, they separated limited vs extensive ILD (mean conventional CII -0.12±0.14 vs -1.48±0.21, p< 0.001, and mean reduced CII -0.25±0.13 vs -1.71±0.20, p< 0.001, respectively).

The two CIIs similarly predicted the presence of ILD [conventional CII AUC 0.72 (95% CI 0.66-0.77) vs reduced CII AUC 0.68 (95% CI 0.62-0.74); p=0.28, Figure 1A-B]. A similar performance was shown for extensive vs limited ILD [conventional CII AUC 0.77 (95% CI 0.68-0.87) vs reduced CII AUC 0.78 (95% CI 0.70-0.87), p=0.86, Figure 1C-D].

A cut-off for conventional CII< -0.96 (85% sensitivity, 62% specificity) or a reduced CII< -1.85 (85% sensitivity, 54% specificity) was chosen for an optimal sensitivity to detect extensive ILD.

Conclusion: We validated the ability of the CII to detect the presence of ILD and identified cut-offs for both conventional and reduced CII to discriminate between extensive versus limited ILD. Further validation of the proposed cut-offs is ongoing to further support its use in clinical practice and research.

Factors Predicting Mortality in an Indian Cohort of Systemic Sclerosis

T G Sundaram[1], Durga P Misra[1], Rudrarpan Chatterjee[1], Sakir Ahmed[2] and Vikas Agarwal[3], [1]Sanjay Gandhi Post Graduate Institute of Medical Sciences, Lucknow, India, [2]Kalinga Institute of Medical Sciences, Bhubaneswar, India, [3]Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow, India

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Systemic Sclerosis & Related Disorders – Clinical Poster I (0387–0413)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Systemic sclerosis is characterised by high morbidity and mortality due to disease-related or treatment-related complications.

Methods: Data of patients of systemic sclerosis between 1990 and March 2020 was retrieved from case files and electronic health records (EHR). We determined the number of deaths in our cohort of 789 patients with systemic sclerosis from EHR and teleconsultation, and their causes. Kaplan-Meier curve was used to calculate survival at 1, 2, 5 and 10 years of follow-up duration We evaluated baseline characteristics of patients of systemic sclerosis who experienced mortality and compared them with live controls, after matching for age, sex and duration of follow-up, in a case-control design.

Results: There were a total of 90 deaths. The causes were 32 due to Interstitial lung disease (ILD) related deaths, 7 Gastrointestinal (GI) related, 6 malignancies, 5 Scleroderma renal crisis (SRC), and 3 Pulmonary arterial hypertension (PAH). Most of these patients (19 out of 32, 59.4%) had infection as the cause of death; 5 had pulmonary tuberculosis. Twenty four patients died in a non-hospital setting. Mean age at death was 38 years (Standard error [SE]- 1.24), and median duration of follow-up was 338 days (95% CI- 27-1619). Male- female ration was 8:82. Kaplan-Meier curve showed survival rate at 1, 2, 5 and 10 years of follow-up was 93.7%, 89.5%, 78.9% and 72.1% respectively. On univariable analysis, patients who died had greater number of hospital admissions, higher modified Rodnan skin score (mRSS), a higher frequency of ILD, PAH, cardiac involvement, SRC and history of infections. Using multivariable adjusted analysis, only mRSS, number of admissions and infections were significantly higher compared to live controls.

Conclusion: Interstitial lung disease and related lower respiratory tract infections were the most common cause of mortality in systemic sclerosis. Infections accounted for 32.22% of the deaths. Higher skin score, infections and number of admissions were identified as significant risk factors for mortality in multivariable adjusted analysis.

Abstract Number: 0410

Long-term Outcomes of Vascular Grafting of Medium Sized Vessels of the Wrist and Hand in Patients with Medication Refractory Systemic Sclerosis Related Raynaud's Phenomenon at the University of Pennsylvania from 2009-2019

Nora Sandorfi[1], Chris Derk[2] and **Nora Hajnoczky**[3], [1]University of Pennsylvania, Philadelphia, [2]University of Pennsylvania, Philadelphia, PA, [3]Albert Einstein Healthcare Network, Wallingford, PA

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Systemic Sclerosis & Related Disorders – Clinical Poster I (0387–0413)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Raynaud's phenomenon (RP) seen in patients with an underlying autoimmune rheumatic disorder have both functional and structural dysfunction at the microvascular level and in more severe forms at the macrovascular level; leading to the characteristic clinical picture. In most cases, preventive actions and pharmacotherapy can be of help. However, a more severe subgroup of patients may develop painful ulcerations, gangrene and digital amputations that are difficult to control. In medication refractory RP, and when medium vessel involvement is identified, surgical revascularization has been attempted. Previous studies have examined the short-term results of revascularization; however long-term outcomes in autoimmune medication refractory RP patients are limited.

Methods: Following Institutional Review Board approval, patients at the University of Pennsylvania between 2009-2019 were identified based on ICD-9 and 10 diagnosis codes for systemic sclerosis (Ssc), Raynaud's and vascular grafting. The patients within the study fulfilled the ACR/EULAR 2013 classification criteria for SSc. Retrospective chart review for pre and postoperative patient reported symptoms, clinical exam findings, and imaging results were collected. Long-term results for digital ulcers, pain, color change and occlusion were compared.

Results: Nine patients, 10 hands (with no prior revascularization), were identified to meet the inclusion criteria. The majority of the patients were female and older than 45 years at surgery. Complete occlusion was noted in all hands at surgery, with revascularization occurring almost exclusively in the ulnar artery, and venous graft most often obtained from the lower extremity. There were no surgical complications and Doppler ultrasound was used to confirm pulsatile blood flow through graft and digits prior to closing. Patients were followed for an average of 24 months with 3 patient deaths within the first two years and one patient who transferred medical care. All other patients are still being followed for symptoms. Ongoing and unremitting digital ulcers, pain and color change were noted in 2 patients, both who had medication mal-adherence. The other patients had subjective and objective resolution, or decrease in digital ulcers, pain, color change (inconsistently noted) and no occlusions.

Conclusion: This is the first long term study to follow patients and attempt to measure the benefits of arterial revascularization in medication refractory SSc -RP patients through digital ulcer, pain, color change and occlusion occurrence. At follow-up, the majority of the hands showed improvement or resolution of Raynaud's symptoms even months - years later.

Pharmacokinetics, Safety, and Efficacy of Subcutaneous Brodalumab for Systemic Sclerosis with Moderate-to-severe Skin Thickening: A Single-arm, Open-label, Multi-dose, Phase 1 Trial

Takemichi Fukasawa[1], Ayumi Yoshizaki[2], Satoshi Ebata[2] and Shinichi Sato[2], [1]Department of Dermatology, The University of Tokyo, Graduate School of Medicine, Tokyo, Japan, [2]University of Tokyo Graduate School of Medicine, Tokyo, Japan

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Systemic Sclerosis & Related Disorders – Clinical Poster I (0387–0413)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: The exact role of interleukin-17 in systemic sclerosis (SSc) has not been established. This trial assessed the pharmacokinetics (PK), safety, and efficacy of multiple subcutaneous doses of brodalumab 210 mg administered every 2 weeks in Japanese SSc patients with moderate-to-severe skin thickening.

Methods: In this open-label, multiple-dose, phase 1 study, eligible patients received 52-week treatment. Primary endpoints were PK and safety. Secondary endpoints included change from baseline in the modified Rodnan Skin Score (mRSS) and Composite Response Index in Systemic Sclerosis (CRISS) score. Exploratory endpoints included lymphocyte subset testing.

Results: Eight patients were enrolled. Mean (SD) age was 53.6 (10.6) years, total mRSS was 23.1 (5.1), and SSc disease duration was 2.2 (1.9) years. Mean (SD) serum brodalumab trough concentration increased to 21.8 (16.7) μg/mL at week 2 and remained almost constant at week 52. Drug-related treatment-emergent adverse events were observed in three patients: oral candidiasis (n=3), vulvovaginal candidiasis (n=1), and arthralgia (n=1). A rapid and significant decrease in mRSS was observed as early as week 4 ($p< 0.005$), which continued until week 52 ($p< 0.0001$). At week 52, all patients achieved a CRISS score ≥0.6. The Th17/Treg balance showed a significant sustained Treg dominance over 52 weeks ($p< 0.05$). The significant decrease in the number of immunoglobulin G^+ class-switched memory B cells and plasmablasts ($p< 0.01$) was accompanied by a significant increase in the number of transitional B cells ($p< 0.05$) by week 52.

Conclusion: Brodalumab demonstrated a rapid, sustained, and significant decrease in mRSS over 52 weeks in Japanese SSc patients with moderate-to-severe skin thickening, which could be attributed to its direct effects on fibroblasts and indirect effects via impacts on B and T cell subsets.

Any digital ischemic complication	217 (80.7%)	69 (93.2%)	148 (75.9%)	**0.001**

Baseline characteristics were compared using Chi square, Fisher exact or Rank sum tests
*86 of 269 SSc patients did not have a nailfold capillary exam documented.

Methods: Medical records of SSc patients meeting ACR/EULAR 2013 classification criteria that underwent upper extremity duplex US with laser doppler flowmetry between Jan 2001-Dec 2018 at our institution were retrospectively reviewed to abstract the presence or absence of MVD (stenosis/occlusion involving the palmar arch, ulnar, radial,

Table 2. Association between macrovascular disease and digital ischemic complications in 269 patients with Systemic sclerosis. Logistic regression models were adjusted for age at duplex US and gender

Digital Ischemic Complication	Macrovascular disease	OR	95% CI	P value
Digital Ulcers	Any MVD vs. None	3.95	1.85-9.51	<0.001
	Unilateral vs. None	4.29	1.6-14.96	0.009
	Bilateral vs None	3.62	1.33-12.69	0.02
Digital Tip pitting/Scars	Any MVD vs. None	1.57	0.90-2.76	0.081
	Unilateral vs. None	1.10	0.55-2.22	0.78
	Bilateral vs None	2.44	1.13-5.55	0.03
Digital Gangrene/Amputation	Any MVD vs. None	3.36	1.87-6.06	<0.001
	Unilateral vs. None	3.40	1.65-7.02	< 0.001
	Bilateral vs None	3.31	1.52-7.16	0.002
Any Digital Involvement	Any MVD vs. None	4.99	2.05-15.0	<0.001
	Unilateral vs. None	4.41	1.48-19.01	0.02
	Bilateral vs None	5.87	1.67-37.29	0.02

brachial, axillary and/or subclavian arteries). Demographics, clinical characteristics, and outcomes were abstracted to evaluate risk factors associated with MVD in SSc and its association with digital ischemic complications. Logistic regression models were adjusted for age at vascular study and gender.

Results: 269 SSc patients (mean age 57.4 ± 13.3 y, 81% female, 93% Caucasian) underwent upper extremity duplex US during the study period. Mean disease duration was 4.8 ± 7.2 y. The majority had limited cutaneous SSc (lcSSc) (78%) and 68% had a positive SSc specific antibody. Cohort characteristics are described in Table 1.

Macrovascular arterial disease was prevalent at the time of duplex US in 74 patients (28%; bilateral in 13%): Ulnar occlusive disease was the most common, noted in 68 patients (25%; bilateral in 11%) followed by radial in 14 (5%), palmar arch in 6 (2%) and subclavian in 4 (1%). No patients had brachial or axillary artery involvement.

SSc patients with MVD were compared to those without MVD, and were noted to have a significantly higher prevalence of centromere pattern-ANA (86% vs 55%, $p < 0.001$), older age (61.7 vs 55.7 y, p=0.002), calcinosis (57% vs 37%, p= 0.005), telangiectasias (96% vs 85%, p=0.02) and GI dysmotility (82% vs 67%, p=0.01). Mean BMI was lower among those with MVD (25 vs 27, p=0.02). Digital occlusive arterial disease (defined as pre- and post-warming blood flow of ≤206 arbitrary units on laser doppler flowmetry) was higher among those with MVD (89.2% vs 80.5%, p=0.09), but did not reach significance. There was no difference in skin sclerosis, nailfold capillary abnormalities, ILD, PAH, renal crisis, cardiac involvement, inflammatory arthritis and myositis among SSc patients with and without MVD.

Patients with MVD had a significantly higher odds of having any digital ischemic complications (digital ulcers, pitting scars, gangrene, amputation) than those without MVD (93.2% vs 75.9%, OR 4.99, p =0.001) (Table 2). The odds of certain digital ischemic complications were even higher among those with bilateral MVD than unilateral or no MVD as shown.

Conclusion: In this largest single center cohort of SSc patients assessed with duplex US, more than 1 in 4 patients had MVD. Ulnar occlusive disease was most common, followed by radial arterial disease. Presence of MVD increased the odds of developing digital ischemic complications 4 to 5-fold among patients with SSc. This study highlights the

high prevalence of MVD in SSc, and need to consider aggressive therapeutic intervention in those with MVD to prevent digital ischemic complications.

Abstract Number: 0413

Predictors of ILD Development and Timing of Onset in Systemic Sclerosis: A Canadian Cohort

Jessica Kapralik, Robert Morton, Malik Farooqi, Karen Beattie, Nathan Hambly and Maggie Larche, McMaster University, Hamilton, ON, Canada

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Systemic Sclerosis & Related Disorders – Clinical Poster I (0387–0413)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: In patients with SSc, interstitial lung disease (SSc-ILD) and pulmonary hypertension affect 50-70% of patients and are the leading cause of death. Recent trials in anti-fibrotic medications have shown promise in reducing rates of lung function decline in patients with SSc-ILD. Identifying SSc-ILD development and initiating therapy early is essential to optimizing therapeutic benefit. We aimed to identify predictors of SSc-ILD and compared early (< 5 years from SSc diagnosis) versus late onset to aid in optimizing targeted screening for SSc-ILD.

Methods: We analyzed data from the Canadian Scleroderma Research Group (CSRG) patient registry. Patients ≥18 years with follow-up until July 2019 were included. Logistic regression modelling by ordinary least squares and forward stepwise regression were run to identify patient factors associated with SSc-ILD development as well as its early onset (< 5 years from SSc diagnosis). Factors associated with incident ILD were determined as were factors associated with early versus late onset using all patients who developed SSc-ILD during follow-up. Bonferroni correction was utilized to limit Type 1 errors.

Table 1: Significant logistic regressions between predictors and ILD incidence

	Univariate	
Predictor	**Odd's Ratio (95%CI)**	**P value**
Baseline DLCO predicted	0.96 (0.95, 0.96)	1.37E-24
Baseline FVC	0.35 (0.28, 0.43)	2.82E-21
Cyclophosphamide (never/unknown)	0.16 (0.10, 0.26)	3.39E-14
ATA	3.85 (2.70, 5.48)	8.62E-14
ACA	0.28 (0.20, 0.40)	1.62E-12
NYHA Level	2.04 (1.67, 2.49)	3.19E-12

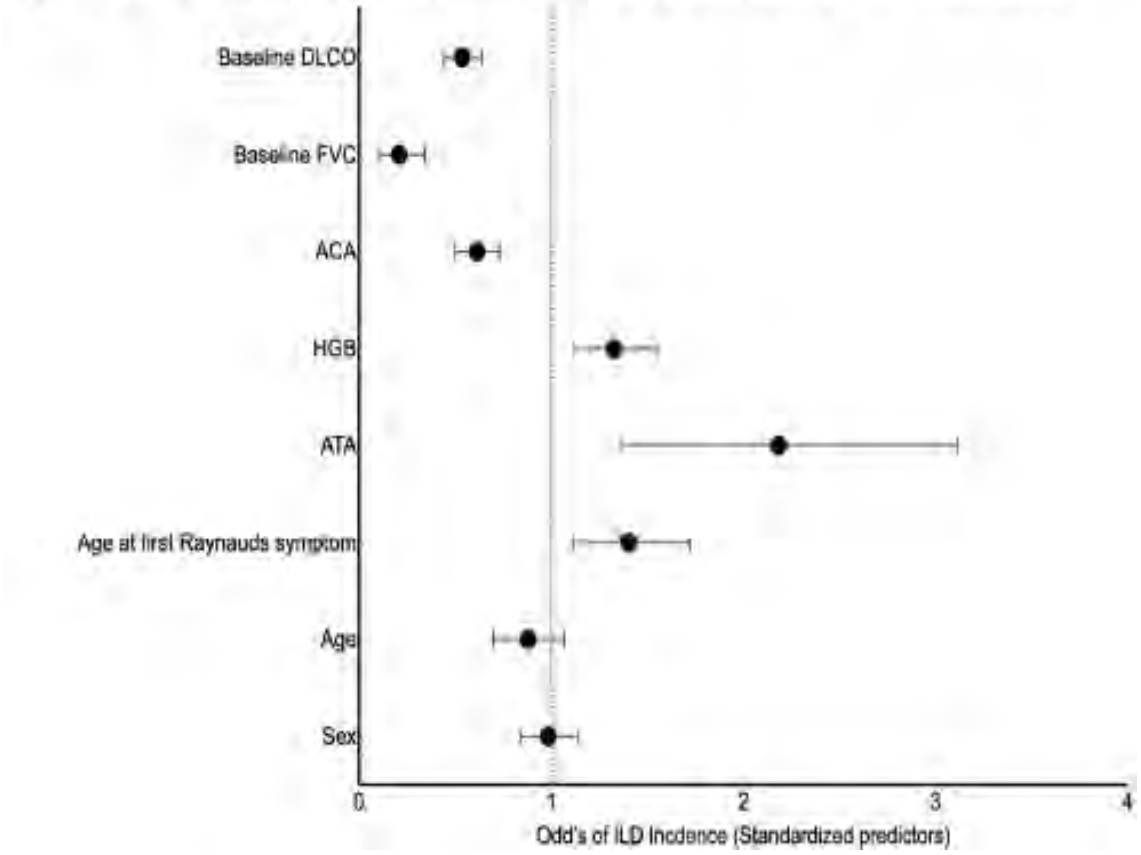
PAH	1.95 (1.34, 2.83)	4.69E-04

Figure 1. Stepwise (forward) selection for predictors of ILD Incidence



Results: Of 1695 patients followed between August 2004 and July 2019, 417 developed SSc-ILD; 227 were incident diagnoses after registry entry. Patients were predominantly middle-aged Caucasian females. General risk factors for ILD including family history, environmental exposures and smoking histories were overall low prevalence in the population and similar between those that did and did not develop SSc-ILD.

Logistic regression identified 12 patient factors associated with increased or decreased odds of developing ILD independent of age and sex (Table 1). Forward stepwise selection revealed 6 significant predictors of SSc-ILD development (Figure 1). Age at SSc diagnosis was the only predictor of early-onset SSc-ILD with older age at SSc diagnosis being associated with increased odds of SSc-ILD onset before 5 years (Table 2).

Conclusion: In a large Canadian cohort we identified 6 factors significantly associated with risk of developing SSc-ILD: baseline pulmonary function (with higher baseline DLCO and FVC reducing risk), antibody status (ATA positivity increasing risk, ACA positivity decreasing risk), elevated hemoglobin and older age at Raynaud's onset. Only older age at SSc diagnosis was predictive of early-onset SSc-ILD .

Table 2: Stepwise selection for early versus late incident ILD

Abstract Number: 0414

Effect of Induction Therapies on Ear, Nose and Throat Involvement in Anti-neutrophil Cytoplasmic Antibody Associated Vasculitis: Results from a Multi-center Cohort Study

Roline Krol[1], Caroline Schaap[1], Paco Welsing[1], Ruth Klaasen[2], Hilde Remmelts[2], Chris Hagen[2], Franka van Reekum[1], Marloes Heijstek[1] and Julia Spierings[1], [1]University Medical Center Utrecht, Utrecht, Netherlands, [2]Meander Medical Center, Amersfoort, Netherlands

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Vasculitis – ANCA-Associated Poster (0414–0436)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Up to 87% of patients with anti-neutrophil cytoplasmic antibody (ANCA)- associated vasculitis (AAV) have ear, nose and throat (ENT) involvement, which can lead to permanent damage and negatively impacts quality of life. Unfortunately guidelines on the optimal management of ENT symptoms are currently lacking and only few studies, mostly with small patient numbers, evaluated the effect of systemic therapies on ENT disease activity. The aim of this study was therefore to compare the impact of induction therapies on ENT symptoms in patients with AAV.

Methods: In this retrospective study, AAV patients with ENT involvement treated at one of the two Dutch centers between January 2010 and April 2020 were included. Clinical, histological and laboratory data were collected from electronic patient records. ENT involvement was defined as 1) at least one ENT symptom according to the Birmingham vasculitis activity score (BVAS) and/or 2) presence of saddle nose deformity. Regression analyses were used to identify associations between the induction agents cyclophosphamide (CYC) and rituximab (RTX) and disease activity while correcting for confounders (follow-up time, age, sex, renal and pulmonary involvement). Some patients (N=41) had a period of treatment with CYC and a treatment period with RTX over the follow-up period. This dependency was taken into account using Generalized Estimating Equation.

Results: In our centers, 213 (67.8%) of 320 AAV patients had ENT involvement. In these 213 patients, median age at disease onset was 52.5 years (IQR 22) and 45.5% was male (N=97). Median BVAS was 12 (IQR 12) at diagnosis and 0 (IQR 2) at last visit. Relapse rate was 0.06 per year (IQR 0.17). At relapse 49.7% (N=78) had ENT involvement and 29.0% (N=60) had ENT activity at last visit (Table 1).

Male patients had a lower risk of ENT activity at last follow-up (OR 0.31 (CI 0.16-0.62), p=0.001) compared to females, as did patients with a lower age at disease onset (OR 0.98 (CI 0.95-0.99), p=0.020). Renal and pulmonary involvement, biopsy results, and ANCA titer, ESR and CRP at diagnosis were not significantly associated with ENT activity at last visit.

In total 140 (65.7%) patients were treated with CYC and 57 (26.8%) with RTX. No statistically significant difference in ENT activity at last visit was observed between patients treated with oral or intravenous CYC compared to RTX (adjusted OR 0.61 (95% CI 0.34-1.09), p=0.093). Furthermore, there was no significant difference in the number of

Pulmonary involvement		101 (47.6%)	78 (56.1%)	30 (52.6%)	0.695
Saddle nose deformity	at diagnosis	11 (6.8%)	5 (5.1%)	6 (14.0%)	0.091
	developed during follow-up	9 (3.5%)	6 (5.2%)	2 (3.9%)	1.000
BVAS at diagnosis, median (IQR)		12.0 (12)	15.5 (11)	12.0 (10)	0.014
BVAS at last visit, median (IQR)		0.0 (2)	0.0 (2)	0.0 (4)	0.324
Total number of relapses, median (IQR)		1.0 (2)	1.0 (2)	2.0 (3)	0.046

AAV: ANCA-associated vasculitis; ANCA: anti-neutrophil cytoplasmic antibody; BVAS: Birmingham vasculitis activity score; CYC: cyclophosphamide; EGPA: eosinophilic granulomatosis with polyangiitis; GPA: granulomatosis with polyangiitis; IQR: interquartile range; MPA: microscopic polyangiitis; MPO: myeloperoxidase; N; number; PR3: proteinase 3, RTX: rituximab.

*p-values were calculated using chi-square tests for categorical data. For continuous variables, p-values were calculated using the Mann-Whitney U test.

patients with at least one ENT relapse between the RTX and CYC group (adjusted OR 0.61 (CI 0.30-1.28), p=0.192). Eight (3.8%) patients received methotrexate as induction therapy. In these patients median age at disease onset was 45.5 years (IQR 30) and 75.0% (N=6) was female. These eight patients had a median relapse rate of < 0.01 per year (IQR 0.16) and three (37.5%) patients had ENT activity at last follow-up.

Conclusion: We found no significant difference in ENT activity at last visit or history of ENT relapse between CYC and RTX treated patients. Importantly, persistent ENT symptoms during flares were observed in a considerable number of patients, which emphasizes the need for further research on optimal management of ENT symptoms in AAV.

Abstract Number: 0415

Utility of the 22-Item Sinonasal Outcome Test Patient-Reported Outcome Instrument in ANCA-Associated Vasculitis

Ellen Romich, Sherry Chou and Rennie Rhee, University of Pennsylvania, Philadelphia, PA

SESSION INFORMATION

Session Date: Saturday, November 6, 2021
Session Title: Vasculitis – ANCA-Associated Poster (0414–0436)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: ANCA-associated vasculitis (AAV) causes sinus symptoms that impact quality of life. The 22-item Sinonasal Outcome Test (SNOT-22) is a patient-reported outcome measure to assess symptoms and quality of life in chronic rhinosinusitis but has not been well-studied in AAV. We compared SNOT-22 scores during remission and active disease in AAV patients with and without sinus involvement and investigated if SNOT-22 scores can predict subsequent relapse.

Methods: Subjects with AAV (granulomatosis with polyangiitis (GPA), microscopic polyangiitis (MPA), eosinophilic granulomatosis with polyangiitis (EGPA) based on 1990 ACR classification criteria or Chapel Hill Consensus Conference nomenclature) and healthy controls were followed longitudinally with measures of disease activity [BVAS/WG, physician global assessment (PGA)], SNOT-22, and treatment. SNOT-22 questions are scored on a 0-5 scale with higher scores for worse symptoms and include 5 subdomains (rhinologic, extra-nasal rhinologic, ear/facial, psycho-

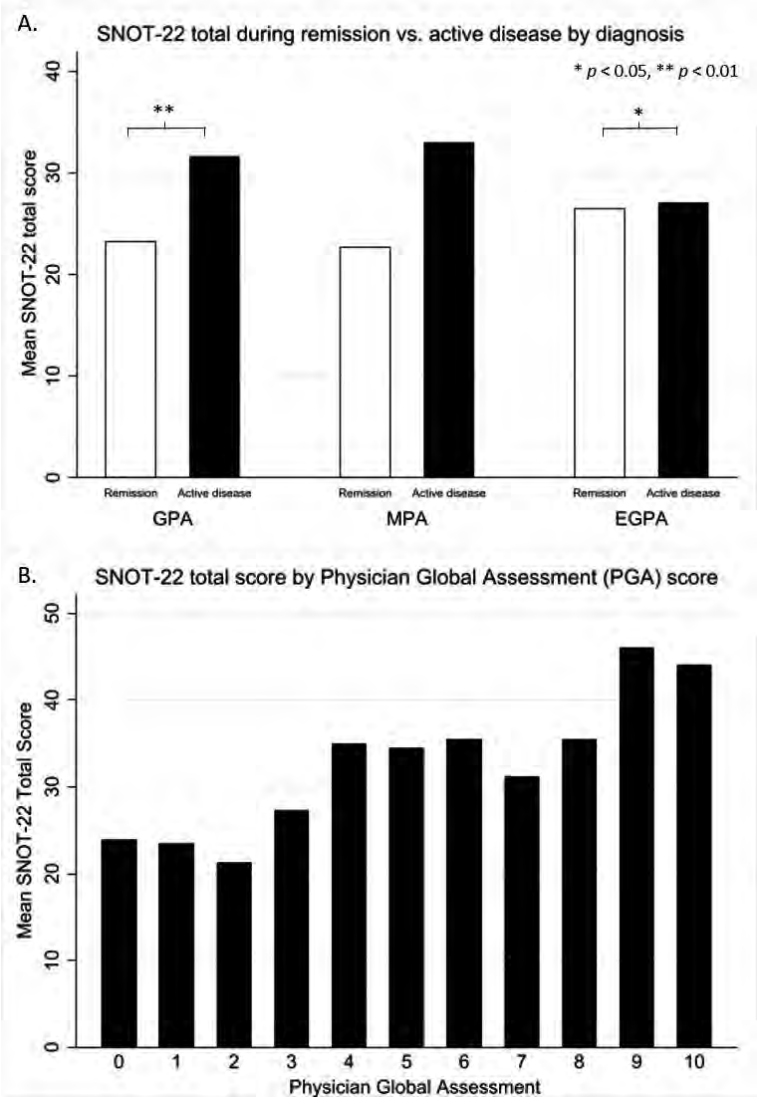

Figure 1. A) SNOT-22 total score at remission and active disease visits according to diagnosis. Asterisks indicate significant differences in adjusted model. B) SNOT-22 total score for all AAV subject visits plotted against Physician Global Assessment showing higher disease activity measure corresponds with higher SNOT-22 total score (p<0.001 in adjusted model).

logical, sleep). Generalized estimating equations evaluated the association between SNOT-22 scores and disease activity. Models were adjusted for concomitant seasonal allergies and use of antibiotics, immunosuppressive drugs, and sinus rinses.

Results: 159 AAV subjects (106 GPA, 21 MPA, 32 EGPA) with 747 visits (110 active disease visits, mean interval 3.5 months) and 70 controls were included (Table 1). Baseline SNOT-22 total scores were higher in AAV vs. controls (mean (SD): 27.5 (1.6) vs. 15.4 (2.1), $p< 0.01$) and higher for AAV subjects with vs. without sinus involvement (mean (SD): 30.3 (20.5) vs. 17.8 (13.2), $p< 0.01$). Adjusted SNOT-22 total scores were significantly higher during active disease vs. remission for GPA and EGPA but not MPA (Figure 1A). Subgroup analyses demonstrated similar results among subjects with a history of sinonasal involvement but not among subjects without baseline sinonasal disease (p=0.3). For all AAV, higher PGA was associated with higher SNOT-22 total (Figure 1B). In GPA, active disease was associated with higher scores in each SNOT-22 subdomain except sleep. Compared to remission visits, active disease was associated with worse scores occurred in the psychological and sleep subdomains for MPA and in the rhinologic subdomain for EGPA (Figure 2). Prior SNOT-22 total scores were not associated with subsequent relapse among all

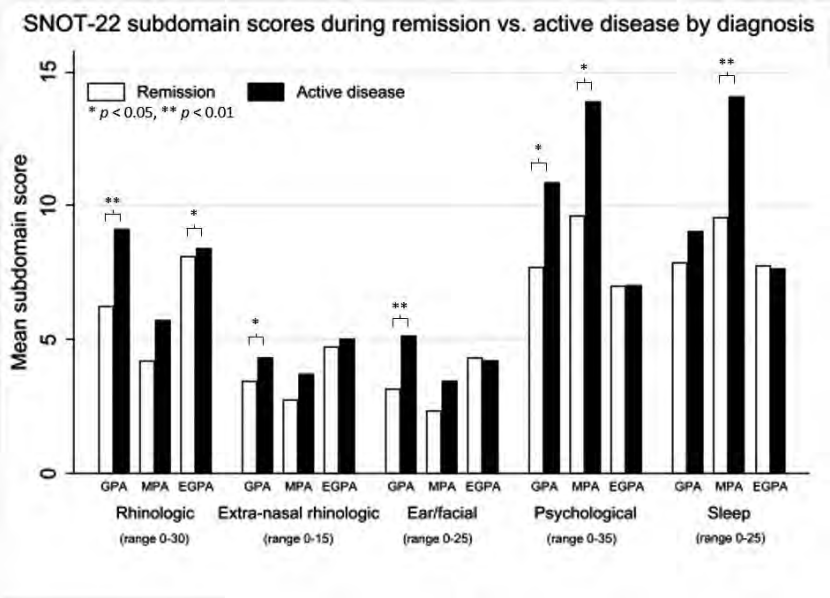

Figure 2. SNOT-22 subdomain scores during remission and active disease. Results demonstrate higher scores during active disease with larger effect on certain subdomains according to diagnosis. Asterisks indicate significant differences in adjusted model.

visits, but when limiting visits to those 2 months apart, increase in SNOT-22 score at prior visits was associated with subsequent relapse (adj OR 1.15 per score change of 5, 95% CI: 1.0-1.3, p=0.03).

Conclusion: In AAV, SNOT-22 scores are higher during active disease vs. remission particularly among patients with previous sinus involvement. The subdomains impacted most by disease activity differ by disease type. When measured within 2 months, change in SNOT-22 scores at remission are associated with subsequent relapse. SNOT-22 may be an informative patient-reported outcome measure to monitor disease activity in AAV patients.

Pharmacological Response of Rituximab Based on Dose Intensity in Maintenance Therapy of ANCA-Associated Vasculitis

Jason Springer[1] and Ryan Funk[2], [1]Vanderbilt University Medical Center, Franklin, TN, [2]University of Kansas Medical Center, Kansas City, KS

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Vasculitis – ANCA-Associated Poster (0414–0436)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Rituximab (RTX) has demonstrated efficacy in maintenance therapy in ANCA-associated vasculitis. However, different dosing protocols have been used in clinical trials and there is no consensus regarding the optimal regiment. The purpose of this work is to evaluate the variability of RTX dosing in a real-world cohort of ANCA-associated vasculitis patients and the relationship with pharmacological response.

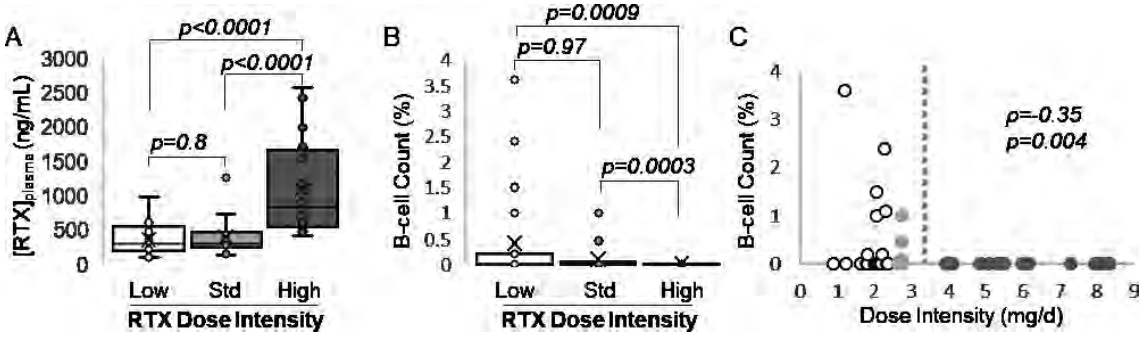

Figure 1

Methods: Patients with a diagnosis of either granulomatosis with polyangiitis (GPA, n=23) or microscopic polyangiitis (MPA, n=5) from a single tertiary care academic medical center were followed prospectively for over 2 years during remission therapy with RTX. All patients met either the 1990 ACR criteria for GPA or the 2012 Chapel Hill Consensus Conference definition for MPA. Dosing of RTX was at the discretion of the treating physician, based on clinical factors and not ANCA titers or B-cell counts. Peripheral blood samples were collected just prior to RTX infusions (i.e. trough of therapy). Demographics, RTX dosing information and laboratory measure of pharmacologic response, including B-cell counts and ANCA titers, were collected throughout the follow-up period. RTX dose intensity was calculated as the RTX dose normalized to dosing interval (mg/d). Stratification of dose intensity was based on a 'standard' dosing regimen of 500mg every 5-7 months with others classified as 'low' or 'high' dosing. Spearman's rank correlations, unpaired T-tests and Wilcoxon rank-sum testing were used as appropriate.

Results: Mean age at enrollment was 60 ± 14 years, with 68% being female. At baseline, 13 patients were positive for PR3-ANCA, 14 MPO-ANCA and 1 ANCA-negative. The mean dose of RTX infusions was 640 ± 221 mg with a mean interval of 210 ± 88 days. The mean peripheral trough concentration of RTX was 622 ± 548 ng/ml. Peripheral RTX concentrations were significantly associated with dose intensity ($p < 0.0001$) (figure 1A). Patients with undetectable B-cells had a significantly higher RTX dose intensity compared patients with detectable B-cells (4.1±2.6 vs 2.7±1.2 mg/d, $p< 0.0001$). Patients with both undetectable B-cells and negative ANCA titers tended to have higher RTX dose intensities (4.4±2.5 vs 2.3±0.5 mg/d, p=0.06). Patients receiving 'standard' dosing regimens (2.4-3.3 mg/d, equivalent to 500mg every 5-7 months) had a significantly higher percentage of B-cells compared to higher dose intensities (p=0.0003) (figure 1B). All patients treated with a dose intensity greater than 3.3 mg/d had undetectable B-cells (figure 1C). In the high intensity group 100% of patients had undetectable B-cells versus 69% and 60% for low and standard dosing (p=0.03) (figure 2A). There were no differences in the groups regarding ANCA negativity (figure 2B). While not significant, there was a dose-dependent relationship between dose intensity and the combination of undetectable B-cells and ANCA negativity (p=0.21) (figure 2C).

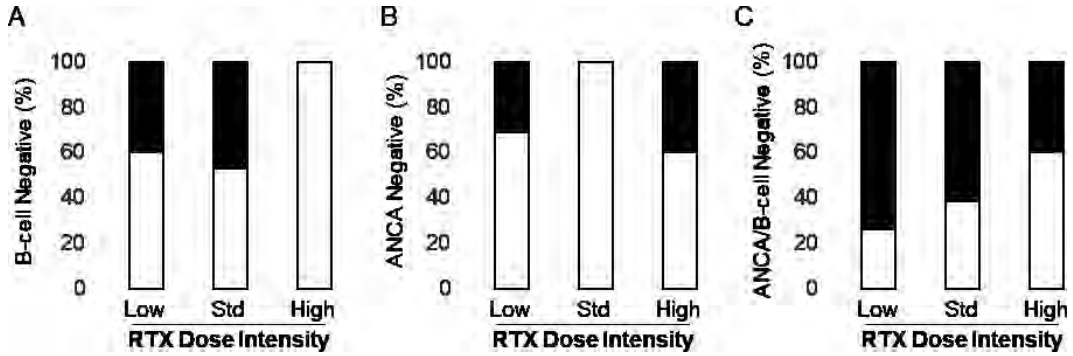

Figure 2

Conclusion: Standard RTX maintenance dosing intensity of 500 mg every 6 months may be inadequate to maintain B cell depletion in a significant number of patients. A target RTX dose intensity of greater than 3.3 mg/d is required to maintain B-cell depletion.

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Vasculitis – ANCA-Associated Poster (0414–0436)

Session Type: Poster Session A

Session Time: 8:30AM–10:30AM

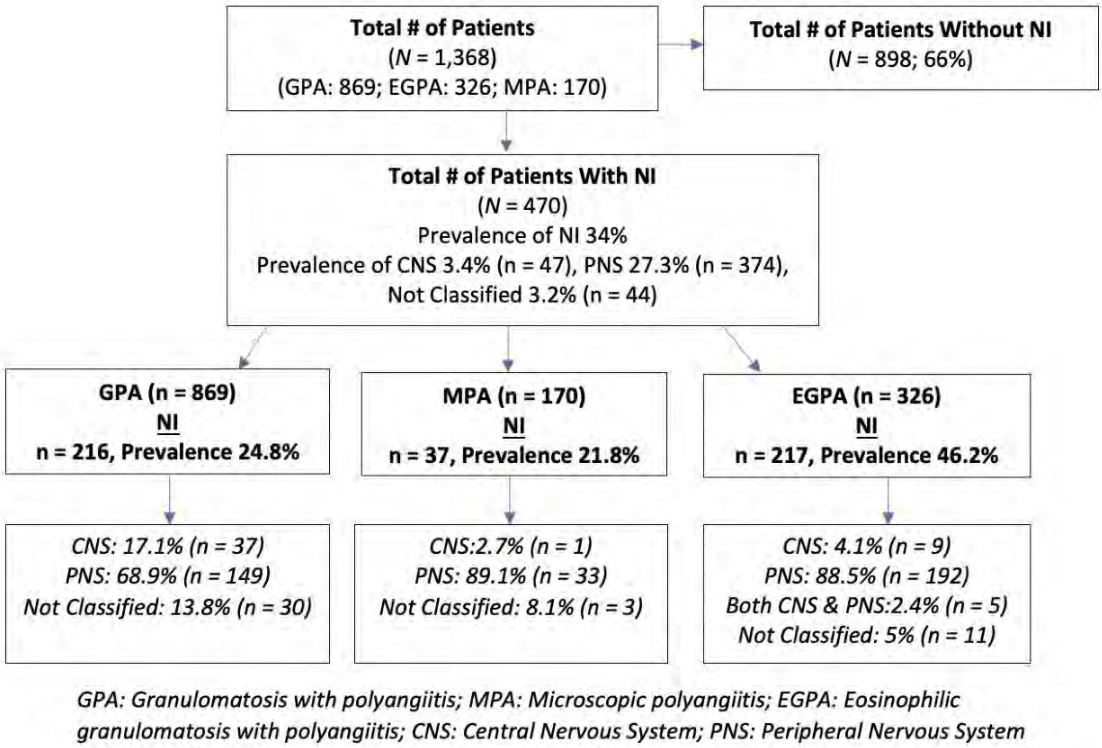

Figure 1. Prevalence of neurologic involvement (NI) in patients with ANCA-associated vasculitis.

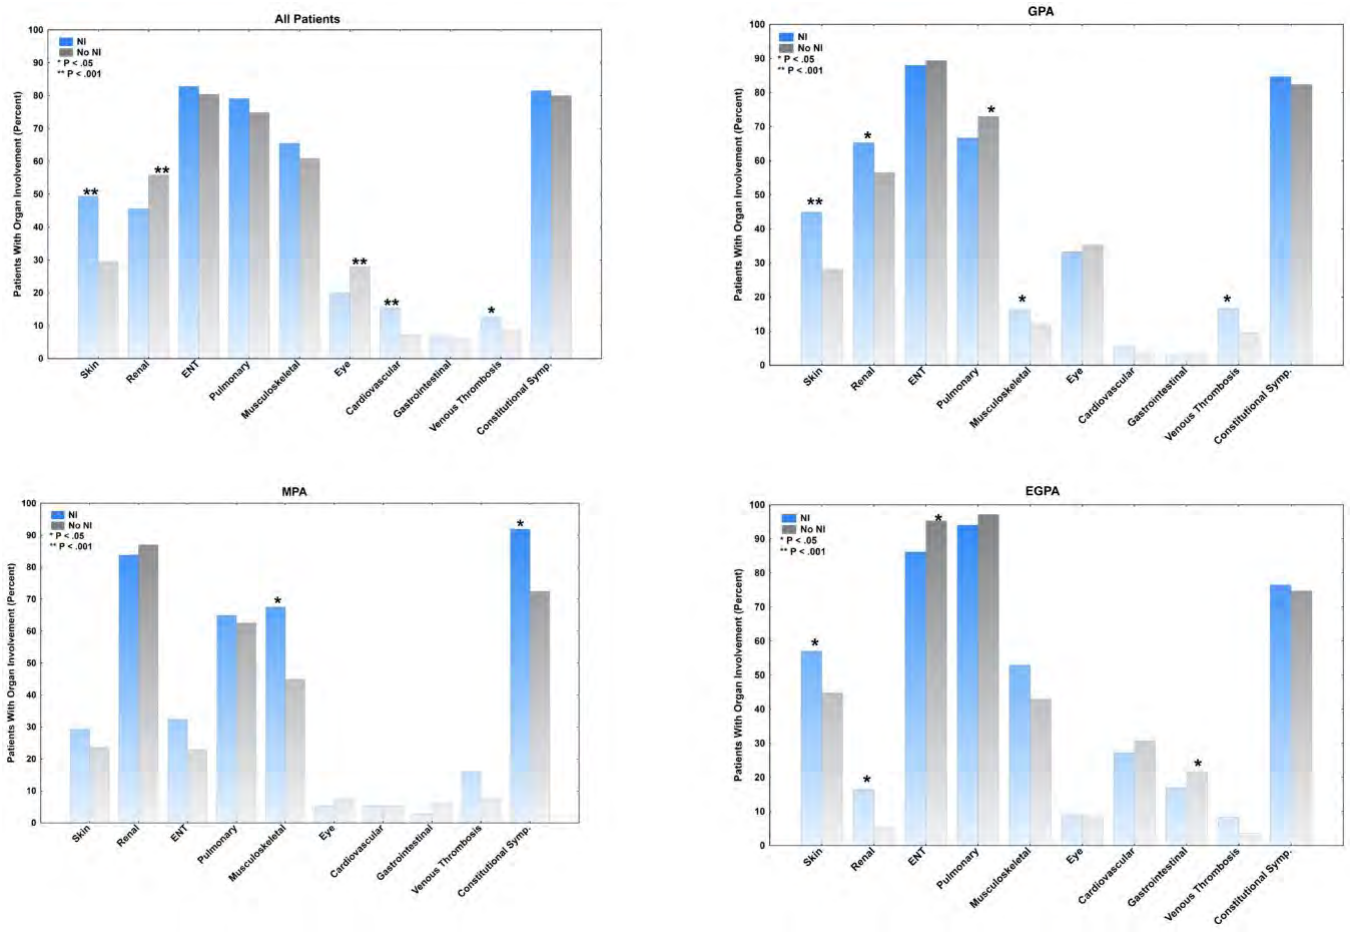

Figure 2. Organ involvement with patient with ANCA-associated vasculitis with and without neurologic involvement (NI) by disease.

Background/Purpose: The prevalence of neurologic involvement (NI) in ANCA-associated vasculitis (AAV), especially central nervous system (CNS) involvement, is not well characterized. This project aimed to describe the prevalence and types of peripheral nervous system (PNS) NI and CNS NI in AAV, and associations of NI with other manifestation of vasculitis.

Methods: Analysis of patients with AAV [granulomatosis with polyangiitis (GPA), microscopic polyangiitis (MPA), or eosinophilic granulomatosis with polyangiitis (EGPA)] participating in a multicenter longitudinal observational study. Data were from 2006-2021 from patients at least 18 years old at enrollment. Standardized forms were used to document patient demographics, disease type, organ involvement, and ANCA status. Patient subsets were compared according to presence or absence of NI.

Results: Data from 1368 patients were available: 470 (34%) had NI (Figure 1) of whom 216 (46%) had GPA, 37 (7.8%) had MPA, and 217 (46.2%) had EGPA. The prevalence of NI was 24.8% (216/869) in GPA, 22% (37/170) in MPA, and 67% (217/326) in EGPA. The prevalence of CNS NI in the total cohort was 47/1368 (3.4%) and the prevalence of PNS NI was 374/1368 (27.3%), with 44 patients (3.2%) having NI that was not classified. GPA was the most common diagnosis in patients with CNS NI (78% compared to 2% in MPA and 19% in EGPA). For PNS NI, EGPA was the most common diagnosis (51% compared to 40% in GPA and 8.8% in MPA).

Patient sex and race did not differ between patients with or without NI. Patients with NI were 53% female and 47% male, 88.7% were White, 1.5 % Black, 3.2% Hispanic, and 4.8% Asian. Mean age at diagnosis of patients with NI

was higher than patients without NI (51.4 vs 47.0 years, p <0.001). NI was associated with skin (49.4% vs. 29.5%, p < 0.001), venous thrombosis (12.8% vs. 8.6%, p= 0.016), and cardiovascular (15.5% vs. 7.2%, p < 0.001) involvement. Patients with NI were less likely to have renal (45.6% vs. 55.9%, p < 0.001), and eye (20 % vs. 28%, p < 0.001) involvement. NI was associated with skin and kidney involvement in EGPA, musculoskeletal, skin, kidney, venous thromboses in GPA and constitutional and musculoskeletal symptoms in MPA (Figure 2).

Patients with NI were more likely to have P-ANCA pattern (43.1 % vs 31.2 % p =0008) and anti-MPO (44.4% vs 30% p < .0001) than patients with no NI.

Conclusion: NI in AAV is common, occurring in approximately one-third of patients, and was most common in EGPA, compared to GPA or MPA. CNS NI occurs more commonly in GPA. NI is associated with various specific organ systems and P-ANCA/anti MPO positivity. These data are informative for clinicians and patients with AAV, and should raise the awareness of this common manifestation of vasculitis. The relationships of NI with other specific manifestations of disease warrants additional study.

Longitudinal Patterns of Renal Function in ANCA-Associated Vasculitis

Jennifer Hanberg[1], Xiaoqing Fu[1], Claire Cook[2], John Stone[3], Hyon K. Choi[4] and Zachary Wallace[5], [1]Massachusetts General Hospital, Boston, MA, [2]Division of Rheumatology, Allergy, and Immunology, Mass General Hospital, Boston, MA, [3]Massachusetts General Hospital Rheumatology Unit, Harvard Medical School, Boston, MA, [4]Massachusetts General Hospital, Lexington, MA, [5]Massachusetts General Hospital, Newton, MA

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Vasculitis – ANCA-Associated Poster (0414–0436)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Renal involvement is common in ANCA-associated vasculitis (AAV). Prior analyses show that end stage renal disease (ESRD) in AAV may be multifactorial. Little is known about the longitudinal course of renal dysfunction in contemporary AAV cohorts. We aimed to identify renal function trajectories using an unbiased approach, and to assess the baseline comorbidities and outcomes associated with these trajectories.

Methods: Patients with a baseline creatinine (30-365 days before treatment initiation) were included from the Mass General Brigham AAV Cohort, a consecutive inception cohort (2002-2017). Follow-up began 1 year before and was

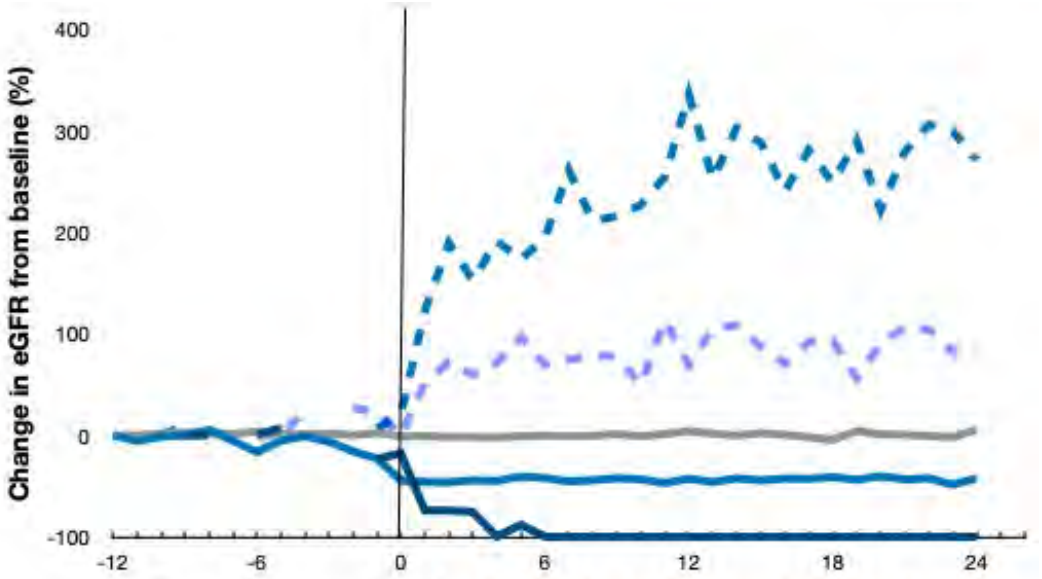
Values reported as N(%), mean ± standard deviation or median (25%-75%)). AAV: ANCA-associated vasculitis. BVAS: Birmingham vasculitis activity score. ESRD: end stage renal disease. eGFR: estimated glomerular filtration rate. Treatment resistance is reported only among those with renal involvement.

truncated 10 years after treatment initiation. Treatment resistance was defined as lack of remission following the first course of therapy; remission was defined by stabilization or improvement of estimated glomerular filtration rate (eGFR) without hematuria for ≥1 month. In patients without repeat urinalysis, stabilization or improvement of eGFR was considered evidence of remission.

We calculated eGFR using CKD-EPI without race multiplier. We used trajectory analysis to identify groups with similar longitudinal change in renal function, defined as percentage of pre-AAV eGFR over the first 24 months of follow up. Final models were selected by fit statistics and face validity.

ESRD was defined as (1) need for dialysis for >60 days, (2) dialysis until death if the patient died between 14-60 days of follow up, or (3) renal transplant, as identified by chart review and United States Renal Data System records.



Number at Risk

Months	-12	-6	0	6	12	18	24
Rapid decline	30	30	29	5	4	4	3
Slow decline	35	35	35	35	35	30	29
Stable	314	314	309	294	291	288	259
Recovery	35	35	35	33	33	33	33
Marked recov.	12	12	12	11	11	11	11

Logistic regression was used to evaluate risk factors for trajectory group membership, and Cox proportional hazards models were used to estimate risk of ESRD in each trajectory group, accounting for competing risk of death.

Results: Of 484 patients in the cohort, 430 were included. We identified 5 groups (Figure): rapid decline (RD) (N=30), slow decline (SD) (N=37), stable (N=316), recovery (N=35) and marked recovery (N=12). The median posterior probability of group membership was >0.98 in all groups, indicating excellent fit.

Age, sex, race and biopsy class were overall similar between groups; however, RD and SD groups tended to be older than those with a stable course, and sclerotic biopsy classification was most common among RD. MPO serology and hypertension (HTN), but not diabetes (DM), were more common in RD and SD than other groups (Table). Treatment resistance was more common in RD than SD (86% vs 43%, $p< 0.001$), and more common in these groups than in the stable and recovery groups.

In a logistic model adjusted for age and ANCA type, baseline HTN (OR 2.3, 95% CI 1.3-4.4) but not DM (OR 0.9, 95%CI 0.4-1.8) was associated with odds of membership in RD or SD groups versus any other group. In an age-adjusted model, the RD and SD groups had a higher risk of ESRD compared to the stable group (HR 647, 95%CI 128-377 and HR 14, 95%CI 4-46, respectively).

Conclusion: In a large AAV cohort, we identified distinct patterns of change in renal function. Baseline HTN was associated with a worse trajectory and treatment resistance was more common among those with a worse trajectory. Both RD and SD groups were associated with higher risk of ESRD.

Post-induction ANCA Titer Does Not Predict Mortality or Renal Outcomes: A Target Trial Emulation Study

Gregory McDermott[1], Xiaoqing Fu[2], Claire Cook[3], John Stone[4], Yuqing Zhang[5] and Zachary Wallace[6], [1]Brigham and Women's Hospital, Brookline, MA, [2]Massachusetts General Hospital, Boston, MA, [3]Division of Rheumatology, Allergy, and Immunology, Mass General Hospital, Boston, MA, [4]Massachusetts General Hospital Rheumatology Unit, Harvard Medical School, Boston, MA, [5]Division of Rheumatology, Allergy, and Immunology, Mass General Hospital, Harvard Medical School, Boston, MA, [6]Massachusetts General Hospital, Newton, MA

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Vasculitis – ANCA-Associated Poster (0414–0436)

Session Type: Poster Session A

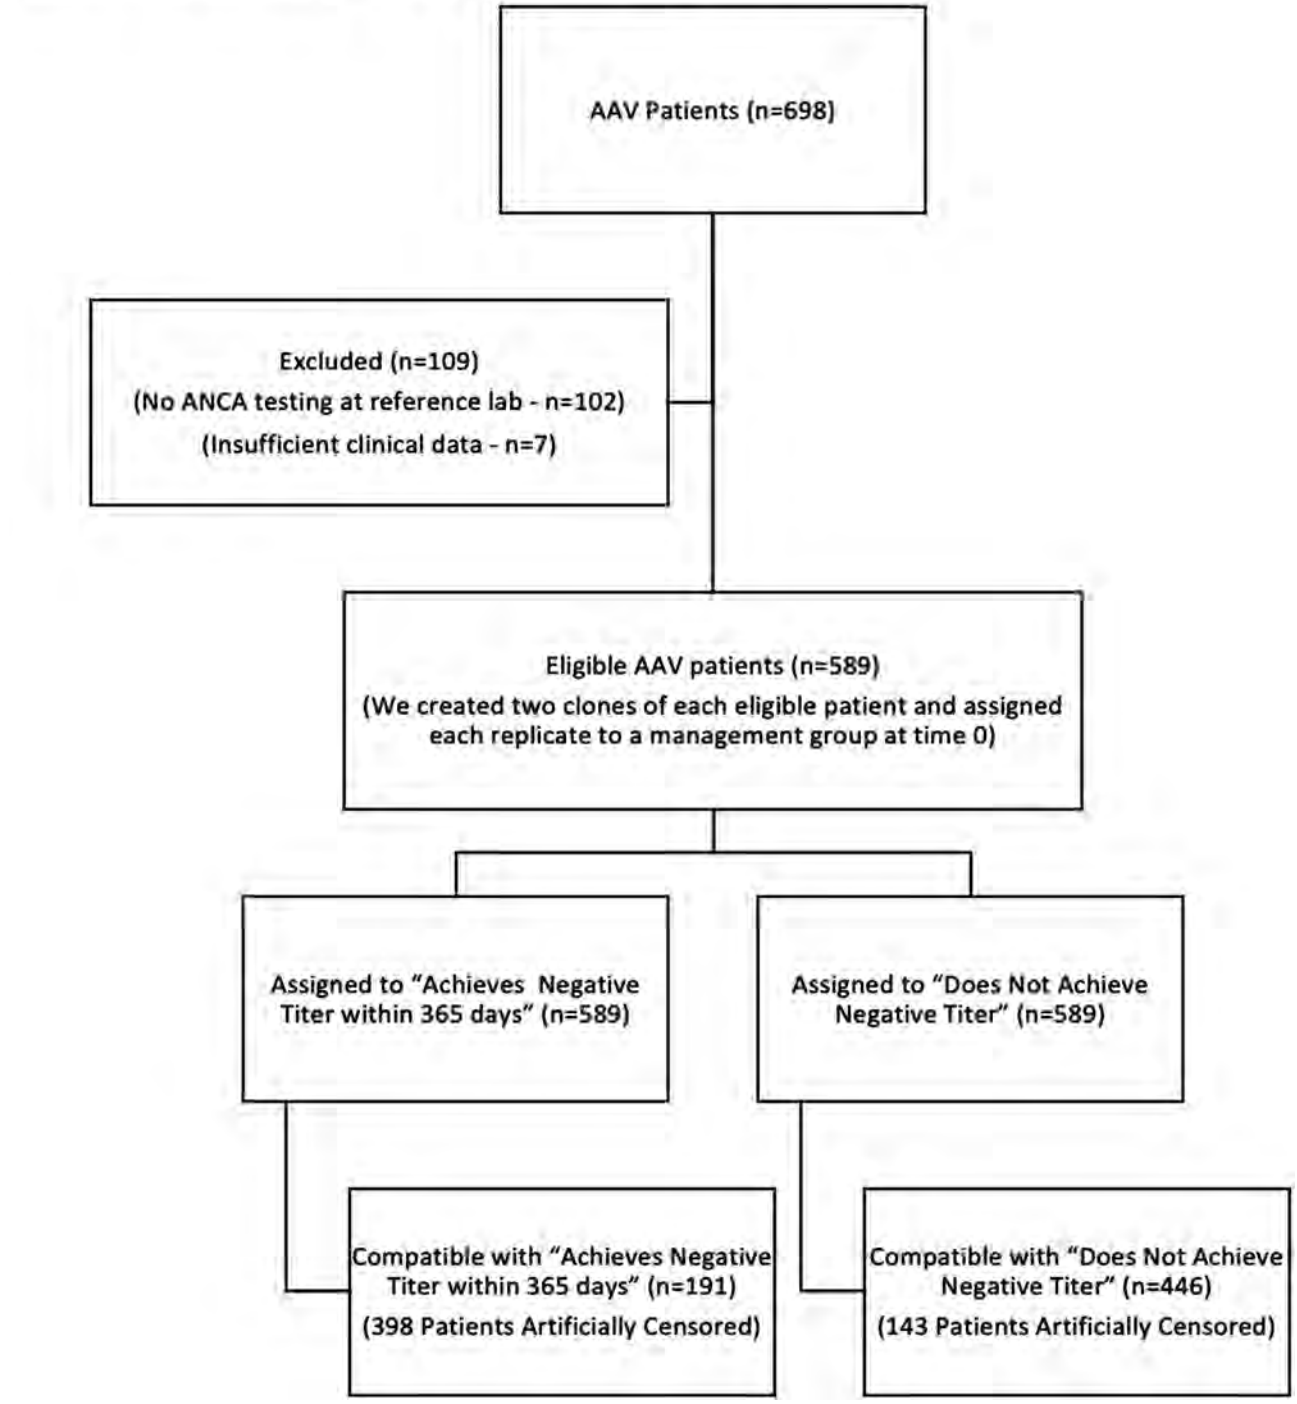
Session Time: 8:30AM–10:30AM

Background/Purpose: Antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis (AAV) is associated with increased risk of end-stage renal disease (ESRD) and death. In most cases, circulating ANCA targeting proteinase-3 (PR3) or myeloperoxidase (MPO) are present and may be pathogenic. Studies of the association of post-treatment ANCA titers with future outcomes have yielded conflicting results. We evaluated the association of achieving a negative ANCA titer during the first year of treatment with ESRD and death.

Methods: Cases were obtained from a consecutive inception cohort of AAV patients who received care at a large multi-hospital system between 2002-2019. All cases were PR3- or MPO-ANCA+. ANCA titers were obtained from a single reference laboratory. Mortality data were obtained from the National Death Index and ESRD status from the United States Renal Data System. To address confounding and immortal-time bias, we performed a target trial emulation study to examine the association of post-induction ANCA titer with risk of ESRD or death using a previously described cloning, censoring and weighting approach. We designed a hypothetical trial with two management strategies: "achieve a negative titer" or "do not achieve negative titer" within 365 days of induction. "Clones" of each patient were included in each hypothetical management arm and censored when they violated the assigned strategy. The composite outcome – risk of ESRD or death within five years – was estimated using Cox models after accounting for informative censoring using inverse-probability-of-censoring weighting and adjusting for baseline covariates.

Results: The study included 589 patients (mean age: 60 years; 58% female; 88% white) with 24.4 ± 24.6 months of mean follow up (Table 1). The majority were MPO-ANCA+ (70%) and had renal manifestations (65%). Rituximab (RTX)-based induction strategies were used in 48%. 32% achieved a negative titer within one year of induction. In the target trial, the HR for the primary outcome of ESRD or death was 1.02 (95%CI 0.84-1.24) in the group that achieved a negative titer compared to the group that did not (Table 2). In analyses stratified by remission induction strategy, the HR for ESRD or death was 0.95 (95%CI 0.72-1.26) in RTX-based and 1.11 (95%CI 0.83-1.48) in cyclophosphamide (CYC)-based regimen users when comparing those who achieved a negative titer vs those who did not. The HR for ESRD or death was 0.85 (95%CI 0.56-1.27) in the PR3-ANCA+ and 1.12 (95%CI 0.90-1.40) in the MPO-ANCA+ groups that achieved a negative titer. There was a trend toward lower risk of death among PR3-ANCA+ patients who achieved a negative titer (HR 0.58 [95%CI 0.33-1.02]).

Figure 1: Flow Chart of Eligible Patients and Target Trial Design



Conclusion: In this target trial using a large cohort of AAV patients, achieving a negative ANCA titer within one year of induction was not associated with improved renal or mortality outcomes. This finding was seen in both RTX- and CYC-treated patients. There was a trend towards decreased risk of death in the PR3-ANCA+ patients who achieved a negative titer, although this did not reach statistical significance. These findings suggest that post-induction ANCA titers have limited ability to predict mortality and ESRD outcomes in AAV.

Development and Validation of a Simulation Model for Maintenance Treatment in ANCA-Associated Vasculitis

Zachary Wallace[1], John Stone[2], Hyon K. Choi[3] and Emily Hyle[4], [1]Massachusetts General Hospital, Newton, MA, [2]Massachusetts General Hospital Rheumatology Unit, Harvard Medical School, Boston, MA, [3]Massachusetts General Hospital, Lexington, MA, [4]Infectious Diseases, Department of Medicine, Massachusetts General Hospital, Boston, MA

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Vasculitis – ANCA-Associated Poster (0414–0436)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: ANCA-associated vasculitis (AAV) care has evolved over the last two decades with several approaches to remission maintenance. However, these approaches have trade-offs regarding the risk of flare, infection, end-stage renal disease (ESRD), and other outcomes which impact morbidity, mortality, and costs. We developed a simulation model to project clinical outcomes in individuals with specific disease features, which can be used to inform clinical decision-making and identify uncertainties that strongly affect outcomes.

Methods: We developed a state-transition, microsimulation model of people with AAV (TreeAge Pro Healthcare 2020). Figure 1 displays the health states; individuals remain in or transition between health states monthly. At model start, individuals draw for demographic and disease-specific characteristics and then transition between the active AAV or inactive states (i.e., relapse/remission, stratified by major/minor severity) and are at risk for severe infection, ESRD, or death. Transition rates are stratified by demographic and disease-specific characteristics. Table 1 shows

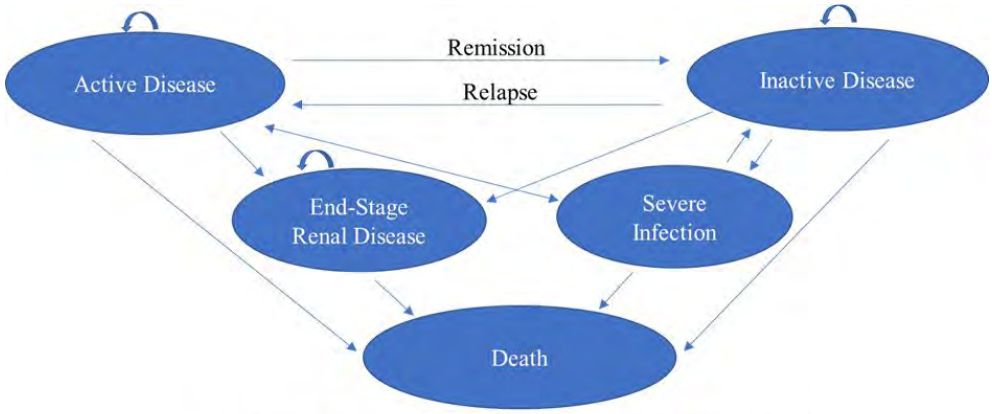

Figure 1. AAV State-Transition Model.

Table 1. Model Input Parameters

Input Parameter	Base Case Value (Ref)	
Baseline Cohort Characteristics[1]		
Age (mean [SD], years)	60.6 (13.0)	
Male (%)	58.2%

model input parameters. The distribution of baseline demographics (i.e., age, sex, ANCA type, renal involvement) are from the MAINRITSAN 2 trial, which compared fixed-schedule rituximab (RTX) to a tailored approach based on rising ANCA or B cell titers for remission maintenance. We obtained probabilities of relapse, severe infection, and ESRD from MAINRITSAN 2, and other clinical trials, cohort studies, and national registries. We estimated mortality based

Table 2. Comparison of AAV Model Projected Outcomes with MAINRITSAN 2 Outcomes Over 28 Months

	Fixed Treatment		Tailored Treatment	
	AAV Model	MAINRITSAN 2	AAV Model	MAINRITSAN 2
Number	10,000	81	10,000	81
Minor Relapse	7.4% (6.9%-7.9%)	6.2% (1.0%-11.4%)	10.1% (9.5%-10.7%)	8.6% (2.5%-14.8%)
Major Relapse	4.3% (3.9%-4.7%)	3.7% (0.0%-7.8%)	7.0% (6.5%-7.5%)	7.4% (1.7%-13.1%)
≥ 1 Severe Infection	19.1% (18.2%-20.0%)	19.8% (11.1%-28.4%)	10.9% (10.3%-11.6%)	10.2% (3.4%-16.4%)
ESRD	0.5% (0.4%-0.6%)	1.2% (0.0%-3.6%)	0.6% (0.5%-0.8%)	0% (0%-0%)
Death	5.9% (5.4%-6.4%)	3.7% (0.0%-7.8%)	5.4% (5.0%-5.8%)	1.2% (0.0%-3.6%)

on disease-specific features and background age- and sex-adjusted rates derived from US life tables. We then used the AAV model to project outcomes with tailored vs fixed-schedule RTX among people in remission at baseline over 28 months, as studied in MAINRITSAN 2. We performed face validity assessment with experts in the field. We used mean average percent error (MAPE) to assess how the model-projected outcomes compared to those observed in MAINRITSAN 2.

Results: Over 28 months, the AAV model projected fewer minor and major relapses with fixed vs tailored RTX (7.4% [95% CI 6.9%-7.9%] vs 10.1% [9.5%-10.7%] and 4.3% [3.9% vs 4.7%] vs 7.0% [6.5%-7.5%]). More patients had at least one severe infection in the fixed vs tailored group (19.1% [18.2%-20.0%] vs 10.9% [10.3%-11.6%]). ESRD was uncommon in both groups (0.5% [0.4%-0.6%] vs 0.6% [0.5%-0.8%]). The mean survival was the same in both strategies (27.0 ± 3.9 vs 27.0 ± 3.8 months). Compared to the MAINRITSAN 2 trials results (Table 2), the projected rates of relapse, severe infection, ESRD, and death in the AAV model were similar (MAPE, 1.5%, range 0.4%-4.3%). Limitations include that we made assumptions regarding differences in mortality rates during active vs inactive disease states.

Conclusion: We established the face validity and internal validation of a novel AAV state-transition model that projects key outcomes, including minor and major relapse, severe infection, ESRD, and death. This model can be adapted to compare other strategies (e.g., azathioprine) and incorporate other health states (e.g., steroid toxicity), quality of life, and costs.

Abstract Number: 0421

Negative vs. Positive Antineutrophil Cytoplasmic Antibody Granulomatosis with Polyangiitis, a Case-control Study

Marta Casal Moura, Samuel D. Falde, Ulrich Specks and Misbah Baqir, Mayo Clinic, Rochester, MN

SESSION INFORMATION

Session Date: Saturday, November 6, 2021
Session Title: Vasculitis – ANCA-Associated Poster (0414–0436)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Antineutrophil cytoplasmic antibody (ANCA) negative granulomatosis with polyangiitis (GPA) is a challenging diagnosis. There is paucity of literature regarding the clinical course of ANCA-negative GPA especially when comparing that of ANCA-positive GPA.

Methods: We conducted a single-center, sex and age matched case-control and case-crossover study of ANCA-negative GPA vs. ANCA-positive GPA patients evaluated at our institution from January 1, 1996 to December 31, 2015. Clinical features, outcomes and correlation with ANCA status were characterized.

Results: We identified 110 patients with ANCA-negative GPA, mostly females (72, 65.5%) with median age of 55 (IQR 39-65) years at the time of diagnosis. Disease severity was milder in ANCA-negative GPA (BVAS/WG = 1 vs. 6 points, p< 0.0001). Mucous membranous/eye manifestations were more frequent in ANCA-negative GPA, whereas general symptoms (fever, weight loss, arthralgia, myalgia), pulmonary and renal involvement were more frequent in ANCA-positive GPA. Time to remission was longer in ANCA-negative GPA (27.7 vs. 18.8 months, p=0.004). Greater number of ANCA-positive GPA patients relapsed at 60 months (21.8% vs. 9.1%, p=0.009) compared to ANCA-negative GPA and time to relapse was shorter (49.8 vs. 54.8 months, p=0.043) in ANCA-positive GPA. Patients with general manifestations, BMI > 30 kg/m^2 and necrotizing granulomatous inflammation were more likely to relapse. ANCA seroconversion from negative to positive was observed in 16 patients. After seroconversion, patients had higher mean BVAS/WG score (p< 0.0001) and increased incidence of relapses (p=0.004) in comparison with the time before ANCA seroconversion. Necrotizing granulomatous inflammation and vasculitis on biopsy at the time of ANCA-negative GPA diagnosis were identified as risk factors for ANCA-positive seroconversion.

Conclusion: ANCA-negative GPA patients have milder disease (BVAS/WG) and are less likely to relapse when compared with patients with ANCA-positive GPA. ANCA seroconversion portends higher disease severity and an increased frequency of relapse.

16	GPA	73, M	Yes	No	Bladder	Localized	**After AAV**	323.90	Alive

Background/Purpose: Many studies linking vasculitis to the development of malignancy based on chronic inflammation, cytotoxicity, emergence of vasculitis as a paraneoplastic disease. Even previous studies emphasize the role of cyclophosphamide, recent AAV cohort studies, where cumulative cyclophosphamide is lower than the historical cohorts, do not show such associations with cancer. The objective was to identify characteristics of adult AAV patients having a history of cancer and compare with AAV patients with no history of cancer.

Methods: In this nationwide study we used Turkish Vasculitis Study Group Registry (TRVaS)-a newly established, multicenter, and e-database of Turkey. Among 517 AAV patients, data regarding cancer was available in 373 (72%) patients. Demographics, clinical characteristics, medications, smoking data were analyzed. Retrospective analysis of patients that presented cancer before AAV diagnosis or after AAV diagnosıs was done. Regarding malignancies, type of cancer, clinical or pathological stage, treatment response were also recorded. AAV patients were groupped according to having cancer after AAV diagnosis or no cancer history. Groups were compared in terms of demographic, clinical features, and medications. Relative risk was measured using the standardized incidence ratio (SIR), which was calculated by the ratio of cancer cases except non-melanoma skin cancer among AAV patients to the expected cases for the background population. The expected number of cases was calculated by multiplying the measured person-years by the incidence rate of cancer in Turkey. Cancer data were obtained from the GLOBOCAN 2020 estimates of new cases in Turkey.

Results: Totally 16 patients had ever cancer history before AAV diagnosis in 6 and after AAV diagnosis in 10 patients. Distribution of cancer diagnosis were lung cancer (n=3), bladder (n=3), skin (n=3), colon (n=2), endometrium, lymphoma, thyroid, larynx, and malign mesenchymal tumor (Table 1). Patients with cancer history were older and male predominant (Table 2). Smoking history was present in 90% of the patients with cancer. In the comparison of AAV patients with cancer after AAV diagnosis with AAV patients with no cancer history, no difference was found in terms of clinical features of AAV except for pulmonary involvement(Table-2). Cyclophosphamide usage and dosages were similar between groups. Cancer risk was found to be over 2 times higher than the general population for the analysis of AAV patients who developed cancer after the diagnosis (SIR: 2.3, 95% CI: 1.2-4.1, P=0.02).

Table 2. Comparison of Cancer (+)AAV patients with AAV patients no cancer history

	Cancer (+) AAV (n=10)	Cancer (-) AAV (n=357)	p
ANCA Clinical Subtypes			
EGPA, n (%)	2 (20)	52 (14.5)	0.59
GPA, n (%)	7 (70)	208 (27.9)	
MPA, n (%)	0 (0)	48 (13.4)	
Unclassified AAV, n (%)	1 (10)	51 (14.2)	
IFA Test at diagnosis			
IFA Not Tested	0 (0)	9/224 (4)	0.79
IFA Negative	3/8 (37.5)	69/224 (30.8)

cANCA pattern	2/8 (25)	84 (37.5)	
ELISA Test at diagnosis			
ELISA Not Tested	1/4 (25)	18/145 (12.4)	0.02
ELISA Negative	0(0)	4/145 (2.8)	
Anti-MPO	1/4 (25))	50/145 (34.5)	
Anti-PR3	1/4 (25)	71/145 (49.0)	
Others	1/4 (25)	2/145 (1.4)	
Male gender, n (%)	9 (90)	185 (51.8)	**0.02**
Age at diagnosis, years mean ± SD	62.4 ± 9.6	49.4 ± 17.1	**0.008**
Age at last visit, years mean ± SD	64.4 ± 7.6	53.4 ± 16.2	**0.03**
Follow-up time, months median (IQR)	8 (26)	36 (100.15)	**0.046**
Death, n (%)	2 (20)	49/353 (13.9)	0.64
Constitutional Symptoms	7 (70)	274/354 (77.4)	0.43
Mucocutaneous Findings	3 (30)	81/354 (22.9)	0.71
Musculoskeletal Findings	2 (20)	97/354 (27.4)	0.73
Eye Findings	2 (20)	54/351 (15.4)	0.66
ENT Findings	6 (60)	175 /353 (49.6)	0.75
Pulmonary Involvement	10 (100)	220/354 (62.2)	**0.02**
Cardiovascular Involvement	0 (0)	7/347 (2)	1
Gastrointestinal Involvement	0 (0)	16/352 (4.6)	1
Nephrological and/or Genitourinary Involvement	7(70)	220/354 (62.1)	0.75
Central Nervous System Involvement	0 (0)	13/353 (3.7)	1
Peripheral Nervous System Involvement	2 (20)	35/352 (9.9)	0.24
Cyclophosphamide	6 (60)	226 (63.0)	1
Rituximab	3 (30)	106 (19.5)	1

Conclusion: It seems AAV patients have an increased risk for overall malignancies as in European cohorts (1). Smoking was the most seen and preventable risk factor. Cyclophosphamide usage with lower doses in recent years decrease the importance of cyclophosphamide-related cancer. Cancer was more seen in AAV patients not only after AAV diagnosis but also before AAV diagnosis. Further studies required to better understand of which came first, the chicken or the egg?

Fisher's exact test used to compare group memberships and ANOVA used to compare continuous variables. Data obtained at flare visits for the non-renal flare and renal flare groups; and at the last visit for the long-term remission group.
ANCA: anti-neutrophil cytoplasmic antibody; cANCA: cytoplasmic ANCA; pANCA: perinuclear ANCA; PR3: proteinase 3; MPO: myeloperoxidase; BVAS: Birmingham Vasculitis Activity Score;
rBVAS: active renal disease per BVAS; eGFR: estimated glomerular filtration rate.

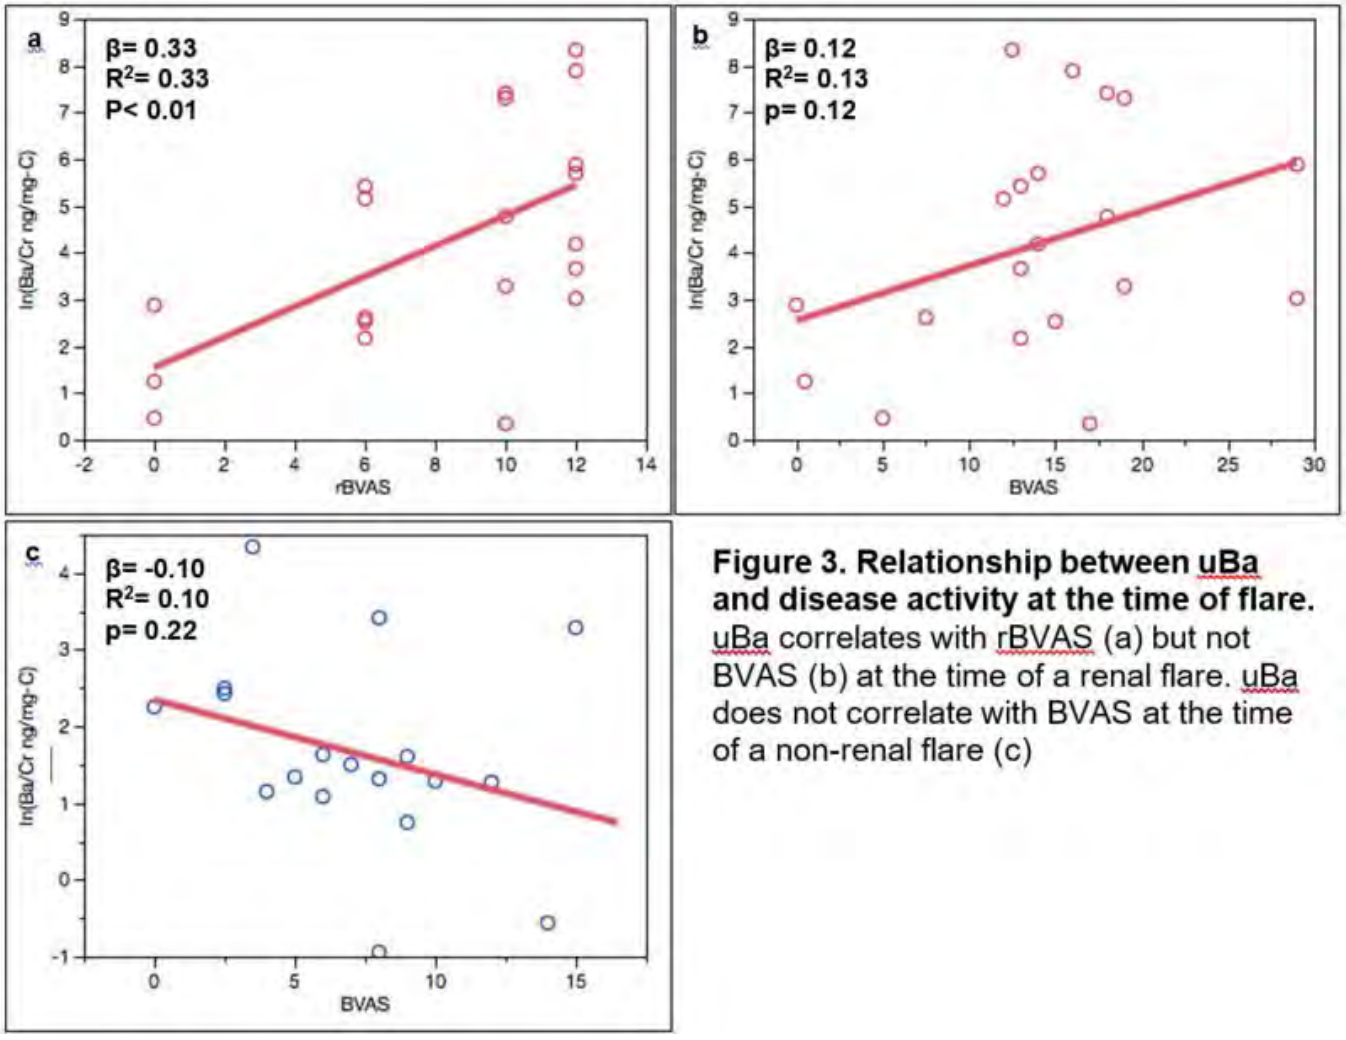

Figure 3. Relationship between uBa and disease activity at the time of flare. uBa correlates with rBVAS (a) but not BVAS (b) at the time of a renal flare. uBa does not correlate with BVAS at the time of a non-renal flare (c)

Background/Purpose: The alternative complement pathway has been implicated in the pathogenesis of ANCA-associated vasculitis (AAV), however it is not clear whether activation of complement occurs systemically or in affected organs such as the kidney. This study measured levels of urinary and plasma complement fragment Ba (uBa and pBa respectively) at multiple timepoints in patients with AAV.

Methods: Ba was measured by ELISA in serial samples of urine (uBa) and plasma (pBa) from 20 AAV patients who developed a renal flare, 20 who developed a non-renal flare, and 20 in long-term remission. Changes in Ba levels were modeled using linear mixed effect models.

Results: Cohort characteristics are given in **Figure.1**. uBa levels increased at renal flare, but did not increase at non-renal flare, and remained stable in long-term remission (**Figure 2a**). pBa levels were stable over time in all groups (**Figure 2b**). uBa correlated with renal AAV activity measured as the renal component of the BVAS score (R^2= 0.33, p< 0.01) (**Figure 3a**), but did not correlate with the overall BVAS score during renal flare (R^2= 0.13, p=0.12) or non-renal flare (R^2= 0.10, p=0.22) (**Figure 3b,c**).

Conclusion: Urine, but not plasma, Ba levels increase at the time of a flare of renal disease in AAV, suggesting intra-renal alternative complement pathway activation. uBa has the potential for use as a surveillance biomarker of renal vasculitis.

Incremental Healthcare Costs of Eosinophilic Granulomatosis with Polyangiitis (EGPA) Compared to Asthma: Retrospective Analysis of Commercial Claims Data in the United States (US)

Christopher Bell[1], Juliana Meyers[2] and Mayank Ajmera[2], [1]GlaxoSmithKline, Research Triangle Park, NC, [2]RTI-Health Solutions, Research Triangle Park, NC

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Vasculitis – ANCA-Associated Poster (0414–0436)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Eosinophilic granulomatosis with polyangiitis (EGPA), formerly Churg-Strauss Syndrome, is a rare, complex multisystem disorder, characterized by vascular inflammation and multisystem organ damage. EGPA manifests as asthma, chronic rhinosinusitis, blood/tissue eosinophilia, and vasculitis. In part due to its rare nature, there is an absence of real-world data quantifying the healthcare cost of EGPA. This study aims to quantify the incremental healthcare resource utilization (HRU) and costs associated with EGPA as compared to asthma using commercial insurance claims data in the United States (US).

Table 1. Study Results			
Variables	EGPA	Asthma	p-value
N	7,183	35,915	
Age, mean (SD)	51.0 (13.9)	51.2 (14.0)	N/A[a]
Female, N (%)	5,294 (73.7)	26,470 (73.7)	N/A[a]
Charlson Comorbidity Index, mean (SD)	2.8 (2.7)	2.8 (2.7)	N/A[a]
≥1 Prescription 12-Month Post-Index, N (%)			
SABA	3,157 (44.0)	16,078 (44.8)	0.204
ICS	2,960 (41.2)	12,290 (34.2)	<0.001
ICS/LABA	1,724 (24.0)	6,789 (18.9)	<0.001
Leukotriene modifiers	1,277 (17.8)	4,859 (13.5)	<0.001
Oral corticosteroids	4,452 (62.0)	13,704 (38.2)	<0.001
≥1 Healthcare Claim 12-Month Post-Index, N (%)			
Inpatient visit	2,580 (35.9)	9,066 (25.2)	<0.001
Emergency department visit	3,076 (42.8)	13,307 (37.)	<0.001
Outpatient hospital visit	6,294 (87.6)	27,738 (77.2)	<0.001
Physician office visit	7,110 (99.0)	35,095 (97.7)	<0.001
Other outpatient care[b]	5,558 (77.4)	25,326 (70.5)	<0.001
Pharmacy claim	6,300 (87.7)	31,390 (87.4)	0.474
12-Month Post-Index Cost (US$2018), mean (SD)			
Inpatient	$17,342 (56,188)	$8,764 (36,869)	<0.001
Emergency department	$1,054 (4,103)	$791 (3,418)	<0.001
Outpatient hospital visit	$10,498 (30,198)	$5,526 (19,898)	<0.001
Physician office visit	$6,009 (14,183)	$3,081 (7,748)	<0.001
Other outpatient care[b]	$3,596 (21,969)	$2,205 (14,894)	<0.001
Pharmacy claim	$5,906 (12,008)	$4,120 (9,300)	<0.001
Total Cost	$44,405 (82,061)	$24,487 (54,691)	<0.001

EGPA: eosinophilic granulomatosis with polyangiitis; ICS: inhaled corticosteroid; LABA: long-acting beta-agonist; N: number; N/A: not available; SABA: short-acting beta-agonist; SD: standard deviation.
[a]Not available due to variable used in matching criteria.
[b]Home health care, laboratory, etc.

Methods: A retrospective analysis was conducted using the IQVIA PharMetrics Plus Database identifying patients (pts) diagnosed with EGPA between 30 September 2008 and 01 October 2018. Prior to the implementation of ICD-10, EGPA diagnosis was based on published ICD-9-based algorithms.[1,2] Post October 2015, EGPA diagnosis was based on ICD-10 code M30.1 (polyarteritis with lung involvement [Churg-Strauss]). The first observed ICD-9/10 claim for EGPA was the index date. An asthma control cohort (ICD-9: 493.X; ICD-10: J45.X) was also identified (date of first asthma claim = index date). Pts in both cohorts were ≥18 years of age with continuous health plan enrollment (6-months pre- and 12-months post-index). Pts in the EGPA cohort were matched to pts in the asthma cohort (matching ratio 1:5) using direct covariate matching (age at index, year of index, gender, geographic region, and Charlson-Comorbidity Index [CCI] score). Results are reported as counts, percentages and means (standard deviation [SD]). Multivariable analysis was conducted to estimate adjusted total, all-cause costs using a generalized linear model (GLM). Statistical comparisons were evaluated at α=0.05 level.

Results: After matching, the EGPA and asthma cohorts consisted of 7,183 and 35,915 pts, respectively. Based on covariate matching, the cohorts were similar in terms of baseline characteristics (mean age: 51 years; 73% female; mean CCI score: 2.8) (Table 1). In the 12-month post-index period, significant differences between the EGPA and asthma cohorts were observed (Table 1) for the following: (1) proportion of pts with asthma-related medication (with exception of short-acting beta-agonists), (2) proportion of pts with ≥1 HRU claim by setting of care (with exception of pharmacy claims); and (3) mean total costs and costs by setting of care. Unadjusted total costs in the 12-month post-index period were $44,404 (82,060) and $24,487 (54,691) in the EGPA and asthma cohorts, respectively ($p< 0.001$). Adjusted total costs in the 12-month post-index period were $34,004 in the EGPA cohort and $19,552 in the asthma cohort (rate ratio: 1.74; 95% confidence internal: 1.68, 1.79; $p< 0.001$).

Conclusion: In the 12-month post-index period, HRU and costs were significantly higher for EGPA patients than asthma pts. This study demonstrates the incremental burden of EGPA and highlights the need for effective treatments that reduce the burden of disease and improve patient outcomes.

Diagnostic Accuracy of Muscle MRI for Muscular Vasculitis in Anti-neutrophil Cytoplasmic Antibody-associated Vasculitis: A Pilot Study

Ryuta Inaba, Daisuke Waki, Keisuke Nishimura, Tomohiro Yoshida, Kaoru Mizukawa, Shintaro Yamamoto, Osamu Iri, Kohei Yo and Hiroyuki Murabe, Department of Endocrinology and Rheumatology, Kurashiki Central Hospital, Kurashiki, Japan

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Vasculitis – ANCA-Associated Poster (0414–0436)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Histopathologic confirmation is the golden standard for diagnosis of anti-neutrophil cytoplasmic antibody-associated vasculitis (AAV), but sometimes can be difficult because of its invasion (e.g. renal biopsy) or low diagnostic yield (e.g. otorhinolaryngological biopsy). Some studies suggest that muscle biopsy (MB) is a useful tool for diagnosis of AAV owing to its safety and high diagnostic yield and muscle MRI could guide the site of MB [1]. However, there are no previous studies focusing on diagnostic yield of muscle MRI for systemic vasculitis. We aimed to assess the positive predictive value (PPV) of a muscle MRI for MB and describe the muscle MRI features of systemic vasculitis.

Methods: We included all AAV patients who performed muscle MRI at diagnosis or recurrence in our center between 2009 and 2020. The proof of muscular vasculitis was based on the presence of necrotizing vasculitis on MB. As previously reported in polyarteritis nodosa, MRI findings are evaluated with a focus on muscle and fascial lesions. Muscle MRI findings were classified into the following four categories: "diffuse", "patchy", "perivascular", and “myofasciitis” [2]. Duplication of MRI findings was allowed and counted in each category. We calculated PPV of muscle MRI for muscular vasculitis and compared characteristics of the patients with MB positive and those with MB negative.

Results: Among 68 AAV patients with a muscle MRI performed, 62 patients had a positive finding of muscle MRI. Of the positive MRI results, 35 patients (56.5%) presented diffuse pattern, 21 (33.9%) patients presented patchy pattern, and 6 patients (9.8%) presented perivascular pattern, and 39 patients (62.9%) had myofasciitis pattern. Among 39 patients with myofasciitis, there were 29 patients with diffuse pattern, 8 with patchy pattern, 2 with perivascular pattern, and none with myofasciitis alone. Open biopsy was performed in 36 patients (85.7%), and needle biopsy was performed in 6 patients. 31 patients were positive for MB, 10 patients were negative for MB. Among the patients underwent MB, PPV of a muscle MRI for muscular vasculitis was 75.6% (31/41). Comparing MB positive patients and MB negative patients, the clinical diagnosis of MPA (93.8% vs 63.6%), receiving open biopsy (93.5% vs 63.9%), and the diffuse pattern (75.0% vs 9.1%) and myofasciitis pattern (65.6% vs 18.2%) were significantly higher in MB

Table 1 Baseline clinical and biological characteristics in patients with MB positive and MB negative. positive patients. There was no significant difference in clinical and laboratory features including vascular disease activity between the two groups.

Conclusion: Muscle MRI can predict the positivity of MB and muscular vasculitis with a high probability. In addition, specific MRI findings (diffuse and myofasciitis patterns) can predict a positive muscle biopsy with high probability.

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Vasculitis – ANCA-Associated Poster (0414–0436)

Session Type: Poster Session A

Session Time: 8:30AM–10:30AM

Background/Purpose: ANCA-associated vasculitides (AAV) are multisystem diseases that can have multiple ophthalmic manifestations. Although there are some data on ocular disease in granulomatosis with polyangiitis (GPA), even less are available for microscopic polyangiitis (MPA) and eosinophilic granulomatosis with polyangiitis (EGPA). Further, there also few reports differentiating symptoms seen at disease onset compared to later in the course of the illness, or whether ophthalmic manifestations are related to other anatomically local disease or systemic manifestations in general.

Methods: Patients with GPA, MPA, or EGPA enrolled in a longitudinal study between April 2006 and April 2021 were included in this study. Data concerning diagnosis, demographics, cranial disease manifestations and their time of onset, treatment, and ocular complications were extracted. Prevalence of ophthalmic manifestations at disease onset and incidence of manifestations over the course of follow up, median time to onset of new manifestations and complications, and correlations with otolaryngologic and neurologic manifestations of disease were calculated.

Results: Data from 1389 patients were included for analysis which included 6392.8 patient-years of follow up. There were 852 cases of GPA, 165 cases of MPA, and 372 cases of EGPA; with 258 (30.3%), 7 (4.2%), and 13 (3.5%) ocular manifestations present at baseline, respectively (Table 1). The most common manifestations seen were conjunctivitis/episcleritis and scleritis, though 38.5% of the ocular manifestations in EGPA were retinal vasculitis. Multiple ophthalmic manifestations were seen in 79 (9.3%) of patients with GPA, and in none with EGPA. In GPA, the prevalence of

IQR: inter-quartile range; *denotes a single patient

manifestations was similar when stratified by c-ANCA/PR3 positivity, except for conjunctivitis/episcleritis ($p< 0.01$). Inflammatory ocular manifestations presented earlier in the disease course (Table 2). During follow up, 6.6% patients with GPA had incident ocular manifestations, while such events were rare in MPA (0.6%) and EGPA (0.5%). There were no significant correlations seen between ophthalmic, otolaryngologic, and neurologic manifestations of disease. The most common complication seen across all 3 diseases was cataracts, seen in 9.1-15.3% of patients. Non-cataract complications followed a similar pattern to other manifestations: 67 (7.9%) patients with GPA experienced such complications followed by 10 (2.7%) of those with EGPA, and 7 (4.2%) of those with MPA (Table 3).

Conclusion: Among patients with AAV, ophthalmic manifestations and complications are common in GPA, but rare in MPA and EGPA. Inflammatory eye conditions are the most common ophthalmic manifestation seen, and cataracts

Table 3. Ophthalmic complications of disease in patients with ANCA-associated vasculitis

Complication: n (%)	GPA n=852	MPA n=165	EGPA n=372
Any ocular complication	154 (18.1)	19 (11.5)	65 (17.5)
Any non-cataract complication	67 (7.9)	7 (4.2)	10 (2.7)
>1 ocular complication	32 (3.8)	3 (1.8)	2 (0.5)
Visual impairment or diplopia	23 (2.7)	2 (1.2)	1 (0.3)
Blindness in one eye	8 (0.9)	1 (0.6)	0
Cataracts	112 (13.1)	15 (9.1)	57 (15.3)
Optic atrophy	6 (0.7)	0	0
Optic neuritis	8 (0.9)	0	0
Retinal changes	4 (0.5)	1 (0.6)	2 (0.5)
Peripheral vascular retinal changes	27 (3.2)	3 (1.8)	7 (1.9)
Orbital wall destruction	12 (1.4)	0	0

are the most common complication. New ophthalmic manifestations after disease onset are rare. These data are informative for clinicians caring for patients with AAV and investigators studying this spectrum of vasculitis.

Session Title: Vasculitis – ANCA-Associated Poster (0414–0436)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Antineutrophil cytoplasm antibody (ANCA)-associated vasculitides (AAV) are a group of multisystem inflammatory diseases of the small blood vessels. Infections are serious complications in AAV and often associated with premature mortality. Existing studies on the risk of infection in AAV patients and relative risk when compared to the general population suffer from small sample sizes, selected hospitalized samples and lack of control of potential confounders. To evaluate the independent effect of AAV on the risk of severe infection and infection-related mortality.

Methods: Using administrative data from British Columbia, Canada and a previously validated AAV case definition, we conducted an age- and gender- matched cohort study of all patients with incident AAV between January 1, 1997 and March 31, 2015. The non-AAV individuals were randomly selected from the general population and 10:1 matched to the AAV patients on age, sex and AAV index year. Primary outcome was the first severe infection after AAV onset necessitating hospitalization or occurring during hospitalization. Secondary outcomes were infection-related mortality and total number of severe infections. To evaluate the relative risk of severe infection outcomes for AAV patients relative to general controls, we used: 1) Cox proportional hazard models to compute hazard ratios for the first severe infection as well as for the infection-related mortality; 2) Poisson regression to compute the rate ratios for total counts of infections. These analyses were controlled for the baseline variables listed in Table 1 to assess independent effects of AAV on infection outcomes.

Results: We identified 559 AAV patients and matched them with 5,590 non-AAV individuals from the general population (57% females, mean age 54), yielding 187 and 510 first severe infections (Table 2) during 2,603 and 36,111 person-years follow-up, respectively. The crude incidence rate ratios were 4.85, 3.72 and 5.08 for first severe infec-

tion, infection-related mortality and total counts of infections, respectively. After adjusting for all confounders, the independent effect of AAV on the risk of for first severe infection, infection-related mortality and total number of severe infections was 3.77, 3.84 and 3.29, respectively.

Conclusion: In this population-based study, we found AAV was associated with increased risks of first severe infection (3.8-fold), infection-related mortality (3.8-fold) and a greater total number of severe infections (3.3-fold). This highlights the higher risks of infection in AAV patients.

Baseline characteristics of individuals with AAV and without AAV. Abbreviations: AAV, Antineutrophil cytoplasm antibody-associated vasculitides; SD, standard deviation; COPD, chronic obstructive pulmonary disease; NSAIDs, non-steroidal anti-inflammatory drugs including cyclooxygenase-2 inhibitors; HRT, hormone replacement therapy; CVD, cardiovascular diseases. *All baseline characteristics were measured over one year prior to the start of follow-up except that age was measured at the start date of the follow-up.

Risk of severe infection in AAV relative to non-AAV during follow-up. Abbreviations: AAV, Antineutrophil cytoplasm antibody-associated vasculitides; IR, incidence rate; IRR, incidence rate ratio; HR, hazard ratio; CI, confidence interval. *Adjusted for covariates listed in Table 1.

ANCA Positivity and ANCA Associated Vasculitis in Patients with Rheumatoid Arthritis

Courtney O'Brien, Veena Ranganath and Tannaz Kermani, University of California Los Angeles, Los Angeles, CA

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Vasculitis – ANCA-Associated Poster (0414–0436)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Anti-neutrophil cytoplasmic antibody (ANCA) associated vasculitis (AAV) with rheumatoid arthritis (RA) has been reported rarely, and, studies have found ANCA positivity in RA. The objective of the study was to describe a cohort of patients with RA and AAV and to compare patients with RA+AAV to those with RA+ANCA positivity without AAV.

Methods: In this retrospective study, a cohort of patients with RA+ANCA positivity evaluated at an academic center were included. Data abstracted included demographics, seropositivity, ANCA specificity, clinical characteristics of RA, diagnosis of AAV and clinical features of AAV.

Results: The study included 77 patients, mean (±SD) age 60.2 (17.2) years, 78% female. ANCA serologies included perinuclear (p)-ANCA in 58%, cytoplasmic (c)-ANCA in 26%, myeloperoxidase (MPO) in 43% and proteinase 3 (PR3) in 26%. Twenty patients (26%) were p-ANCA/MPO positive, 3 patients (4%) c-ANCA/PR3 positive, 7 patients (9%) were p-ANCA/PR3 positive and 1 patient (1%) was c-ANCA/MPO positive.

Twenty-five patients (32%) had a diagnosis of AAV; 9 (36%) microscopic polyangiitis (MPA), 8 (32%) granulomatosis with polyangiitis (GPA), 1 (4%) eosinophilic granulomatosis with polangiitis (EGPA), 1 (4%) GPA versus rheumatoid vasculitis (peripheral ulcerative keratitis, scleritis, sudden hearing loss, MPO positive). In 6 patients (24%) diagnosis was unclassifiable (1 interstitial lung disease attributed to vasculitis, 3 cutaneous vasculitis with ulcerations, 1 case of multiple digital infarctions from vasculitis, 1 leukocytoclastic vasculitis). Diagnosis of RA preceded vasculitis in 92% cases, was concurrent in 4% and followed vasculitis in 4%. Clinical manifestations of AAV are in Table 1. Among patients with RA+ANCA positivity but no diagnosis of AAV, 1 patient had nasal septal perforation with polyposis, 1 patient had vasculitic rashes and neuropathy attributed to vasculitis from RA, 2 patients had retinal vasculitis.

A comparison of patients with RA+AAV, and, patients with RA+ANCA without AAV is in Table 2. A higher proportion of patients with ANCA positivity via indirect immunofluorescence (IIF) along with antibody specificity to MPO or PR3 had a clinical diagnosis of AAV. These findings remained significant even if the 6 patients with unclassifiable disease were excluded (data not shown).

Table 1: Clinical manifestations of ANCA-associated vasculitis in patients with concurrent diagnosis of Rheumatoid Arthritis.

Clinical Manifestation	N (%)

Other	4 (16)	17 (31)	
Unknown or Declined	2 (8)	8 (15)	
Ethnicity, N (%)			
Hispanic/Latino	12 (48)	10 (19)	0.01
Seropositivity, N (%)	16 (64)	28 (54)	0.45
RhF positive	13 (56)	21 (41)	0.31
CCP positive	7 (32)	20 (43)	0.44
RhF and CCP positive, N (%)	4 (18)	13 (27)	0.56
p-ANCA	18 (72)	27 (52)	0.14
c-ANCA	8 (32)	12 (23)	0.42
MPO	15 (60)	18 (35)	0.05
PR3	8 (32)	12 (23)	0.42
p-ANCA/MPO or c-ANCA/PR3	16 (64)	7 (14)	<0.001
Any positive ANCA on IIF and positive ELISA	20 (80)	11 (21)	<0.001
Joint erosions on x-ray	7/19 (37)	11/42 (26)	0.55

SD = standard deviation, N= number, RhF = rheumatoid factor, CCP = cyclic citrullinated peptide, p-ANCA = perinuclear ANCA, c-ANCA = cytoplasmic ANCA, MPO = myeloperoxidase, PR3 = proteinase 3, IIF = indirect immunofluorescence, ELISA = enzyme linked immunosorbent assay

Conclusion: AAV in RA included an even number of cases of GPA and MPA. The diagnosis of RA almost always preceded the diagnosis of AAV and renal involvement was the most commonly present manifestation of AAV. There was uncertainty regarding attribution of isolated cutaneous vasculitis to RA or AAV and 24% of this cohort diagnosed as AAV had isolated skin disease. Many patients without vasculitis had positive MPO or PR3 antibodies. The presence of ANCA via IIF with MPO or PR3, even if discordant, separated patients with RA+AAV from those without vasculitis highlighting the need for clinical vigilance in this subset of patients with RA. The immune mechanisms underlying this rare overlap need to be elucidated.

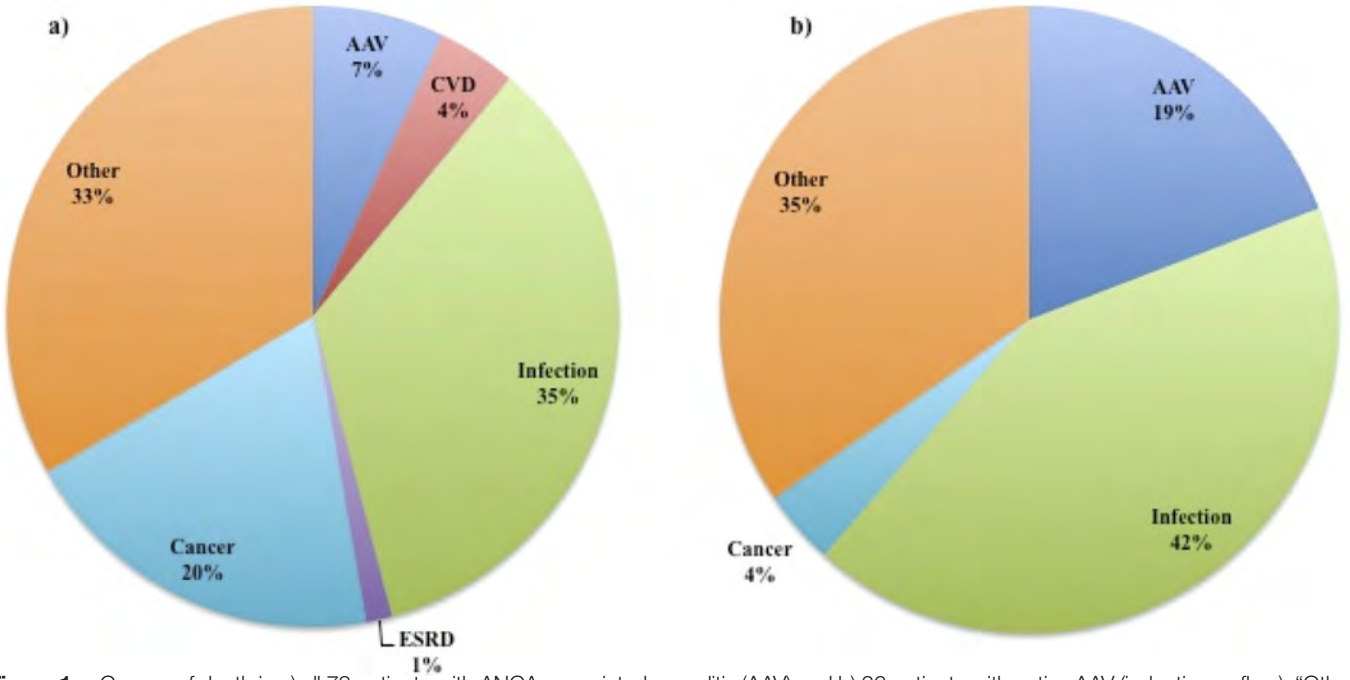

Figure 1. Causes of death in a) all 72 patients with ANCA-associated vasculitis (AAV) and b) 26 patients with active AAV (induction or flare). "Other" deaths included conditions unrelated to AAV such as surgical complications, valvular heart disease, dementia, and cardiac arrest of unknown etiology. CVD: cardiovascular disease (defined as acute ischemic CV event); ESRD: end-stage renal disease.

design, and develop interventions to improve survival, comprehensive data on causes and characteristics of death in a real-world, contemporary AAV cohort are needed.

Methods: We identified patients from a multi-center consecutive inception AAV cohort who were diagnosed and died between 2002-2017. Death was ascertained by linkage to the electronic health record and the National Death Index; death certificates were obtained. Two rheumatologists independently reviewed each chart to extract death details; differences were resolved by consensus. Each death was categorized as resulting from active vasculitis, acute ischemic cardiovascular (CV) event, infection, ESRD, cancer, or other. AAV disease status at the time of death was categorized as "induction" (≤ 6 months since treatment initiation), "flare" (increased disease activity within 6 months), or "remission." We extracted details regarding treatment and place of death. We also determined the sensitivity of a diagnosis of AAV on a death certificate by tabulating the presence of AAV ICD-10 codes (M31.3, M31.7) on any line.

Results: Of 484 patients in the AAV cohort, 130 (27%) died and 72 had records from the time of death available for review. Characteristics of the cohort are included in Table 1. The mean age at death was 71 years, and the median time from diagnosis to death was 4.4 years. 67 out of 130 (52%) were male. Of deaths with EHR data available at the time of death (n=72), 42 (64%) occurred during periods of remission, 21 (29%) during induction, and 5 (7%) during flare. The majority occurred while on immunosuppression (53, 74%), and 47 (65%) occurred in acute care hospitals (Table 2). The most common cause of death was infection (25, 35%), followed by cancer (14, 20%), AAV (5, 7%), acute ischemic CV events (3, 4%), ESRD (1, 1%), and other (24, 33%), which included cardiac arrest of uncertain cause (Figure 1). Deaths from active AAV were rare (5, 7%): cerebral vasculitis (n=1), pulmonary disease (n=3), and multi-organ failure (n=1). Among those with active AAV (induction or flare), infection remained the most common cause (11, 42%). The sensitivity of death certificates for identifying patients with AAV was 21% (24 of 116 certificates); in 3 cases, AAV was misclassified as other vasculitis.

Conclusion: In a contemporary AAV cohort, most deaths were infectious and occurred in remission on maintenance immunosuppression; deaths from active AAV were rare, and some of cardiac etiology were difficult to classify. These results highlight the need for personalized strategies that reduce infection risk during remission maintenance without

sacrificing disease control. Additional studies are needed to understand the burden of CV disease in AAV. The use of national death certificate data to estimate the burden of death due to AAV will underestimate the impact of AAV on death.

Sex, ANCA-type, and BVAS-adjusted	1.53 (1.05, 2.21)	1.0 (Ref)
*Age as time scale		

Background/Purpose: Despite treatment advances, ANCA-associated vasculitis (AAV) remains associated with excess morbidity and mortality. Interstitial lung disease (ILD) is an increasingly recognized manifestation of AAV but its prevalence, characteristics, and outcomes remain poorly defined. Additionally, most studies of AAV-ILD have been performed in AAV cohorts assembled in Asia where MPO-ANCA+ disease is highly prevalent. We sought to characterize factors associated with AAV-ILD and mortality in AAV-ILD in a large North-American-based AAV cohort.

Methods: AAV-ILD cases were identified by screening a consecutive inception PR3- or MPO-ANCA+ AAV multicenter cohort assembled between 2002 and 2019 for ICD-9/10 codes relevant to the diagnosis of ILD. Each case identified by this screen then underwent a manual review of the electronic health record (EHR) and available chest imaging. Two board-certified radiologists reviewed all available computer tomography (CT) scans of the chest for each patient to assess for interstitial lung disease and classify the type of ILD (UIP vs non-UIP). Patients with uncertain radiographic features were considered to not have ILD. Demographics, AAV disease features, results of pulmonary function tests, and comorbidities were extracted from the EHR. The baseline Birmingham Vasculitis Activity Score/Wegener's Granulomatosis (BVAS/WG) was determined for each patient. All-cause mortality was assessed by linkage to the National Death Index. Univariate analyses were used to assess the association of demographic- and disease-specific factors with AAV-ILD. Unadjusted and adjusted Cox proportional hazard models with age as the time scale were used to assess the association of AAV-ILD with death among patients with AAV.

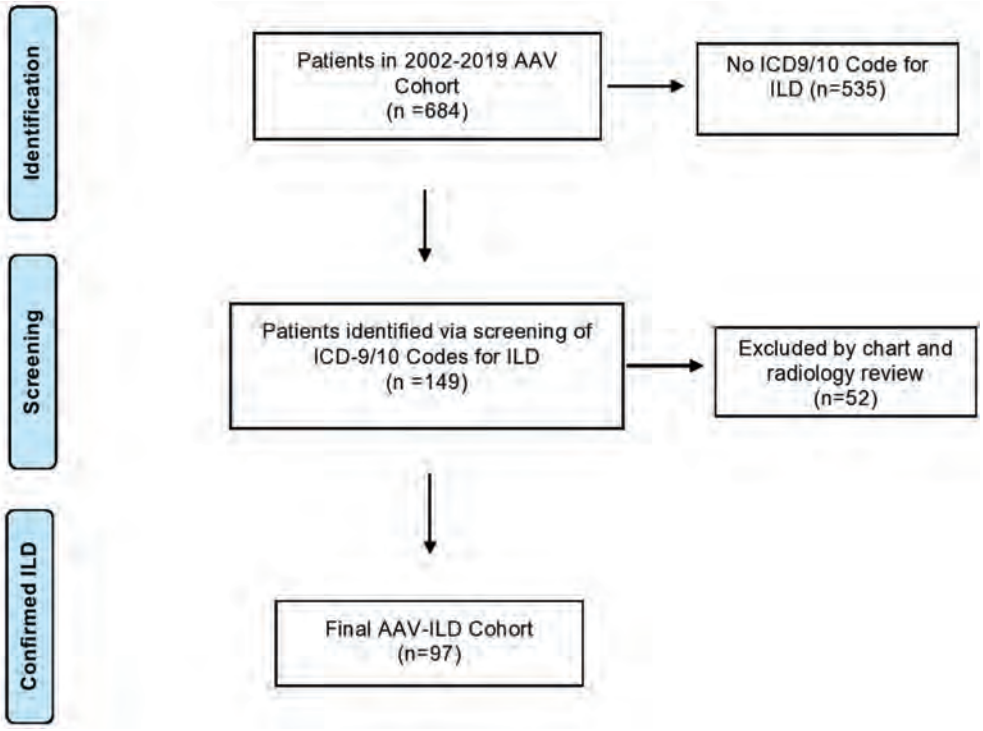

Figure 1. Patient Identification and Screening for ILD Inclusion.

Results: Of 698 patients from the cohort, 14 were excluded because of insufficient records and 684 were screened (Figure 1). Of those screened, 97 (14.2%) had AAV-ILD. Patients with AAV-ILD were older (67±12yrs vs 58±18yrs, p< 0.001) than those with AAV-non-ILD; sex distribution was similar (55% vs 60% female, p=0.7) (Table 1). Compared to AAV-non-ILD, AAV-ILD patients were more often MPO-ANCA+ (97% vs. 64%, p< 0.001) and less often had head and neck involvement (31% vs 45%, p=0.01). The diagnosis of ILD preceded or occurred concurrently with the diagnosis of AAV in 85 (88%) patients. The ILD pattern was classified as UIP in 29 (30%) patients with AAV-ILD. The mean (SD) FVC % predicted among AAV-ILD patients was 79±20% and adjusted DLCO % predicted was 53±22% (Table 1). AAV-ILD was associated with a 53% higher risk of death than AAV-non-ILD in analyses adjusted for age, sex, baseline BVAS/WG, and ANCA type (HR=1.53, 95% CI 1.05, 2.21) (Table 2).

Conclusion: In a large North American cohort of AAV patients, we estimated the prevalence of AAV-ILD as 14% and observed strong associations with MPO-ANCA positive disease. In the vast majority of cases, AAV-ILD was present prior to or at the time of AAV diagnosis, highlighting that it is a feature that may precede other manifestations of AAV. Compared with AAV patients without ILD, those with ILD have a higher risk of all-cause mortality. Additional studies are needed to understand the response of ILD in AAV to conventional AAV treatment regimens.

Clinical Characteristics and Outcomes of ANCA-Associated and Non Immune-Mediated Hypertrophic Pachymeningitis: A Comparative Study

Eduardo Martin-Nares, Lilian Guadalupe Cano Cruz and Andrea Hinojosa-Azaola, Department of Immunology and Rheumatology, Instituto Nacional de Ciencias Médicas y Nutrición Salvador Zubirán, Mexico City, Mexico

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Vasculitis – ANCA-Associated Poster (0414–0436)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Hypertrophic pachymeningitis (HP) is an infrequent manifestation in autoimmune and non-autoimmune conditions. The differences in clinical characteristics and outcomes of ANCA-associated and non-immune-mediated HP have not been thoroughly explored.

We aimed to explore the clinical characteristics and outcomes of patients with ANCA-associated HP (ANCA-HP) in comparison to non-immuno-mediated HP (NIM-HP) from a single center.

Methods: We performed a retrospective single center study. We included patients with a diagnosis of HP that were followed from 2003 to 2020 in a referral center. HP was defined as focal or diffuse thickening with or without enhancement visualized on magnetic resonance imaging of the brain or spine. ANCA-associated-vasculitis were diagnosed according with the 1990 American College of Rheumatology Classification Criteria, 2012 Chapel Hill Consensus nomenclature and/

Table 1. Etiologies of non-immune-mediated hypertrophic pachymeningitis

Etiology	N = 33 n (%)
Infectious HP	10 (30.3)
Tuberculosis	6 (18.2)
Micobacterium bovis	1 (3%)
Mucormicosis	1 (3%)
Bacterial abscess	1 (3%)
Syphilis/HSV-1	1 (3%)
Neoplastic HP	23 (69.7)
Non Hodgkin lymphoma	6 (18.2)
Meningioma	4 (12.1)
Meningeal carcinomatosis	3 (9.1)
Multiple myeloma/Plasmocytoma	3 (9.1)
Erdheim-Chester disease	2 (6)
Acute lymphocytic leukemia	2 (6)
Chronic myeloid leukemia	1 (3)
Rosai-Dorfman disease	1 (3)
Hodgkin lymphoma	1 (3)
HP: hypertrophic pachymeningitis; HSV-1: herpes simplex virus-1	

or the European Medicines Agency Consensus algorithm for the classification of vasculitis. The underlying disease in NIM-HP patients was diagnosed by using international accepted criteria as appropriate. NIM-HP were further subclassified in infectious HP and neoplastic HP. We performed a comparison between the ANCA-HP and the NIM-HP group using Student t-test or Mann-Whitney U test for continuous variables, and Chi-square or Fisher's exact test for categorical variables.

Results: We included 52 patients with HP. Nineteen (36.5%) were ANCA-HP and 33 (63.5%) NIM-HP. All ANCA-HP patients had diagnosis of granulomatosis with polyangiitis; 11 (57.9%) were PR3-ANCA positive, 3 (15.8%) MPO-ANCA positive, 2 (10.5%) double positive, 2 (10.5%) C-ANCA positive, and 1 (5.2%) P-ANCA positive. Thirty-three were NIM-HP (63.5%); of them, 10 (19.2%) were infectious HP and 23 (44.2%) neoplastic HP (Table 1). Forty-nine (94.2%) patients had cranial, 2 (3.8) spinal, and 1 (1.9%) cranial/spinal HP. In 24 (46.2%) patients HP presented after, in 10 (19.2%) before, and in 18 (34.6%) concomitant to the underlying disease diagnosis. Forty (76.9%) patients had associated comorbidities.

The clinical presentation, laboratory findings and outcomes of our cohort are shown in Table 2. Patients with ANCA-HP presented more frequently with headache, papilledema, ataxia, and cranial neuropathy (especially VII, VIII, IX, X and XII nerves), extra-neurological involvement, leukocytosis, and less frequently with altered mental status and hypoglycorrhachia. Furthermore, ANCA-HP presented more commonly remission ever, however, relapses were more frequent. In both groups, at a median follow-up time of 40 (IQR 17.5-72) months, 6 (11.5%) patients with neoplastic HP died.

Conclusion: ANCA-HP and NIM-HP had specific differences in clinical presentation and laboratory findings that may allow clinicians to suspect one cause over the other in clinical practice. The disparities in outcomes reflect the relapsing-remitting nature of ANCA-associated vasculitis.

Table 2. Characteristics of patients with hypertrophic pachymeningitis

	Total	ANCA-HP (n=19)	NIM-HP (n=33)	p
Female, n (%)	26 (56)	8 (42.1)	18 (54.5)	0.56
Age, mean ± SD, years	43.7 ± 14.1	42.3 ± 13.9	44.4 ± 14.4	0.61
Craneal, n (%)	49 (96.1)	17 (94.4)	32 (97)	1.0
Time to diagnosis, median (IQR), days	30 (10-120)	26.5 (3-120)	37 (10-210)	0.40
Comorbidities, n (%)	40 (76.9)	14 (73.7)	26 (78.8)	0.67
Acute, n (%)	20 (38.5)	9 (47.4)	11 (33.3)	0.31
Subacute, n (%)	13 (25)	2 (10.5)	11 (33.3)	0.06
Chronic, n (%)	16 (30.8)	8 (42.1)	8 (24.2)	0.17
Asymptomatic, n (%)	3 (5.8)	0	3 (9.1)	0.17

Anti-IL5 Therapy in Eosinophilic Granulomatosis with Polyangiitis (EGPA): A Longitudinal Follow-up Study ≥ 24months

Allyson Egan[1], Pasupathy Sivasothy[2], Lisa Willcocks[2], Rachel Jones[2], Marcos Martinez Del Pero[3] and David R.W. Jayne[4], [1]Vasculitis and Lupus Centre, Cambridge University Hospital, University of Cambridge, London, United Kingdom, [2]Vasculitis and Lupus Centre, Department of Medicine, Cambridge University Hospital, Cambridge, United Kingdom, [3]Vasculitis and Lupus Centre, Cambridge University Hospital, Cambridge, United Kingdom, [4]University of Cambridge, Cambridge, United Kingdom

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Vasculitis – ANCA-Associated Poster (0414–0436)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: In the randomized, placebo-controlled MIRRA trial for relapsing and refractory eosinophilic granulomatosis with polyangiitis (EGPA), adjuvant therapy with 300mg anti-IL5 mAB Mepolizumab [MEPO] for 12 months (M), accrued longer times in remission, reduced steroid exposure and reduced relapse rates[2]. The aim of this study is to analyze the outcome of 100mg MEPO monthly s/c for a minimum of 24M in EGPA. Changes to adjuvant immunosuppression and indications for anti-IL5 class switch from MEPO 100mg s/c to Benralizumab (BRZ) or Reslizumab (Res) were assessed.

Methods: In this retrospective descriptive study, 20 EGPA patients received 100mg s/c MEPO every 4 weeks for a minimum of 24M (maximum duration 43M). Anti-IL5 therapy was switched between agents for poor response or intolerance. Time points of assessment included MEPO commencement, 6, 12, 18 and 24 months.

Results: Overall, there was a 50% reduction in steroid usage by 12 months. This continued to fall out to 24M. All 20 EGPA patients receiving anti -IL5 therapy, ranging from 24-43 months remain on therapy. 50% have remained on 100mg s/c MEPO and 50% have switched to an altenative anti-IL5 agent - 9 switched to benralizumab, 1 initially on benralizumab to reslizumab. All remain on anti-IL5 therapy after switch. Three patients had a break of therapy, but all resumed anti-IL5 treatment. 8 have anti-IL5 monotherapy as their maintenace regimen, an additional 6 weaned off conventional immunosuppressants. 6 continued or commenced conventional immunotherapy therapy which is well tolerated. ANCA serology normalized in all four positive patients by 12 months.

Conclusion: The relapsing nature of EGPA places a potential dependency of therapy on steroids, underscoring the importance of pathway specific biologics to minimize exposure, prevent tissue damage and ensure early response to therapy. There was a 50% reduction in steroid dosage in this study by 12 months and steroid requirements continue to decrease to 24 M. Longer-term anti-IL5 therapy is continuing in all 20 patients due to clinical benefits achieved.

Table 1. EGPA patients commenced on Mepolizumab [100mg s/c]

Demographics	All [n=20]	
Gender ratio M/F	7 M: 13 F	
ANCA positive/ negative	3 Anti-MPO, 1Anti-PR3 positive/ 16 ANCA negative

15	31	Continue	MEPO	31		
16	31	Restart/Switch	BRZ	12	8	
17	26	Continue	MEPO	26		
18	26	Switched	BRZ	12	14	MMF stopped
19	24	Switched	BRZ	21	3	
20	24	Switched	BRZ	12	12	AZA stopped

Response to therapy

Prednisolone dose [N= 20]	**M0**	**M6**	**M12**	**M18**	**M24**
Mean ±SD	18 mg ± 10.31	12.26 mg ±6.8	9.37mg ± 5.3	9.71mg ± 8.1	7.7 mg ±7.08

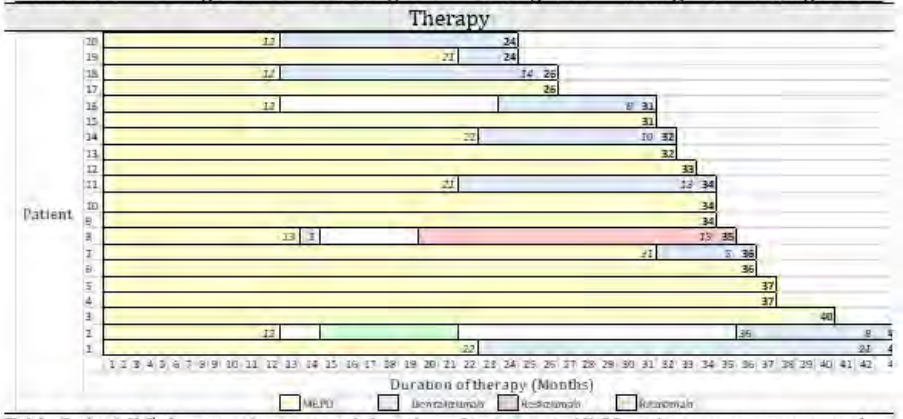

Table 3: Anti-IL5 therapeutic agent and duration of treatment. All 20 patients were commenced on MEPO 100mg s/c. 50% (N=10) remain on MEPO, whilst 10 switched to Benralizumab (BRZ). One subsequently converted to Reslizumab (RES). Three had a break from anti-IL5 therapy but returned to treatment with good response including steroid reduction. one had rituximab between anti-IL5 courses.

Anti-IL5 therapeutic agent, duration of treatment and adjuvant therapy.

Anti-IL5 monotherapy is effective in some cases. Adjuvant immunotherapy is well tolerated and reduced in some cases. This study demonstrates that anti-IL5 therapy serves as a favorable model for steroid minimization in EGPA.

Use of 2-Mercaptoethane Sodium Sulfonate Prophylaxis in Cyclophosphamide-Treated Patients with ANCA-Associated Vasculitis: Results of an Electronic Survey

Lukas Joos[1], Solange Gonzalez Chiappe[1], Thomas Neumann[1] and Alfred Mahr[2], [1]Kantonsspital St.Gallen, St.Gallen, Switzerland, [2]Kantonsspital St. Gallen, St.Gallen, Switzerland

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Vasculitis – ANCA-Associated Poster (0414–0436)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Co-prescribing mesna with CYC for AAV aims to prevent the potential urotoxic effects of CYC. We investigated current clinical practice related to prescribing mesna prophylaxis or not for CYC-treated patients with AAV.

Methods: We searched MEDLINE for publications with the MeSH term "ANCA-associated vasculitis" over a 10-year period. Email addresses of authors were extracted from the online information. These authors were invited by email to participate in an online SurveyMonkey® survey asking about the characteristics of the respondent, their experience with AAV, and their practice in using CYC to treat AAV and in using mesna in CYC-treated patients with AAV and the underlying rationale. We compared 15 response variables to identify factors associated with the use of mesna. Response variables with multiple categories were first analyzed across all categories; if the omnibus test result was significant, additional analyses were used to identify the categories, which were the sources of group separation. Statistical analyses involved Pearson's chi-square test or Fisher's exact test. For multiple-response variables, the Rao-Scott correction was applied.

Results: The 139 participants were from 34 countries and were essentially MDs (98%) who mainly worked in rheumatology (50%), nephrology (25%) or internal medicine/immunology (18%). Mesna was given with CYC systematically, never, or on a case-by-case basis by 68%, 19% and 13% of respondents, respectively. As compared with systematic mesna-prescribers, never/occasional mesna-prescribers reported a longer time since receiving their degree (≥ 15 years: 80% vs 50%, P< 0.001), were more frequently based in England/United States (than in France/Germany/Italy) (78% vs 21%, P< 0.001), had longer involvement in care of patients with AAV (≥15 years: 62% vs 37%, P=0.006), had less practice in using intermittent pulse therapy as the exclusive/predominant CYC administration scheme (62% vs 89%, P< 0.001), and, as a rationale underpinning their mesna practice, had less adherence to local operational procedures (47% vs 73%, P=0.002) or (inter)national management guidelines for AAV (16% vs 49%, P< 0.001).

Conclusion: Practice with regard to prescribing mesna in conjunction with CYC to treat AAV is heterogeneous. Systematic mesna use prevailed over never or occasional use. The decision to prescribe mesna may be based more on circumstantial than structural reasons.

Protein Profiling in Pre-dating Samples Separate MPO-ANCA Vasculitis from PR3-ANCA Vasculitis

Mikael Brink[1], Ewa Berglin[1], Aladdin Mohammad[2], Andrey Alexeyenko[3], Kristina Lejon[1] and Solbritt Rantapaa-Dahlqvist[4], [1]Umeå Universitet, Umeå, Sweden, [2]Lund University, Lund, Sweden, [3]Karolinska Institutet, Stockholm, Sweden, [4]Ume University, Umea, Sweden

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Vasculitis – ANCA-Associated Poster (0414–0436)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis (AAV) is considered a chronic relapsing condition, with unknown etiology. This study was undertaken to gain insight to the molecular processes and potential biomarkers in blood samples collected prior to the onset of symptoms

Methods: The National Patient Register and Cause of Death register were searched for AAV-ICD codes and linked to the registers of five biobanks and eighty-five AAV cases were identified (34 males, 51 females) with samples >1month< 10years from AAV symptom onset. For each case two controls matched for sex, age, and sampling date were included. Samples were analyzed using ELISAs for PR3- or MPO-ANCA specificities. Ninety-two protein markers were analyzed using Olink Inflammation panel, (OLINK, Uppsala, Sweden) with 73 eligible after quality control.

Results: Eight protein markers were significantly altered between pre-AAV and controls, with higher levels of CCL23, CXCL5 ($p< 0.01$-0.05) and lower levels of Flt3L, STAMBP, ADA, TNFB, CX3CL1 and IL-15RA ($p< 0.01$-0.05) in the pre-AAV individuals. Nine protein markers were found significantly associated with time to symptom onset; CXCL9, CD244, VEGFA, CXCL1, TNFSF9, OPG, CSF-1, IFN-gamma and CD40 ($p< 0.01$-0.05). In pre-AAV individuals, six proteins were associated with MPO-ANCA-positivity compared with the MPO-ANCA-negative pre-AAV individuals which showed no overlap with the seven proteins related to PR3-ANCA-positivity.

Conclusion: To our knowledge our study is the first to analyze for and identify protein markers before symptom onset in AAV. This allowed for further studies of underlying cellular and molecular mechanisms in AAV pathogenesis as well as the diversification into PR3-ANCA and MPO-ANCA subphenotypes.

Myeloperoxidase Activity in Individuals with Antineutrophil Cytoplasmic Antibodies (ANCA) Can Be Inhibited by RLS-0071

Parvathi Kumar[1], Pamela Hair[1], Ulrich Thienel[1], Kenji Cunnion[1], Neel Krishna[2] and Christos Gabriel[3], [1]ReAlta Life Sciences Inc, Norfolk, VA, [2]ReAlta Life Sciences Inc., Norfolk, VA, [3]Children's Hospital of The King's Daughters, Norfolk

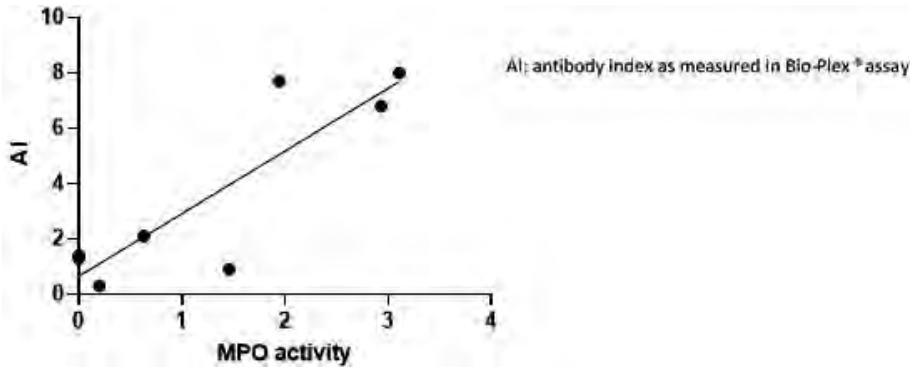
SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Vasculitis – ANCA-Associated Poster (0414–0436)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Anti-neutrophil cytoplasm antibodies (ANCA) are immunoglobulin G (IgG) autoantibodies directed against constituents of primary neutrophil granules (Davies, Moran et al. 1982). There is strong clinical, in vitro and in vivo evidence to suggest that ANCAs are pathogenic (Jennette and Falk 2014) causing pauci-immune necrotizing and crescentic glomerulonephritis (NCGN) and systemic small vessel vasculitis. One of the major target antigens for ANCA is myeloperoxidase (MPO) (Schreiber, Xiao et al. 2006). Both MPO and the reactive oxidants it generates have been implicated as participating in tissue injury in a large number of inflammatory conditions (Nicholls and Hazen 2005). There is no available information as to activity of circulating MPO in individuals with AAV although there is limited evidence that MPO-ANCAs, extracellular MPO, and in situ immune complexes composed of MPO and anti-MPO antibodies may have an important role in the pathogenesis of glomerular capillary injury in MPO-ANCA associated vasculitis (Arimura, Kawashima et al. 2013). Additionally, MPO can stimulate Neutrophil Extracellular Trap (NET) formation which exacerbate inflammation contributing to the dysfunction in AAV as evidenced by NETs found on kidney biopsy specimens from patients with small vessel vasculitis (Kessenbrock, Krumbholz et al. 2009). ReAlta's lead compound, RLS-0071, is a PEGylated peptide which has exhibits inhibition of MPO activity in animal models and ex vivo and demonstrates inhibition of MPO activity on an equimolar basis to the prototypical MPO inhibitor ABAH (4-aminobenzoic acid hydride). RLS-0071 also inhibits neutrophil mediated NETosis in vitro and in vivo (Hair, Enos et al. 2019, Enos, Hair et al. 2020).

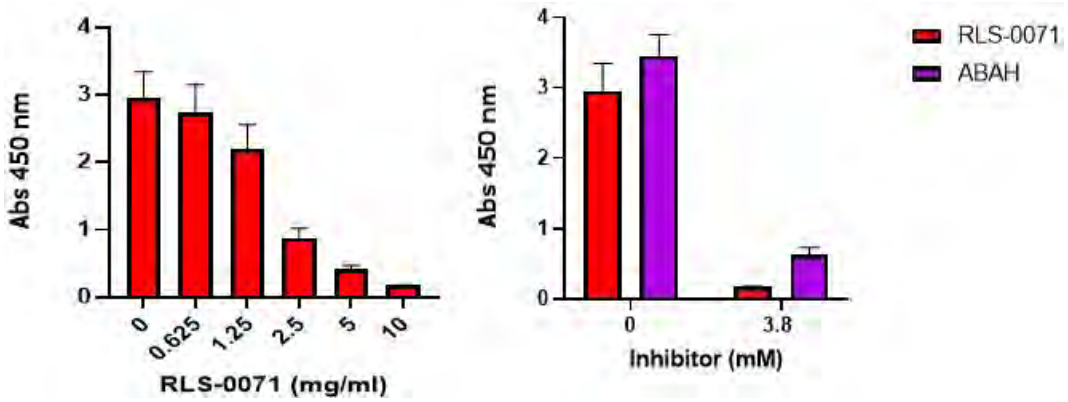
Methods: To better understand the role of MPO in ANCA associated pathophysiology, we conducted pilot analyses measuring MPO activity in plasma samples acquired commercially from individuals with known ANCA. AI (Antibody Index) units were available for each sample which represents a composite score of anti- MPO, anti- PR3 and anti-GBM antibody titers. MPO activity was measured using a TMB oxidation assay in which absorbance was measured a 450nm in a plate reader. The efficacy of RLS-0071 to inhibit MPO activity was evaluated in this assay.

Results: MPO activity as measured at 450nm absorbance ranged from 0 to 3.105. A positive correlation between MPO activity with the AI units in patient samples was observed (R^2= 0.76; p=0.0046). Addition of increasing concentrations of RLS-0071 to the patient samples showed a dose dependent decrease in MPO activity to a similar level as that observed with the MPO inhibitor ABAH.

Conclusion: In this pilot study, plasma from patients with ANCA demonstrated a wide range of MPO activity with the AI units trending with plasma MPO activity. Additionally, RLS-0071 inhibited MPO activity in plasma acquired from individuals with ANCA associated pathophysiology. Future studies will focus on elucidating relationships between MPO activity, MPO quantity, free plasma DNA as a surrogate measurement of NETs and anti-MPO titers.



Positive correlation between MPO activity with AI (composite score of anti- MPO, anti- PR3 and anti- GBM antibody titers)



Dose responsive decrease in MPO activity by RLS-0071 comparable to prototypical MPO inhibitor ABAH

Ocular and Orbital Manifestations of Granulomatosis with Polyangiitis: A Systematic Review of Published Cases

Madeleine Yeakle[1], **Allen Tsiyer**[1], Daniel Bishev[1], Kayvon Moin[1], Victoria Garofalo[1], Allison Parrill[1], Alexander Hatsis[2], Tyler Wickas[2] and Prachi Anand[3], [1]American University of the Caribbean School of Medicine, Cupecoy, Netherlands Antilles, [2]Department of Ophthalmology, Nassau University Medical Center, East Meadow, NY, [3]Department of Rheumatology, Nassau University Medical Center, East Meadow, NY

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Vasculitis – ANCA-Associated Poster (0414–0436)
Session Type: Poster Session A
Session Time: 8:30AM–10:30AM

Background/Purpose: Granulomatosis with polyangiitis (GPA), formerly known as Wegener's Granulomatosis, is a systemic autoimmune condition caused by granulomatous inflammation of small and medium arteries, arterioles and venules (1). While GPA most commonly affects the upper respiratory tract, lungs and kidneys; ophthalmologic symptoms including orbital and ocular manifestations contribute to morbidity in GPA patients. Ophthalmic manifestations of GPA occur in up to 58% (2) of patients involving the optic nerve, eyelid and orbital structures (3). Diagnoses recorded in current literature include scleritis, episcleritis, keratitis, proptosis, sclerochoroidal granulomas (4), ptosis, uveitis, sclerouveitis, and retinal vein occlusion (5). We aim to systematically analyze published cases of orbital and ocular GPA to characterize symptoms, complications, and outcomes. This may increase provider awareness to prevent misdiagnoses and complications, and lessen patient disease burden.

Methods: On March 21st, 2021, a literary search was conducted from the following electronic databases: PubMed, Web of Science, and Scopus using the MeSH terms "(Orbital OR Ocular) AND (Wegener's OR Wegener OR polyangiitis OR granulomatosis) following PRISMA guidelines (#CRD42021244745). The search included case reports and series discussing patients diagnosed with GPA confirmed ocular or orbital symptoms. We restricted our search to articles published or translated articles in the English language. All articles were included regardless of patient age, gender, sex, ethnicity, or country of origin.

Results: The literature search returned 2,579 articles with 372 meeting inclusion criteria representing 158 (54.1%) female and 134 (45.9%) male patients. The mean age of ocular or orbital symptom presentation and GPA diagnosis were 47.99 and 45.81 years of age, respectively. Fifty percent were not previously diagnosed with GPA prior to presenting with ocular or orbital symptoms. The most common presenting symptom was vision impairment (54.5%) followed by orbital mass (43.8%), proptosis (40.4%), eye pain (39.7%), and extraocular muscle limitation (33.9%). Histopathological examination of orbital/ocular biopsy identified granulomas in 48.5% of patients. Proteinase 3 anti-neutrophil cytoplasmic antibody (c-ANCA) and perinuclear anti-neutrophil cytoplasmic antibody (p-ANCA) positivity was found in 60.4% and 9.9% of patients, respectively. Systemic manifestations of GPA included pulmonary (34.6%), genitourinary (21.9%) and central nervous system (6.5%) among patients. Overall, 18.9% patients relapsed, 11.9% suffered blindness and 3.4% were treated with enucleation. Death was reported in 3.8% of cases. Patient outcomes encompassed full resolution (30.1%), partial resolution (47.3%), and unknown (21.6%).

Conclusion: Our review found that half of patients without prior GPA diagnosis presented with ocular and orbital symptoms. Clinical awareness and early diagnosis of ophthalmological GPA may prevent disease-related complications and improve patient outcomes.

Session Title: Abstracts: Immunological Complications of Therapy (0437–0440)

Session Type: Abstract Session

Session Time: 9:00AM–10:00AM

Background/Purpose: Rituximab (RTX) has been associated with impaired humoral response to vaccination. This study aim was to identify the predictors for a lack of humoral response to the BNT162b2 mRNA vaccine in patients with autoimmune inflammatory rheumatic diseases (AIIRD) treated with RTX.

Methods: We conducted a sub-analysis of the prospective multicenter study investigating immunogenicity of the two-dose regimen BNT162b2 mRNA vaccine in adult AIIRD patients, including rheumatoid arthritis (RA), systemic lupus erythematosus, systemic vasculitis, and inflammatory myositis treated with RTX compared to controls with-

Table 1. demographic and clinical characteristics of AIIRD patients treated with rituximab (RTX) and controls

Table 3. Stepwise backward model logistic regressions predicting seropositive result*.

Variable	OR	95% CI	p-value
RA	0.04	0.003-0.621	REF
SLE	0.536	0.033-8.784	0.662
ANCA-associated vasculitis	0.223	0.047-1.057	0.059
Other systemic vasculitis	0.476	0.038-5.98	0.566
IIM	0.333	0.057-1.956	0.223
Serum IgG level (prior the last RTX course)	1.002	1-1.004	**0.013**
Total RTX courses	0.875	0.744-1.03	0.108
Time interval between last RTX course and BNT162b2 vaccine	1.007	1.003-1.011	**0.002**

* Original model included SLE, ANCA associated vasculitis, other systemic vasculitis, IIM, disease duration, serum IgG levels, cumulative rituximab dose, rituximab last course dose, total rituximab courses, and time interval between the last rituximab course and BNT162b2 vaccine. Including and staying criterion was $p < 0.2$. RA was considered as a reference for diagnosis. RA, rheumatoid arthritis; SLE, systemic lupus erythematosus; ANCA, antineutrophil cytoplasmic antibody; IIM, idiopathic inflammatory myopathies; IgG, immune globulin G; RTX, rituximab.

out rheumatic diseases or immunosuppressants use. Data on the serum IgG level prior to administration of the last course of RTX were collected. Post-vaccination serum IgG levels against SARS-CoV-2 spike S1/S2 proteins were measured 2 - 6 weeks after the 2nd vaccine dose. Seropositivity was defined as IgG ³15 binding antibody units (BAU)/ml.

Statistical analysis included a stepwise backward multiple logistic regression for predicting a seropositive result on AIIRD patients with all data available (n=92), starting with all individual variables showing the significance level < 0.2 between seropositive and seronegative result.

Results: A total of 98 AIIRD patients (75.5% females) and 122 controls (64.8% females) were included in the study (table 1). AIIRD patients were significantly older vs controls, mean±standard deviation (SD) 62.3±14.6 vs 50.8±14.6 years, p>0.0001, respectively. Among AIIRD patients, 4 had a past history of lymphoma. Following vaccination, the seropositivity rate and S1/S2 IgG levels (mean±SD) were significantly lower among AIIRD patients vs controls, 38.8% (n=38) vs 100%, $p < 0.0001$ and 49.9±81 vs 218.4±81.2 BAU/ml, $p < 0.0001$, respectively.

Seronegative and seropositive AIIRD patients treated with RTX significantly differed by the total number of RTX courses, mean 5.9±4.0 vs 3.9±3.2, p=0.012; IgG levels prior to administration of the last course of RTX, 880.4±306.8 vs 1233±624 mg/dl, p=0.0036 and the interval between the last RTX course and vaccination, 158.3±157.9 vs 410.6±459.7 days, p=0.0019 (table 2). Multivariate logistic regression predicting a seropositive response to vaccination in patients treated with RTX showed that RA conferred the highest probability for a positive response, while ANCA-associated vasculitis conferred the lowest probability for a positive response. The odds ratio (OR) of ANCA associated vasculitis

was marginally significant (OR = 0.223, p=0.059). Two other variables –IgG level prior the last course of RTX and interval (days) between the last RTX course and vaccination – were associated with a seropositive response: for every 1 mg/dl IgG increment - OR 1.002, 95%CI 1-1.004, p=0.013, and for every day increment - OR 1.007, 95%CI 1.003-1.001, p=0.002, respectively. (table 3)

Conclusion: In AIIRD patients treated with RTX, high exposure to RTX over time, low IgG levels prior to the last RTX course, and a short interval between the last RTX course and BNT162b2 vaccination predicted the absence of a humoral response to vaccination. These data should guide the optimal timing of vaccination in patients treated with RTX.

Abstract Number: 0438

Rheumatological Immune-Related Adverse Events of Immune Checkpoint Inhibitors Based on the FDA Adverse Event Reporting System

Alicia Rodriguez-Pla, Mayo Clinic Arizona, Scottsdale, AZ

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Abstracts: Immunological Complications of Therapy (0437–0440)
Session Type: Abstract Session
Session Time: 9:00AM–10:00AM

Background/Purpose: Immune checkpoint inhibitors (ICIs) provide effective treatment for many cancers but, presumably due to persistent activation of the immune system, they cause a variety of immune-related adverse events (irAEs) in almost every organ. Rheumatological manifestations have been reported in ~5-10% of patients treated with ICIs. We aimed to analyze the rheumatological irAEs (rh-irAEs) reported to the FDA Adverse Event Reporting System (FAERS) from October 2012 through March 2021.

Methods: From October 1st, 2012, to March 31st, 2021, we studied all case reports found on the FAERS database when any of the following seven FDA-approved ICIs, nivolumab, pembrolizumab, ipilimumab, atezolizumab, durvalumab, avelumab, or cemiplimab, was the primary suspect of the reported adverse events (AEs).

Of the 6,090 different AEs reported for the ICIs, we selected 186 irAEs, which were rheumatological manifestations, or were associated with rheumatological conditions. We calculated the frequencies of rh-irAEs for each ICI. RStudio v1.4.1106 was used for general data analysis and the R package openEBGM v0.8.3 was used for the calculation of disproportionality scores such as the Empirical Bayes Geometric Mean (EBGM) with its 90% two-sided credibility interval, frequently used in safety signal detection models. Drug-event combinations with an EBGM 5% lower limit credibility interval ≥ 1 were considered significant.

Results: During the study period, 90,974 individual case safety reports (ICSR) included 236,239 AEs with one ICI as the primary suspect of the AE. The highest frequency of AEs was reported for nivolumab (49.6%), followed by pembrolizumab (23.4%), ipilimumab (12.6%), atezolizumab (8.6%), durvalumab (4.6%), avelumab (0.9%), and cemi-

Table 1. The 5 most frequent rheumatological immune-related adverse events by checkpoint inhibitor

ICI	Rheumatological irAEs	N	%
Nivolumab	Arthralgia	755	12.8
	Back pain	581	9.8
	Myalgia	381	6.4
	Arthritis	346	5.9
	Muscular weakness	333	5.6

Nivolumab	Musculoskeletal stiffness	94	1.04	1.22	1.43
Nivolumab	Rheumatic disorder	40	1	1.26	1.58
Pembrolizumab	Myalgia	225	1	1.11	1.23
Pembrolizumab	Pain in extremity	168	1	1.13	1.27

ICI: Immune checkpoint inhibitor. IrAEs: Immune-related adverse events. N: number of drug-even combination. EBGM: Empirical Bayes Geometric Mean. EBGM 05: Lower limit of the 90% credibility interval of EBGM. EBGM 95: Upper limit of the 90% credibility internal of EBGM. The table is sorted in decreasing order of EGBM 05.

plimab (0.3%). The AEs were more frequent in males (62.7%) than in females (37.3%). Of the total ICSRs, 84.2% were expedited because they reported serious, unexpected irAEs.

Rh-irAEs were 11,203 (4.7%) out of the 236,239 AEs reported. These rh-irAEs were reported in 3,898 (4.3%) out of the 90,974 ICSRs. For the ICSRs containing rh-irAEs, 78.5% were expedited. Unspecific complains, such as arthralgia, myalgia or muscle weakness were among the most frequent rh-irAEs. Avelumab and atezolizumab were associated with Sjogren's syndrome and sarcoidosis. Durvalumab, avelumab, atezolimumab and cemiplimab were all associated with myositis (Table 1). Twenty-one drug-event combinations were significant for EBGM (Table 2). Of those, nivolumab and pembrolizumab were the two most frequent ICI, with 7 and 6 significant drug-event combinations, respectively.

Conclusion: Approximately 5% of the reported ICIs-associated AEs were rh-irAEs. The most frequent complaints were unspecific, such as arthralgia, myalgia, or muscle weakness. Arthritis, myositis, Sjogren's syndrome, and sarcoidosis were also relatively frequent. The improved understanding of the mechanism of action of the ICIs and the characteristics of the rh-irAEs may help to elucidate the pathogenesis of the autoimmune disorders that they trigger.

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Abstracts: Immunological Complications of Therapy (0437–0440)

Session Type: Abstract Session

Session Time: 9:00AM–10:00AM

Background/Purpose: Immune-related adverse events (irAEs) are a frequent and serious complication of immune checkpoint inhibitor (ICI) treatment for cancer, which can resemble primary rheumatic diseases. Predictors associated with development of rheumatic irAEs have not been well characterized in previous studies due to lack of a comparator group and sample size limitations. The aim of this study was to identify predictors at time of ICI initiation associated with rheumatic irAEs as well as *de novo* inflammatory arthritis, the most common type of rheumatic irAE.

Methods: We performed a case-control study of all cancer patients initiating an ICI at a large tertiary academic health care system and cancer center (2011-2020). We screened for rheumatic irAEs through a comprehensive medical record review of all patients evaluated by a rheumatologist or prescribed an immunomodulator (IM) after initial ICI prescription (baseline), using electronic query. IMs are one of 55 medications used to treat irAEs based on published guidelines. Two board-certified rheumatologists confirmed the presence and type of rheumatic irAE case by independent medical record review. Controls had no pre-existing rheumatic disease, did not receive glucocorticoids, had no IM or rheumatologic evaluation after ICI, and survived at least 6 months after initial ICI (since patients with

early demise may not have an opportunity to develop a rheumatic irAE). We found no patients with rheumatic irAEs on medical record review of 100 random controls (negative predictive value 100%). Predictors at the initiation of ICI included: cancer type (the most prevalent cancer, lung cancer was the reference group), ICI regimen, pre-existing autoimmune disease, and glucocorticoid use. Multivariable logistic regression estimated odds ratios (ORs) for rheumatic irAE case status. A similar analysis was performed to find predictors of *de novo* inflammatory arthritis.

Results: We found 8,028 ICI recipients (mean age 65.5 years, 43.1% female, and 31.8% with lung cancer). We identified 226 (2.8%) confirmed rheumatic irAE cases and 118 (1.5%) with *de novo* inflammatory arthritis. There were 2,312 controls without rheumatic irAEs included in analyses. Baseline predictors of rheumatic irAE case status were: melanoma (OR 4.01, 2.51-6.40) or genitourinary (GU) cancer (OR 2.19, 1.37-3.48, ref=lung cancer), combination ICI (OR 2.35, 1.48-3.74, ref=PD-1), pre-existing autoimmune disease (OR 2.04, 1.46-2.86), and glucocorticoid use within one year prior to ICI (OR 2.13, 1.51-2.98, ref=non-use) (**Figure 1**). Baseline predictors of *de novo* inflammatory arthritis were similar: melanoma (OR 2.95, 1.60-5.43) or GU cancer (OR 2.39, 1.34-4.26, ref=lung cancer), combination ICI (OR 2.31, 1.26-4.26, ref=PD-1), pre-existing autoimmune disease (OR 2.74, 1.79-4.19), and glucocorticoid use one year prior to ICI (OR 1.96, 1.26-3.06, ref=non-use) (**Figure 2**).

Conclusion: In this large study of patients who received an ICI, we found melanoma, GU cancer, pre-existing autoimmune disease, and glucocorticoid use within 1 year of ICI may be novel predictors of rheumatic irAEs. The possible biologic basis of these associations should be the subject of future research.

Figure 1. Multivariable odds ratios (OR) for development of rheumatic irAEs (n=226 cases), compared to 2,312 controls*

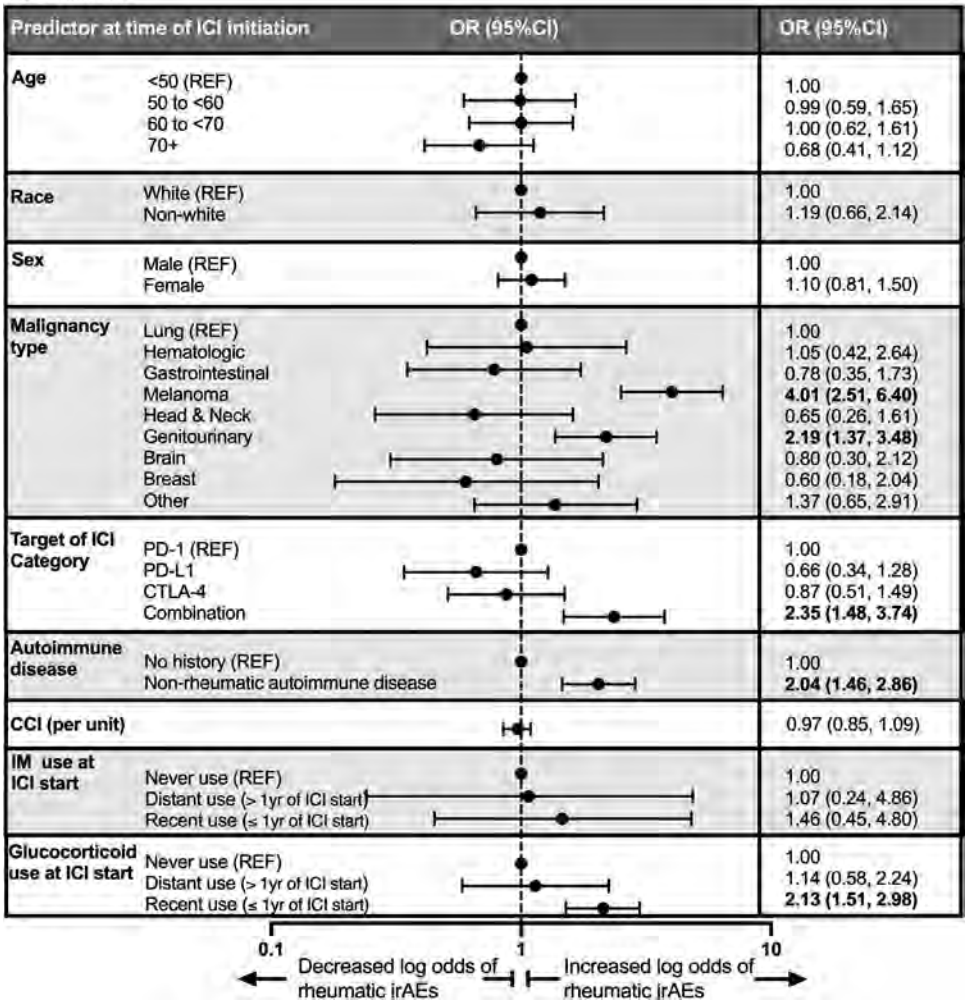

Figure 2. Multivariable odds ratios (OR) for development of *de novo* inflammatory arthritis (n=118 cases), compared to 2,312 controls*

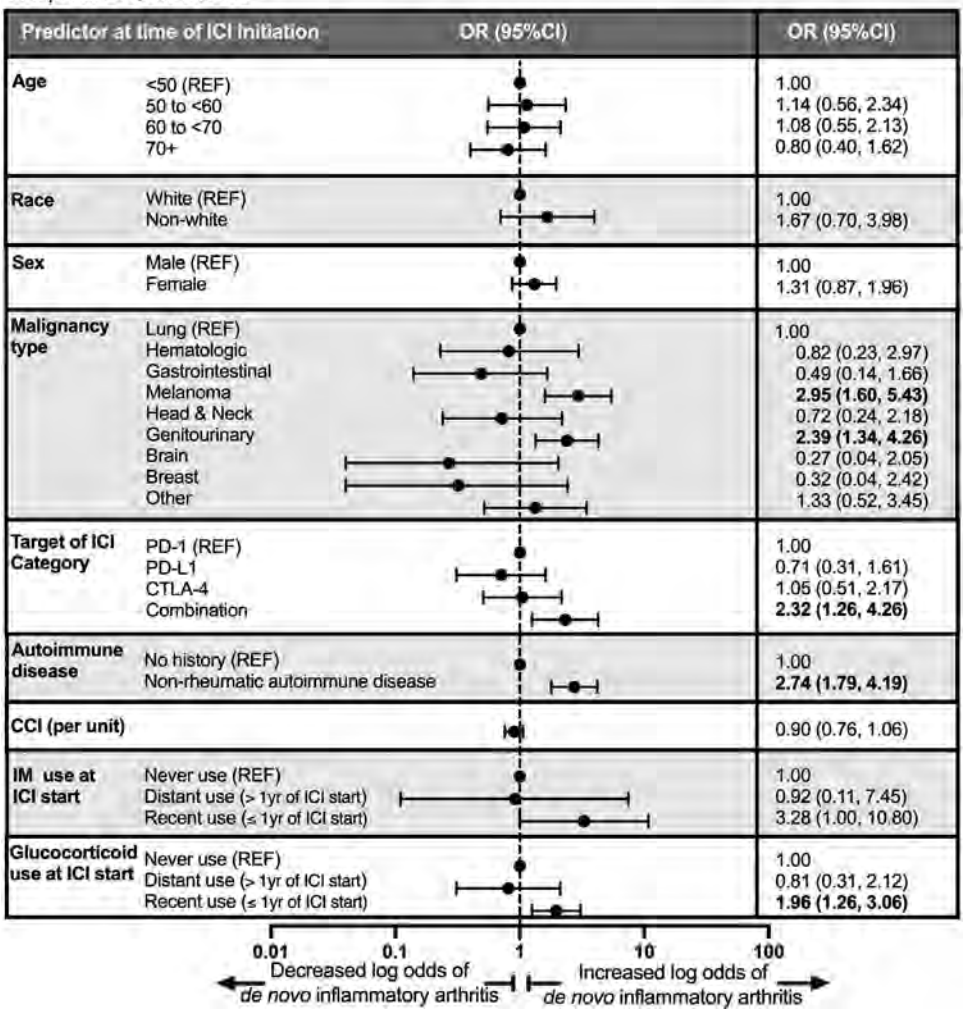

Bolded values have p<0.05. *Controls were patients without rheumatic disease at baseline, used no glucocorticoid or immunomodulator after baseline, and had no rheumatologic evaluation after baseline. Multivariable models were mutually adjusted for all covariates listed in the column. CCI, Charlson Comorbidity Index; CI, confidence interval; CTLA-4, cytotoxic T-lymphocyte-associated protein 4; ICI, immune checkpoint inhibitors; IM, immunomodulator; irAE, immune-related adverse event; OR, odds ratio; PD-1, programmed cell death protein 1; PD-L1, programmed death ligand 1; REF, Reference.

Bolded values have p<0.05. *Controls were patients without rheumatic disease at baseline, used no glucocorticoid or immunomodulator after baseline, and had no rheumatologic evaluation after baseline. Multivariable models were mutually adjusted for all covariates listed in the column. CCI, Charlson Comorbidity Index; CI, confidence interval; CTLA-4, cytotoxic T-lymphocyte-associated protein 4; ICI, immune checkpoint inhibitors; IM, immunomodulator; irAE, immune-related adverse event; OR, odds ratio; PD-1, programmed cell death protein 1; PD-L1, programmed death ligand 1; REF, Reference.

Autoantibody positivity (positive/checked)	
Any type autoantibody	96/152
ANA	84/138
RF	18/88
CCP	6/54

primary autoimmune disease. Our study aimed to better understand the association between autoantibody positivity and irAE development.

Methods: Patients with cancer who were treated with ICIs from 1/1/2011 to 12/21/2020 and had a rheumatic autoantibody checked were retrospectively identified. Rheumatic autoantibodies evaluation in our study focused on the following serologies: Antinuclear antibody (ANA), Rheumatoid factor (RF), Cyclic citrullinated protein (CCP), but also included analysis of other serologies (anti–Sjögren's-syndrome-related antigen A and B autoantibodies (SSA, SSB), double-stranded DNA, antineutrophil cytoplastic antibodies, angiotensin converting enzyme). Logistic regression model was used to evaluate the relationship between autoantibody analysis and irAE development as well as cancer outcome. Specificity, sensitivity and predictive values were also estimated. Cancer outcome was defined by objective response rate (ORR).

Results: 152 total patients were identified for review. Demographics are as noted in table 1. Of the patients who had rheumatic autoantibodies ordered, 90 (59%) were found to have irAE development. After adjusting for age at cancer diagnosis, sex, race, diagnosis of malignancy, and ICI group, patients with pre-ICI autoantibody positivity had greater odds of irAE development (OR 17.5, 95% CI 1.76-174.10, p=0.015). Development of irAE was associated with a 3.43 greater odds of an ORR for primary malignancy (95%CI: 1.35-8.72, p=0.01). There was no significant association with post-ICI autoantibody testing and any-type irAEs and the sensitivity, specificity, positive predictive value, and negative predictive value of any autoantibody positivity in development of irAEs were as follows: 63%, 30%, 56%, and 37% respectively. Subgroup analysis of rheumatic irAEs revealed a strong association between RF and CCP; for ICI-arthritis, RF showed sensitivity=0.24 and specificity=0.90 while CCP showed sensitivity=0.10 and specificity=0.98. Negative predictive values of RF and CCP for development of ICI-arthritis were 0.84 and 0.82 respectively.

Conclusion: Our results demonstrate strong association with pre-ICI autoantibody positivity and any-type irAE development as well as high specificity of RF and CCP for ICI-arthritis. Our findings justify prospective evaluation of rheumatic serologies and association with irAE development.

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Abstracts: Muscle Biology, Myositis & Myopathies (0441–0444)

Session Type: Abstract Session

Session Time: 9:00AM–10:00AM

Background/Purpose: Inclusion body myositis (IBM) is the most common idiopathic inflammatory myopathy occurring in patients over the age of 45 years. Since immune suppression has not been effective, modulating the cytoprotective "heat shock response" (HSR) represents a candidate therapeutic approach targeting both inflammation and degeneration. In a pilot study, arimoclomol, an amplifier of the HSR, was safe and well tolerated with some trends suggesting efficacy at 8 months in subjects with IBM. Our aim is to present the efficacy and safety/tolerability data from a phase 2/3 randomized controlled trial of arimoclomol in IBM (NCT02753530).

Methods: In this international multicenter, double-blind, placebo-controlled trial, subjects were randomized (1:1) to receive either arimoclomol citrate 400 mg or matching placebo capsules three times a day (1,200 mg/day) for 20 months. The primary outcome measure was the change from baseline to Month 20 in the IBM Functional Rating Scale (IBMFRS) total score. Hierarchically ordered key secondary outcome measures included hand grip strength (strongest hand), Modified Time Up and Go, Manual Muscle Testing (24 muscles), 6-minute walk test distance, and the Short-Form 36 health survey. Other outcome measures included patient and clinician impressions, and other measures of muscle strength and function. Drug safety and tolerability were evaluated.

Results: One hundred fifty-two IBM subjects fulfilling ENMC 2011 criteria were randomized with mean age 67.2 years (SD 8.1), mostly men (76%), mean disease duration 98 months (SD 58), and mean baseline IBMFRS of 27.4 (SD 4.6). The IBMFRS declined by a mean of 3.25 points with arimoclomol vs. 2.26 points with placebo over 20 months (p=0.11). Secondary efficacy outcome measures did not show any statistically significant treatment group differences. Most frequently reported AEs observed with higher incidence in arimoclomol group were gastrointestinal disorders (54.8% vs. 39.7%). Patients receiving arimoclomol were more likely to discontinue treatment due to AEs (17.8% vs. 5.1%). The relative frequency of serious AEs was comparable in the two treatment arms (arimoclomol 15.1% vs. placebo 23.1%). Elevated transaminases were reported in the first three months and were more frequently observed with arimoclomol than with placebo (15.4% vs. 6.4%).

Conclusion: This trial did not demonstrate a benefit of arimoclomol in IBM with respect to its primary and secondary efficacy endpoints.

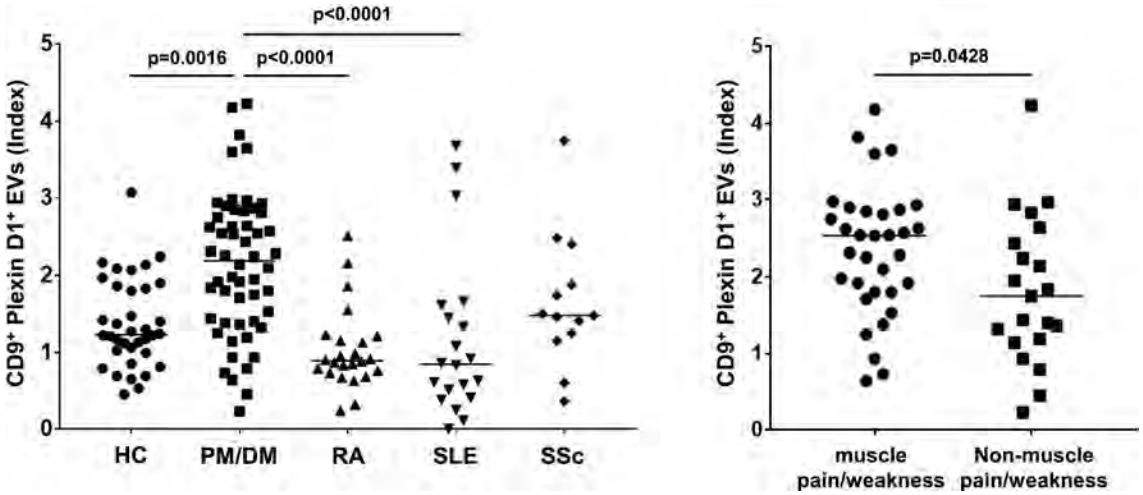
SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Abstracts: Muscle Biology, Myositis & Myopathies (0441–0444)
Session Type: Abstract Session
Session Time: 9:00AM–10:00AM

Background/Purpose: Extracellular vesicles (EVs), including exosomes and microvesicles, are small membrane vesicles released by almost all cell types and are found circulating in blood and other body fluids. Circulating EVs are promising as a novel type of systemic biomarker for various different diseases because their cargoes (miRNAs, mRNAs, and proteins) reflect their cellular origin and function. Increasing evidence suggests that surface proteins (e.g. membrane proteins) on EVs, especially exosomes, are altered in pathological conditions and useful as non-invasive biomarkers for cancer diagnosis and prognosis. However, they have rarely been employed as serum biomarkers for autoimmune diseases. The aim of this study is to identify disease-specific surface proteins on EVs as novel serum biomarkers of polymyositis and dermatomyositis (PM/DM).

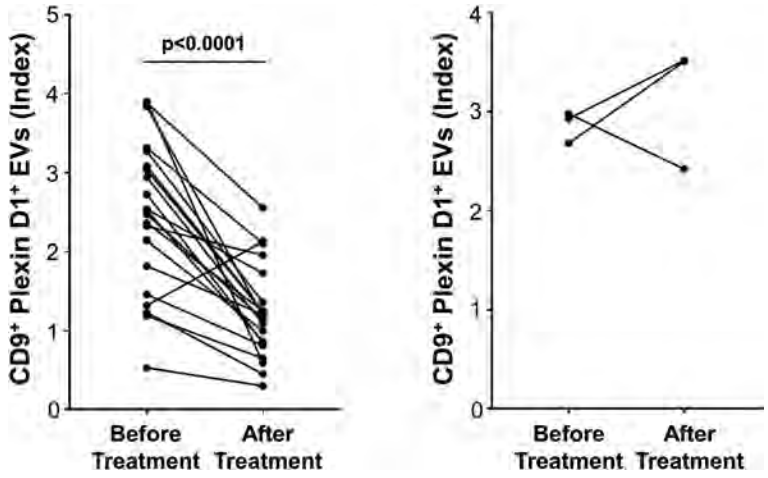
Methods: Serum EVs were purified by size exclusion chromatography using sera of 10 PM/DM, 23 patients with other autoimmune diseases and 10 healthy controls (HC). Comprehensive proteomic analysis of serum EVs was performed by liquid chromatography-tandem mass spectrometry (LC/MS). We identified membrane proteins preferentially present in serum EVs of PM/DM patients by bioinformatics and biostatistical analyses. We developed sandwich ELISA for directly detecting serum EVs expressing disease-specific membrane proteins and measured their expression levels using sera of 54 PM/DM, 24 rheumatoid arthritis (RA), 20 systemic lupus erythematosus (SLE), 13 systemic sclerosis patients, and 36 HC.

Results: LC/MS analysis identified 1,220 proteins in serum EVs. From the volcano plots combining different bioinformatics analyses (DAVID gene ontology and UniProtKB/Swiss-prot), we identified 5 membrane proteins as significantly upregulated in serum EVs of PM/DM patients. Of these, Plexin D1 was enriched in those from PM/DM patients relative to HC (p=0.0237) or patients without PM/DM (p=0.0593). Using our sandwich ELISA, we found that levels of Plexin D1-positive EVs (Plexin D1$^+$ EVs) in serum were significantly greater in PM/DM patients than in HC (p=0.0016), RA (p< 0.0001) or SLE patients (p< 0.0001). Serum levels of Plexin D1$^+$ EVs were greater in those PM/DM patients with muscle pain or weakness (p=0.0428). Serum levels of Plexin D1$^+$ EVs were correlated with levels of aldolase (r_s=0.481, p=0.027), total blood cells (r_s=0.381, p=0.046), neutrophils (r_s=0.450, p=0.019), and platelets (r_s=0.408, p=0.031) in PM/DM patients. Finally, serum levels of Plexin D1$^+$ EVs decreased significantly in patients with PM/DM in clinical remission after treatment (p< 0.0001).

Conclusion: We have identified levels of circulating Plexin D1$^+$ EVs as a novel serum biomarker for PM/DM.



Serum levels of Plexin D1-positive EVs are higher in PM/DM patients with associated muscle pain or weakness



Serum levels of Plexin D1-positive EVs are decreased in PM/DM patients after treatment. Change of serum levels of CD9+ Plexin D1+ EVs in PM/DM patients after treatment in 21 PM/DM patients who achieved clinical remission (left) and 3 PM/DM patients who did not (right).

Safety and Efficacy of Belimumab in the Treatment of Adult Idiopathic Inflammatory Myositis (Polymyositis and Dermatomyositis)

Priyal Chadha[1], Sonali Narain[2], Preeya Nandkumar[3], Cristine Sison[4], Elena Schiopu[5], Todd Levine[6], James Tsang[7] and **Galina Marder**[8], [1]SUNY Upstate Medical University, Syracuse, NY, [2]Northwell Health, Great Neck, NY, [3]Division of Rheumatology, Department of Medicine, Northwell, Great Neck, NY, [4]Biostatistics Unit , Department of Molecular Medicine, Feinstein Institutes for Medical Research at Northwell Health, Zucker School of Medicine at Hofstra/Northwell, Great Neck, NY, [5]University of Michigan, Ann Arbor, MI, [6]Phoenix Neurological Associates, Phoenix, AZ, [7]Center for Research Informatics & Innovation (CRII), Feinstein Institute for Medical Research at Northwell Health, Zucker School of Medicine at Hofstra/Northwell, Great Neck, NY, [8]Division of Rheumatology, Department of Medicine, Donald and Barbara Zucker School of Medicine at Hofstra/Northwell, Great Neck, NY

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Abstracts: Muscle Biology, Myositis & Myopathies (0441–0444)

Session Type: Abstract Session

Session Time: 9:00AM–10:00AM

Background/Purpose: Treatment of Idiopathic Inflammatory Myositis (IIM) includes steroids and immunosuppressive agents. Targeting IL6, IL1, TNF for treatment of IIM has not been successful, and the role of B-cell depleting therapy remains uncertain. This study was designed to assess the safety and efficacy of belimumab for IIM patients.

Methods: We conducted a 40-week multicenter randomized, double blind, placebo controlled clinical trial with a 24-week open label extension of intravenous (IV) belimumab for adult patients with refractory IIM. All patients met Peter and Bohan criteria and ACR 2017 classification criteria of polymyositis / dermatomyositis (PM/DM) with PM diagnosis adjudication. Refractory IIM was defined as inadequate response/ intolerance to 3 months of glucocorticoids and/or at least one immunosuppressive agent (IS). Standard Core Set Measures (CSM) with MMT8 < 125/150 were used to define active disease. Patients on standard of care (SoC) therapy were randomized 1:1 to IV belimumab 10mg/kg or placebo for 40 weeks followed

Incidence of Serious Adverse Events (SAE) and Adverse Events

weeks. Descriptive statistics (means, SDs, medians, ranges, frequencies, proportions) are presented. The Mann-Whitney test and Fisher's exact test were used to analyze continuous and categorical variables, respectively.

Results: 16 patients were randomized, 15 received at least 4 doses of belimumab or placebo to be included in the analysis (9 belimumab; 6 placebo) (Baseline characteristics are in Table 1).

The proportion of patients reaching DOI by week 40 was numerically higher in belimumab arm (belimumab 37.5% / SoC 16.7 %). The mean TIS was similar between 2 groups (mean (SD) belimumab 38.8 (24.9)/ SoC 37.9 (5.8). At week 64, 42.9 % of patients on belimumab achieved DOI, while no patients in the original SoC arm did. Numerically more patients on belimumab had moderate or major improvement than on SoC (belimumab 62.5%/ SoC 33.3%) at week 40, and (belimumab 57.1% /SoC 40.0 %) at week 64. Of 15 patients only 2 had a major response at week 40 (TIS= 72.5) that sustained to week 64; both had received belimumab. Infections were evenly distributed between two arms. One patient in the belimumab arm had an adjustment disorder exacerbation, determined not to be belimumab related and the drug was continued with no interruption (Table 3).

Conclusion: In this 40-week multicenter randomized, double blind placebo-controlled trial with 24 weeks open label phase, we observed numerically higher proportion of patients on belimumab reaching DOI vs. on SoC only arm. A higher proportion of patients on Belimumab achieved sustained moderate or major TIS at 40 and 64 weeks compared to SOC. Detected differences were not statistically significant, however the sample size was small.

Session Title: Abstracts: Muscle Biology, Myositis & Myopathies (0441–0444)
Session Type: Abstract Session
Session Time: 9:00AM–10:00AM

Background/Purpose: Numerous Covid-19 vaccines have demonstrated efficacy and safety against SARS-CoV-2 in general population. Despite favorable adverse effect (ADRs) profile of vaccines, there have been concerns regarding activation of aberrant immune responses. Moreover, vaccine safety data in idiopathic inflammatory myopathies (IIM)

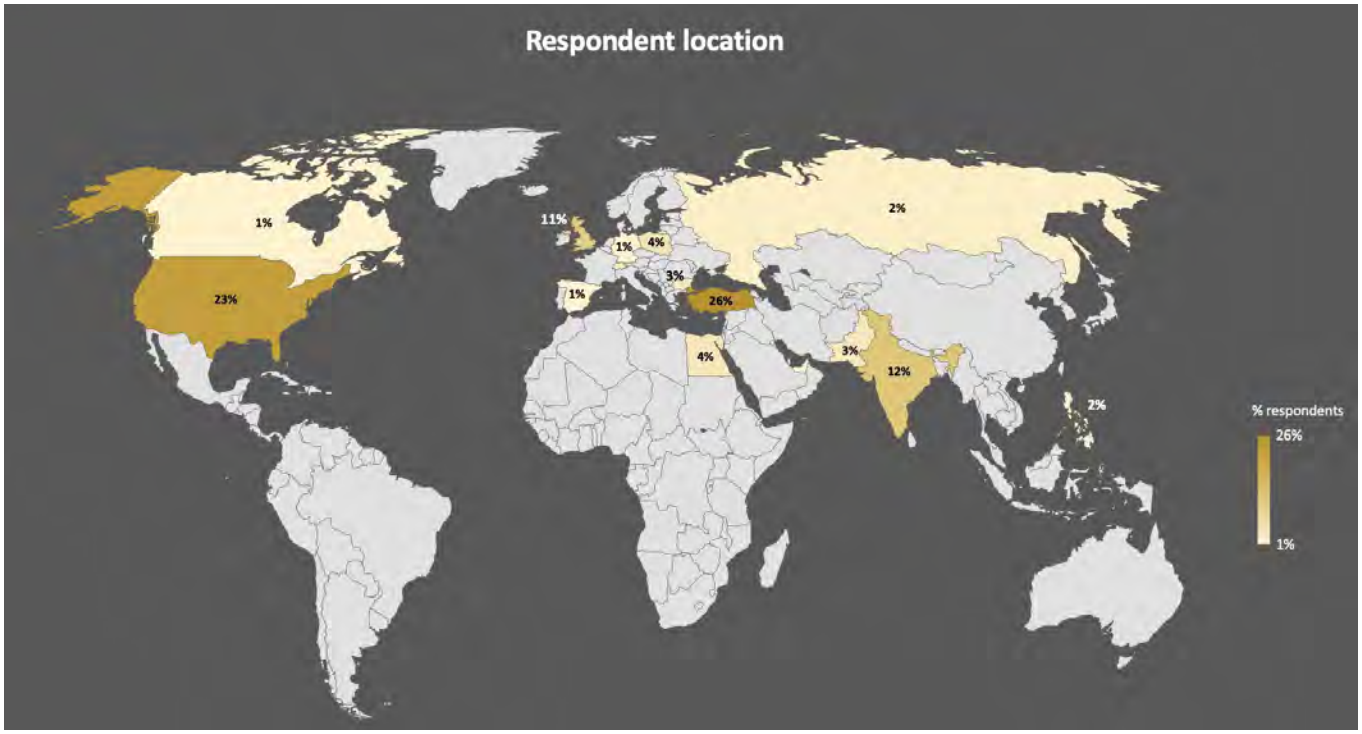
and other systemic autoimmune diseases (AID) is rather limited. We aimed to evaluate safety of Covid-19 vaccines in IIMs patients in comparison with other AIDs and non-autoimmune disease controls using a patient reported world-wide electronic survey by an international CoVAD study group.

Methods: We developed an extensive self-report e-survey to assess safety of the COVID-19 vaccine in IIMs and other AIDs and non-autoimmune controls. The questionnaire was pilot tested, validated and translated into 15 languages on surveymonkey.com, and vetted by international experts. The survey questions were designed to evaluate previous COVID infection, current vaccination status, as well as short term (within one week) as well as long term (1-12 months) adverse drug reactions (ADRs) following vaccine administration. Rheumatologists from >50 centers conducted the e-survey to their patients as well as their non-autoimmune family members. In addition, the survey was floated on social



Respondent location

media platforms and online patient support group members across the world. We analyzed the data from baseline survey (Feb – May 2021, 7-day ADRs) for descriptive statistics as well as inter-group comparison using chi-square or t-test.

Results: A total of 7467 subjects attempted the survey with mean age of 42.6 years, 71.4% female, 60.9% Caucasians with most patients from US, European Union and India (table 1, figure 1). Among these 5219 (69.9% of respondents) were fully vaccinated and 1540 (20.2%) were not vaccinated with vaccine hesitancy (657,42.7%) and non-availability (534, 34.7%) being the most common reasons. Among 5927 vaccinated respondents, 979 (16.5%) had IIM, 2566 (43.3%) other AIDs, and 2382 (40.1%) were controls.

Respondents with IIM were elder (60 years) than other AIDs and controls (42.6 and 34.7 year respectively) (Table 1, Figure 1). A total of 875 (15.3%) respondents got Covid-19 infection, with significantly lower proportion of IIM patients (76, 2.2%) as compared to AIDs (403, 15.7%) and controls (404, 16.9%), $p < 0.0001$. Notably IIM patients were also less likely to be symptomatic than AIDs and controls when they got infected [RR 0.6 (0.4-1.0), 0.4 (0.3-0.7)].

Overall, 51.0% IIM had some symptoms (minor ADRs) after vaccination with only 6.0% being severe ADRs. IIM patients were equally prone to minor reactions as compared to controls (Table 2). However, they were more prone to anaphylaxis, marked dyspnea, and severe rashes. Overall, IIM exhibited higher prevalence of severe ADRs as compared with other AIDs. However, there was no difference in hospitalization among the groups.

Conclusion: IIMs patients had a modest increase in severe ADRs 7-day post vaccination as compared to controls as well as other autoimmune diseases, although not contributing to increased hospitalization. The survey in ongoing and will have much larger patient population and longitudinal results in future.

Figure 3. Percent change from baseline in bone turnover markers

Background/Purpose: Denosumab (DMAb) is approved for the treatment of glucocorticoid (GC)–induced osteoporosis (GiOP). In a phase 3, international, active-controlled, double-blind, double-dummy study, treatment with DMAb was superior to treatment with risedronate (RIS) in terms of increase in BMD at both lumbar spine (LS) and total hip (TH) in GC-treated patients with osteoporosis (Saag KG et al *Arthritis Rheumatol*. 2019;71:1174–1184). In this post hoc subgroup analysis, we evaluated the efficacy of DMAb vs RIS in patients with GiOP and RA.

Methods: This post hoc subgroup analysis included both GC-initiating and GC-continuing patients (≥ 7.5 mg daily prednisone or equivalent for < 3 and ≥ 3 months before screening, respectively) with GiOP and RA who were randomized 1:1 to receive DMAb (60 mg every 6 months) or RIS (5 mg once daily) for 24 months. All patients received daily calcium (≥ 1,000 mg) and vitamin D (≥ 800 IU). The primary objective of this analysis was to test if increases in LS BMD by DXA at month 12 were greater with DMAb vs RIS based on the mean difference in percent change from baseline. Secondary objectives included between-group comparisons of the mean percent change from baseline in LS, TH, and femoral neck (FN) BMD and in serum type 1 collagen C-telopeptide (sCTX) and procollagen type 1 N-telopeptide (P1NP) at months 12 and 24; safety was assessed through the incidence of treatment-emergent adverse

events (TEAEs). BMD changes were analyzed using repeated measures analysis of covariance (ANCOVA). Serum CTX and P1NP were reported as median and interquartile ranges.

Results: A total of 300 patients (DMAb = 143; RIS = 157) were included in this analysis. Mean (SD) prednisone-equivalent doses at baseline for the DMAb and RIS groups were 10.5 (4.2) mg and 10.3 (4.6) mg, respectively. The mean difference (95% CI) in percent change from baseline in BMD between the DMAb and RIS groups was significant at LS, TH, and FN at both timepoints assessed (month 12 LS: 1.8% [0.7–2.8]; Figure 1). The mean percent change from baseline in BMD at month 24 was significant at LS, TH, and FN with DMAb and only at LS with RIS (Figure 2). A significant decrease in the sCTX and P1NP levels was observed in DMAb vs RIS patients during the first 5 months; however, the percent changes from baseline for both sCTX and P1NP were not significantly different between the DMAb and RIS groups at months 12 and 24 (Figure 3). The overall incidence of TEAEs was similar between the 2 groups (DMAb: 78.3%; RIS: 75.8%), including that of TEAEs of interest—infections (DMAb: 30.8% vs RIS: 34.4%) and cardiac disorders (DMAb: 4.9% vs RIS: 6.4%). The incidence of osteoporotic fractures was numerically lower in the DMAb (n = 9; 6.3%) vs RIS (n = 15; 9.6%) group.

Conclusion: Compared with RIS, treatment with DMAb showed significantly larger gains in BMD in patients with GiOP and RA receiving GC treatment. The overall safety profile was similar for both treatments.

Clinical Characteristics, Including History of Myocardial Infarction and Stroke, Among US PMO Women Initiating Treatment with Romosozumab and Other Anti-osteoporosis Therapies

Jay Lin[1], Carrie Nielson[1], Mary Oates[1], Cynthia Deignan[2] and Zhigang Yu[1], [1]Amgen Inc., Thousand Oaks, CA, [2]Amgen, Inc., Agoura Hills, CA

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Abstracts: Osteoporosis & Metabolic Bone Disease – Basic & Clinical Science (0445–0448)
Session Type: Abstract Session
Session Time: 9:30AM–10:30AM

Background/Purpose: This study is an ongoing USFDA post-marketing requirement (2020-2024) to assess the impact of boxed warning on romosozumab (romo) treatment and the feasibility of future comparative safety analysis using real-world data. As of March 2021, about 14,958 person-years of exposure to romo have been reported in US. Results from the first interim report utilized Optum claims and supplemental EHR data covering the period between April 2019–March 2020.

Methods: This is a retrospective, repeated analysis within five 1-year (yr) blocks of calendar time following marketing approval of romo in 2019. Women at least 55 yrs old who had newly initiated romo, denosumab (dmab), zolendronate (zol), PTH analogues, or oral bisphosphonates (BPs) were included. We describe the proportion of women who experienced a myocardial infarction (MI) or stroke in the year before drug initiation, as well as history of cardiovascular

(CV) diseases, osteoporosis, other comorbidities and concomitant medications, and healthcare utilization using all available historical data up to 19 years. Four pairwise comparisons were conducted to describe the differences in the above histories compared with romo, before and after propensity score (PS) matching. Standardized mean differences (SMD) >0.1 indicated imbalance between groups.

Results: Patients newly initiating romo (N=1,946; mean age 74.8 yr) were older than zol (N=6,292; 72.9 yr), PTH (N=1,517; 70.7 yr), and oral BPs (N=38,544; 72.1 yr). Romo patients had increased prevalence of chronic diseases (eg, hypertension, hyperlipidemia, type II DM) and healthcare utilization, and had more prior fractures and OP treatments (**Table 1-3**). Using all available historical data, the proportion of patients with MI/stroke history was higher in romo patients (9%/11.5%) than dmab (6.8%/8.6%), PTH (7.4%/9.0%), zol (5.9%/7.0%) and oral BPs (5.4%/6.0%) (**Table 2**). When limited to 1 yr before treatment initiation, the proportions of patients with MI/stroke in romo were very low (MI: 0.4%, N=8; stroke: 0.5%, N=9) and similar to other OP treatments (all SMDs< 0.1). All baseline characteristics were balanced after PS matching.

Conclusion: Patients who initiated romo were a high OP-risk population and generally had more comorbidities including CV risk factors. Nevertheless, the low proportion of patients who had a MI/stroke within 1-yr prior to treatment initiation suggests the label boxed warning language may have had the intended effect on patient selection.

Table 2. History of MI, stroke, other cardiovascular diseases and selected comorbidity

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Abstracts: Osteoporosis & Metabolic Bone Disease – Basic & Clinical Science (0445–0448)

Session Type: Abstract Session

Session Time: 9:30AM–10:30AM

Background/Purpose: Orally-available bone anabolic agents represent a major unmet medical need for patients with osteoporosis. Widespread use of parathyroid hormone (PTH)-based osteo-anabolic therapies is limited by the need for daily injections. PTH stimulates bone formation via activating a signaling cascade in osteocytes that inhibits salt inducible kinases (SIK) 2 and 3. The purpose of this study is to test a novel, orally-available SIK2/SIK3 inhibitor (SIK2/SIK3i) in preclinical osteoporosis models.

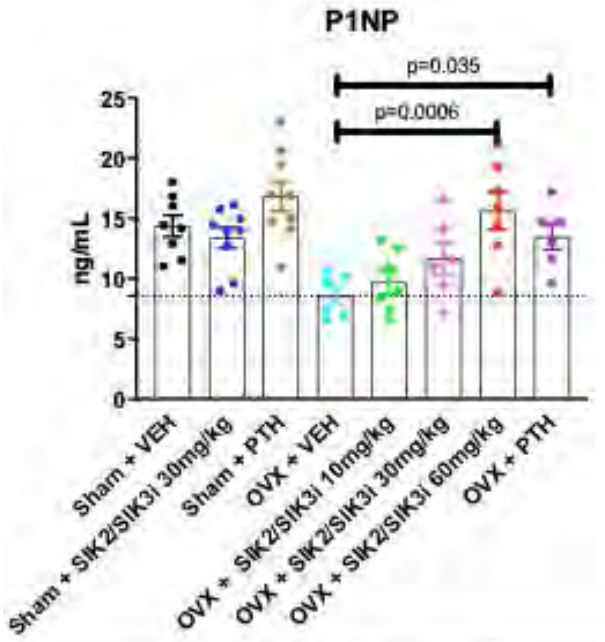

Figure 1. Fasting serum was collected in OVX mice after 6 weeks of drug treatment. In OVX animals, SIK2/SIK3i treatment led to dose dependent increases in the bone formation marker P1NP.

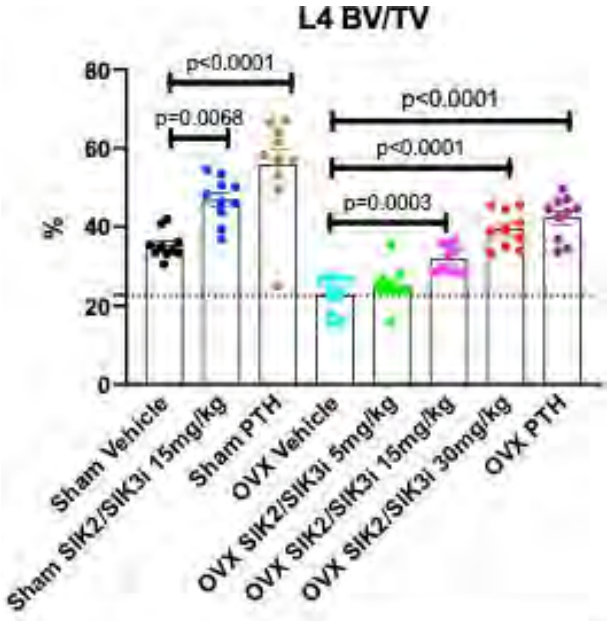

Figure 2. L4 vertebral bodies were analyzed by µCT to measure bone volume fractions in OVX rats. 8 weeks of SIK2/SIK3i treatment led to dose dependent increases in L4 trabecular bone mass.

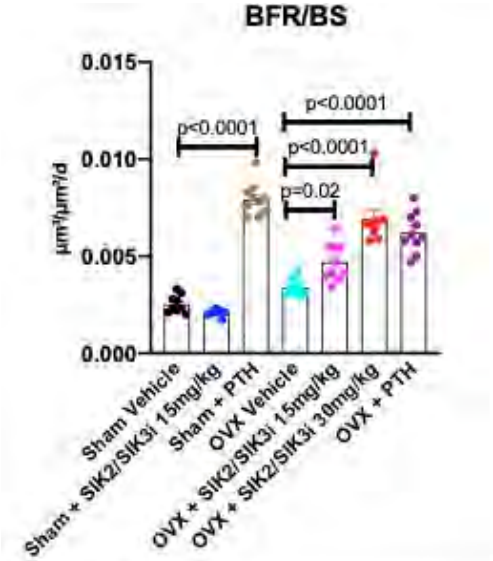

Figure 3. Dynamic histomorphometry was performed in OVX rats following dual calcein labeling to measure the bone formation rate. SIK2/SIK3i treatment led to dose dependent increases in bone formation in OVX animals.

Methods: An osteocyte-like cell line was treated with PTH and SIK2/SIK3i. Cells were treated for 60 minutes followed by immunoblotting for phosphorylated forms of SIK2/SIK3 substrates HDAC4/5. Cells were treated for 4 hours followed RT-qPCR to measure gene expression.

A SIK2/SIK3 inhibitor was tested in two models of post-menopausal bone loss: oophorectomized (OVX) mice and rats. Direct comparison was made to treatment with intermittent PTH. 64 twelve-week-old Balb/c mice were subjected to sham (n=26) or OVX (n=38) surgery. 5 weeks later, mice were treated for 6 weeks with vehicle (n=15), SIK2/SIK3i 10 mg/kg PO BID (n=8), SIK2/SIK3i 30 mg/kg PO BID (n=17), SIK2/SIK3i 60 mg/kg PO BID (n=8), or PTH 1-34 100 mcg/kg SC (n=16). Upon sacrifice, fasting serum was collected to measure bone turnover markers P1NP and CTX, along with femur and L5 vertebrae for μCT, and femurs for histomorphometry.

Next, 80 twelve-week-old Sprague-Dawley rats were subjected to sham (n=30) or OVX (n=50) surgery. 8 weeks later, rats were treated for 8 weeks with vehicle (n=20), SIK2/SIK3i 5 mg/kg PO BID (n=10), SIK2/SIK3i 15 mg/kg PO BID (n=20), SIK2/SIK3i 30 mg/kg PO BID (n=10), and PTH 1-34 40 mcg/kg SC (n=20). Fasting serum was collected at 1, 4, and 8 weeks. At sacrifice, femur and L4 vertebral bodies were collected for μCT, histomorphometry, and biomechanical testing. Two-way ANOVA followed by Tukey post-hoc tests were performed.

Results: In Ocy454 cells, SIK2/SIK3i treatment led to dose-dependent reductions in SIK2/SIK3 substrate HDAC4/5 phosphorylation. SIK2/SIK3i treatment suppressed SOST mRNA expression (EC_{50} = 310 nM).

In OVX mice, SIK2/SIK3i led to dose-dependent increases in the bone formation marker P1NP (p=0.0006) (Figure 1). In OVX mice, SIK2/SIK3i increased L5 bone mass (p=0.0001) and femur cortical thickness (p=0.038) by μCT. Histomorphometry showed that SIK2/SIK3i increased mineralizing surface (p=0.0142) and bone formation rate (p=0.009).

Increased bone anabolism was also observed in OVX rats treated with SIK2/SIK3i, which also led to initial increases in serum P1NP, followed by increased levels of both P1NP and CTX at later time points. SIK2/SIK3i increased trabecular bone mass in OVX rats in femur (p< 0.001) and L4 vertebrae (p< 0.001) (Figure 2). Mechanical testing of L4 vertebrae demonstrated proportionate increases in bone strength and bone mass. Finally, SIK2/SIK3i increased bone formation rate in a dose-dependent manner (p< 0.001) to a degree similar to that of PTH (Figure 3).

Conclusion: SIK2/SIK3i increases trabecular bone formation and bone mass in OVX rodents. Orally-available small molecule SIK2/SIK3 inhibitors may represent a promising new treatment strategy for post-menopausal osteoporosis.

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Abstracts: Osteoporosis & Metabolic Bone Disease – Basic & Clinical Science (0445–0448)

Session Type: Abstract Session

Session Time: 9:30AM–10:30AM

Background/Purpose: Impaired bone quality and strength estimated by high resolution peripheral quantitative computer tomography (HR-pQCT) in patients with rheumatic diseases on long-term glucocorticoid (LTGC) therapy could discriminate patients with and without fragility fracture, independent of areal bone mineral density (aBMD) (1). The aim of this study was to ascertain whether compromised vBMD, bone microarchitecture and estimated bone strength at baseline in rheumatic disease patients on LTGC therapy could predict incident fragility fracture.

Methods: Two hundred and twenty rheumatological patients on LTGC with (n=110) or without (n=110) fragility fracture who participated in a cross-sectional study with dual-energy X-ray absorptiometry (DXA) and HR-pQCT done

vBMD: volumetric bone mineral density; Ct.: cortical; Tb: trabecular; pTb: peripheral region adjacent to the cortex; mTb: the central medullary region; BV/TV: bone volume fraction; Est: estimated.

between 2014-2016 were invited to have a 5th year follow-up assessment. All patients had a repeat assessment with 1) aBMD and 2) HR-pQCT 3) spine radiographs. The occurrence of new fragility fracture after 5 years was documented. The baseline clinical characteristics, aBMD, FRAX and HR-pQCT parameters in patients who experienced a new fragility fracture during the 5-year follow-up period (incident fracture group) were compared with patients who did not (control group).

Results: In this interim analysis, a total of 109 patients were recruited. The mean age of the patients at the 5th year visit was 61.9 ± 12.2 years and there was a female predominance of 81.7%. Systemic lupus erythematosus (50.9%) and rheumatoid arthritis (21.3%) were the commonest rheumatological diagnoses. At baseline, 46.8% and 32.1% of the patients were osteopenic and osteoporotic respectively, 15.6% had a prevalent fracture. The baseline 10-year major osteoporotic and hip fracture risks by fracture risk assessment tool (FRAX) were 14.5 ± 13.7 and 6.5 ± 9.8 respectively. After 5 years, 35 (32.1%) of the patients developed new fractures (24 vertebral, 11 non-vertebral). The clinical characteristics of the incident facture group and the control group are shown in table 1. There was no difference in the aBMD and FRAX scores between the two groups. When comparing the HR-pQCT parameters, the incident fracture group had significantly lower tibial stiffness and failure load than the control group (table 2). Multivariate logistic regression confirmed that baseline bone stiffness (p=0.024) and failure load (p=0.026) over tibia were independent predictors of new fractures after adjusting for age, gender, prevalent fracture and osteoporosis status.

Conclusion: We conclude that impairment of bone strength over distal tibia on HR-pQCT predicts the occurrence of incident fracture in rheumatic disease patients on LTGC.

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Abstracts: Spondyloarthritis Including PsA – Diagnosis, Manifestations, & Outcomes I (0449–0452)

Session Type: Abstract Session

Session Time: 9:30AM–10:30AM

Background/Purpose: A delay in diagnosis and management of patients with PsA leads to poor radiographic and functional outcomes [1]. The need to identify which patients might progress radiographically has been recognised by the Group for Research and Assessment of Psoriasis and Psoriatic Arthritis (GRAPPA) as a key area of unmet need within PsA [2]. It is anticipated that biomarkers for radiographic joint damage will help in patient stratification so those with greater likelihood of poor outcome may be treated more timely and aggressively. The identification of such biomarkers would also be useful in clinical research to evaluate novel treatment efficacy in selected subjects at higher risk of rapid progression. The SPIRIT-P1 (NCT01695239) Phase 3 randomized controlled trial (RCT) of ixekizumab, a high-affinity IL-17A antagonist antibody, in active PsA patients resulted in reduced progression of structural damage [3], however 5-10% of patients who progressed may have benefitted from an earlier or more aggressive treatment if identified using biomarkers at the outset. The aim of this study was to use mass spectrometry-based proteomics to identify protein biomarkers which might distinguish at baseline those patients who progress to joint damage from those who will not. Top-ranking protein biomarkers were then combined with key clinical parameters to try to improve the discrimination of progressors (P) from non-progressors (NP) to joint damage.

Methods: Baseline serum samples from 83 PsA patients (28 P and 55 NP) were obtained from the SPIRIT-P1 RCT. Radiographic P showed a >0.5 change from baseline modified total Sharp score at week 24 or 52. Two proteomic analyses were performed: 1) unbiased discovery using mass spectrometry of the 83 baseline samples; and 2) targeted analysis of in-house panel of 206 proteins originally developed to distinguish between arthropathies. Univariate and multivariate machine learning random forest modelling was undertaken on the 2 proteomic datasets.

Results: Unbiased discovery proteomics resulted in the identification of 74 unique peptides which were significantly differentially expressed (ANOVA $p < 0.01$). Random forest modelling identified 15 top-ranking peptides which could distinguish NP from P with a ROC AUC of 0.94. Univariate analysis of the 206 proteins measured by targeted proteomics revealed 4 differentially expressed peptides (ANOVA $p < 0.01$) and random forest modelling revealed the top 15 candidate peptides could distinguish P from NP with a ROC AUC of 0.85. The baseline clinical data was combined with candidate peptides biomarkers in additional random forest models and this revealed improved model performance.

Conclusion: Data from 2 complimentary proteomic approaches was subjected to univariate and multivariate machine learning statistical analysis which revealed a total of 103 candidate biomarker peptides corresponding with 69 proteins that can potentially discriminate PsA patients who will progress to radiographic damage from those who will not. Random forest models produced convincing ROC AUCs which were improved by inclusion of patient clinical baseline data. The data, whilst promising, requires further validation using separate cohorts of similar patient samples.

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Abstracts: Spondyloarthritis Including PsA – Diagnosis, Manifestations, & Outcomes I (0449–0452)

Session Type: Abstract Session

Session Time: 9:30AM–10:30AM

Background/Purpose: Little is known about the natural history of spinal disease in Ankylosing Spondylitis (AS). Our objective was to identify distinct patterns of change in vertebral involvement over time and to study associated clinical factors.

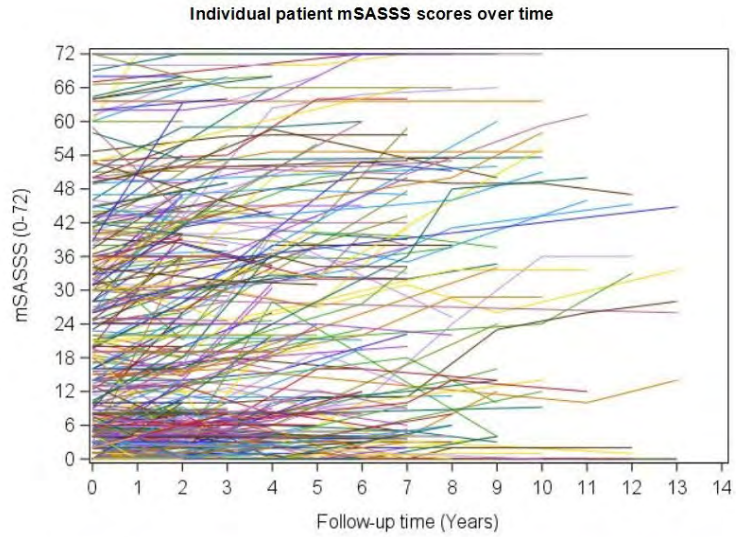

Figure 1. Time in years is along the X-axis and total Modified Stokes Ankylosing Spinal Score is along the Y-axis. Each individual line (n=561) represents a patient in the PSOAS cohort from time in cohort entry with all complete mSASSS scores included with at least 2 sets of radiographs.

Methods: Data were analyzed from the Prospective Study of Outcomes in Ankylosing Spondylitis (PSOAS) cohort. All patients met modified New York Criteria for AS, and had ≥2 sets of radiographs scored by modified Stoke Ankylosing Spondylitis Spinal Score (mSASSS) read by local-rheumatologist and central-radiologist between 2002-2017.

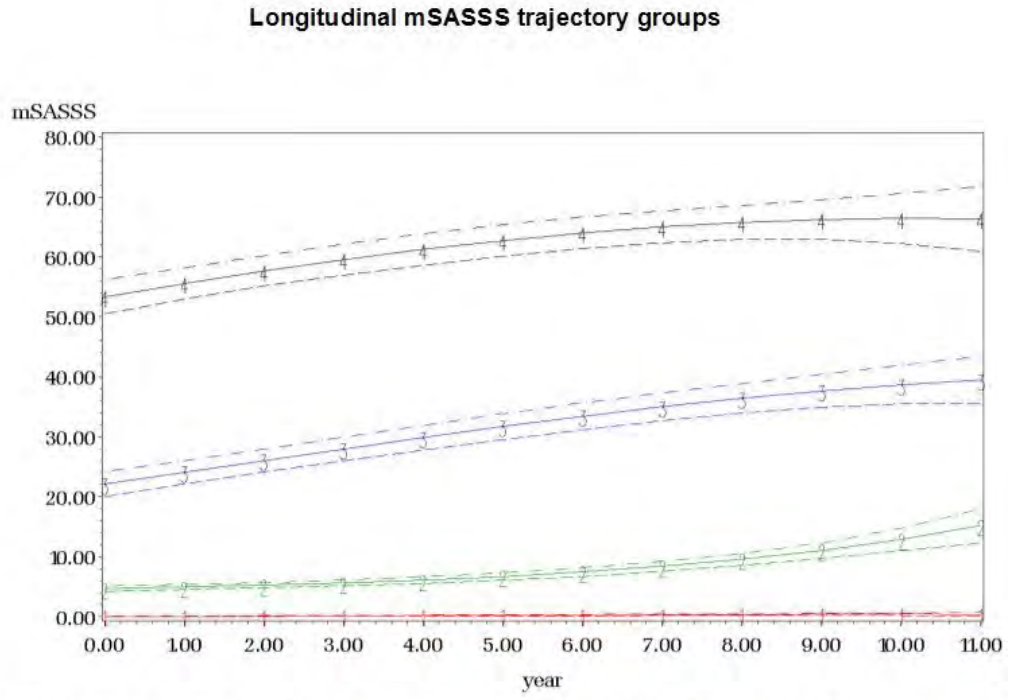

Figure 2. Time in years is along the X-axis and total Modified Stokes Ankylosing Spinal Score is along the Y-axis. The solid line represents the estimated mean with dotted lines representing the 95% confidence Interval. Trajectory groups from this patient cohort (n=561) include are: 1(Red Line) Non-Progressors, Group 2(Green Line) Late Progressors, Group 3 (Blue Line) - Early progressors and Group 4 (Black Line) Rapid Progressors. Including adjustments included: time-variant (Tumor necrosis factor inhibitor use and abnormal C-reactive protein) and time-invariant risk-factors (e.g. gender, smoking, and disease duration).

Table 1. Baseline Predictors of Trajectory group membership in the 4-group mSASSS model (non-progressor group is the reference group)

Variable	Coefficient Estimate	p-value
Late Progressors		
Baseline mSASSS*	-2.09	<0.001
Gender (Male vs. Female)*	0.58	0.02
Disease duration (≥20 years vs. <20 years)*	0.01	<0.001
Smoking history (Yes vs. No)	0.19	0.63
Hx of TNFi (Yes vs. No)	0.09	0.72
C-reactive protein (Elevated vs. Non-elevated)	0.04	0.70
BASDAI (≥4 vs. <4)	0.003	0.95
Early Progressors		
Baseline mSASSS*	-4.24	<0.001
Gender (Male vs. Female)*	1.40	<0.001
Disease duration (≥20 years vs. <20 years)*	0.13	<0.001
Smoking history (Yes vs. No)	0.65	0.14
Hx of TNFi (Yes vs. No)	0.51	0.11
C-reactive protein (elevated vs. non-elevated)	0.28	0.01
BASDAI (≥4 vs. <4)	-0.02	0.66
Rapid Progressors		
Baseline mSASSS*	-5.87	<0.001
Gender (Male vs. Female)*	2.46	<0.001
Disease duration (≥20 years vs. <20 years)*	0.15	<0.001
Smoking history (Yes vs. No)*	0.91	0.04
Hx of TNFi (Yes vs. No)	0.11	0.74
C-reactive protein (Elevated vs. Non-elevated)*	0.30	0.01
BASDAI (≥4 vs. <4)	0.04	0.52

*p<0.05

Group-based trajectory modeling (GBTM) was used to classify patients into distinct groups of longitudinal mSASSS considering sociodemographic and clinical covariables. The optimal trajectory model and number of trajectories was selected using Nagin's Bayesian information Criteria (BIC) (1).

Results: A total of 561 patients with 1618 radiographs was analyzed (Figure 1). The optimum number of trajectory groups identified was four (BIC -4062). These groups were subsequently categorized as: Non-progressors (204 patients, 37% of total), late-progressors (147, 26%), early-progressors (107, 19%) and rapid-progressors (103, 18%) (Figure 2). Baseline predictors associated with higher spinal disease burden groups included: male, gender, longer disease duration, and smoking history (Table 1.). In addition, elevated time-varying C-reactive protein (eCRP) levels were positively associated with higher disease progression groups and time-varying anti-TNF use was associated with decreased mSASSS progression in the rapid-progressor group.

Conclusion: GBTM identified 4 major patterns of spinal disease progression in the PSOAS cohort. Male gender, longer disease duration, eCRP and smoking were associated with higher spinal disease groups. Independent confirmation in other AS cohorts is needed to confirm these radiographic patterns.

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Abstracts: Spondyloarthritis Including PsA – Diagnosis, Manifestations, & Outcomes I (0449–0452)
Session Type: Abstract Session
Session Time: 9:30AM–10:30AM

Background/Purpose: Observational cohort studies have shown that there is low, but still detectable progression level in radiographic sacroiliitis, which might also have an impact on the function in patients with axial spondyloarthritis (axSpA). Recent data showed that tumor necrosis factor inhibitors (TNFi) might retard spinal progression when initiated earlier and taken longer in patients with axSpA. However, the question of whether they also have such an effect on radiographic progression in sacroiliac joints (SIJs) is still unclear.

In this study, we aimed to investigate the longitudinal association between radiographic sacroiliitis progression and treatment with TNFi in patients with early axial SpA in a long-term inception cohort.

Methods: Based on the availability of at least two sets of SIJ radiographs, 301 patients (166 with nr-axSpA, symptom duration ≤5 years and 135 with r-axSpA, symptom duration ≤10 years) from the German Spondyloarthritis Inception Cohort (GESPIC) were included in this analysis. These patients contributed with a total of 737 2-year radiographic

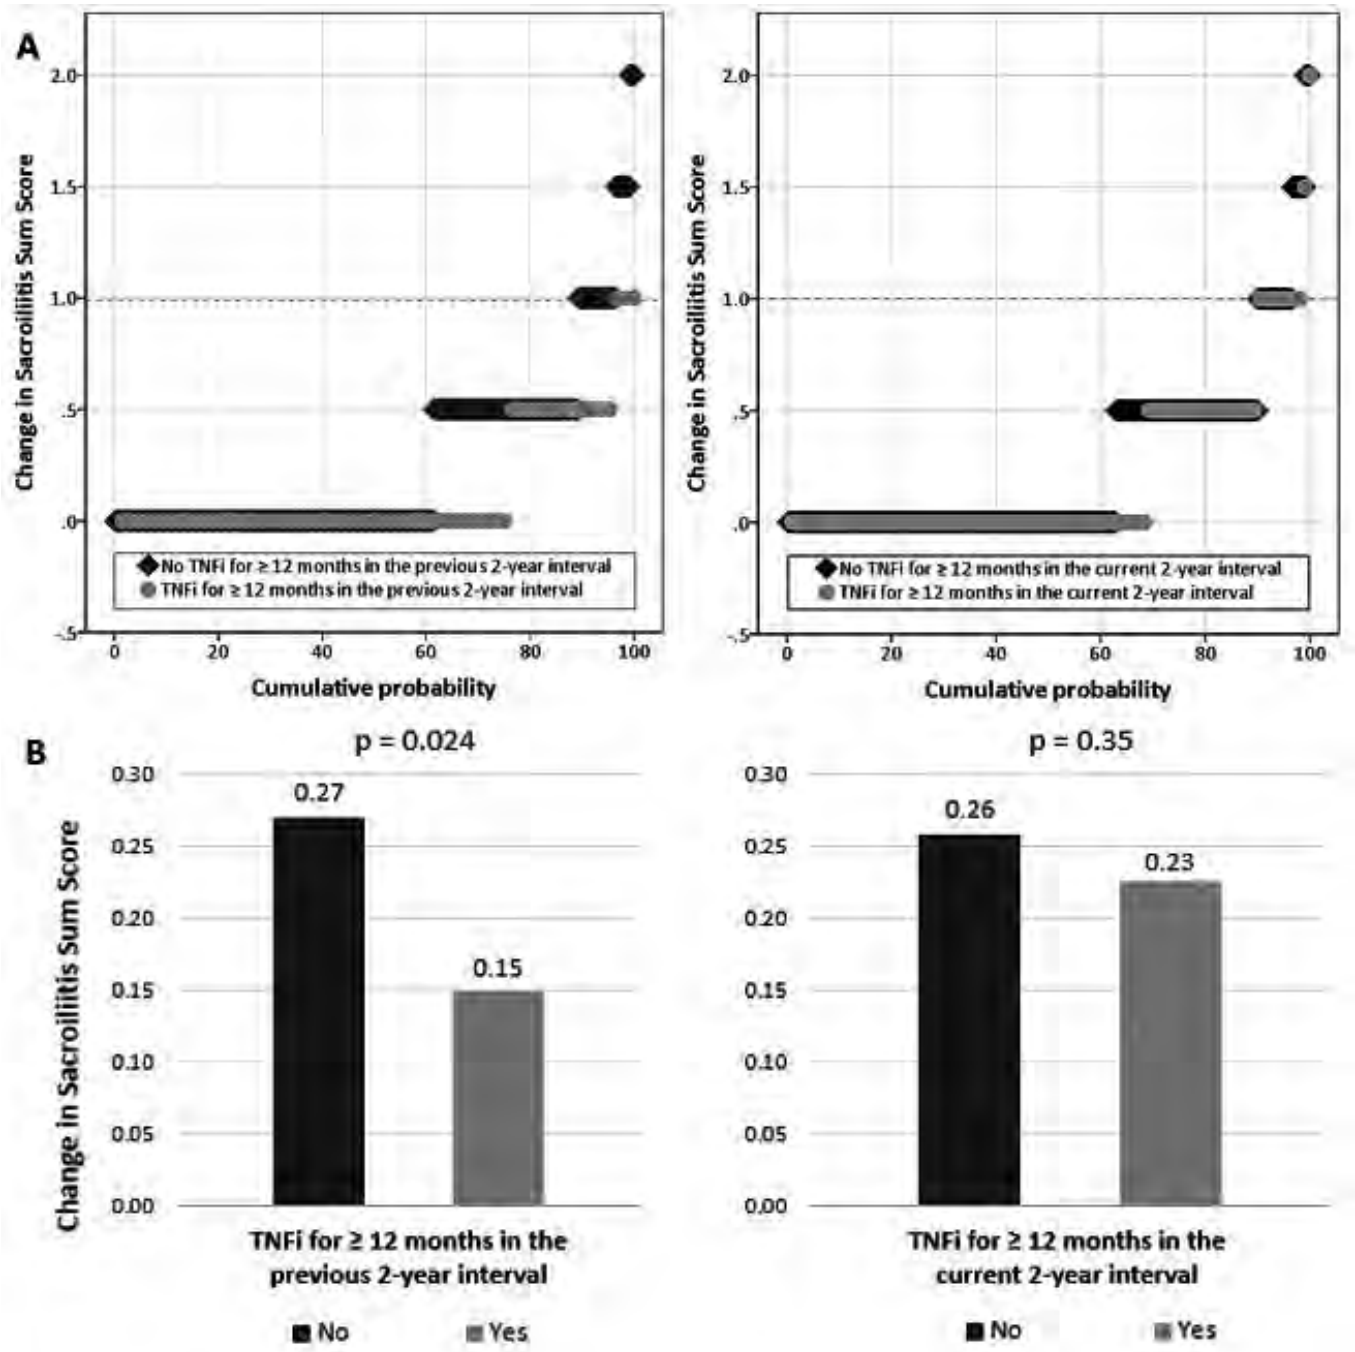

Figure. A). Cumulative probability plot of the 2-year progression in the sacroiliitis sum score, stratified by receiving at least 12 months TNFi in the previous and current 2-year radiographic intervals. B) The change in sacroiliitis sum scores over two years in patients with axial spondyloarthritis treated vs non-treated with TNFi at least 12 months in the previous and current 2-year radiographic intervals.

intervals. Two trained and calibrated central readers scored the radiographs according to the modified New York criteria. If both scored an image as definite radiographic sacroiliitis, the patient was classified as having r-axSpA. The sacroiliac sum score was calculated as a mean of both readers. The association between previous as well as current TNFi use and radiographic sacroiliitis progression, which was defined as the change in the sacroiliitis sum score over 2 years, was analysed using longitudinal generalized estimating equations (GEE) analysis.

Results: At baseline, 9 (3.0%) patients were treated with a TNFi, and 87 (28.9%) patients received at least one TNFi during the entire follow-up period. A total of 141 of the radiographic intervals were covered with TNFi of any duration, while 109

Table. The longitudinal GEE analysis of the association between progression in the sacroiliitis sum score and TNFi use

TNFi treatment definition	Reference	β* (95% CI)
TNFi for ≥ 12 months in the previous 2-year interval	No TNFi for ≥ 12 months in the previous 2-year interval	**-0.09 (-0.18, -0.003)**
Any TNFi use in the previous 2-year interval	No TNFi use in the previous 2-year interval	-0.09 (-0.17, 0.002)
TNFi for ≥ 12 months in the current 2-year interval	No TNFi for ≥ 12 months in the current 2-year interval	-0.03 (-0.11, 0.06)
Any TNFi use in the current 2-year interval	No TNFi use in the current 2-year interval	0.05 (-0.05, 0.14)
TNFi for ≥ 12 months in the previous and ≥ 12 months in the current 2-year interval	No TNFi for ≥ 12 months in the previous and ≥ 12 months in the current 2-year interval	-0.08 (-0.17, 0.004)

* Parameter estimates from the multivariable models adjusted for **sex**, **age** at the beginning of the current 2-year interval, **HLA-B27** positivity, **symptom duration** at the beginning of the current 2-year interval, time-averaged elevated **CRP**, time-averaged **BASDAI**, and time-averaged **NSAID intake score** in the current 2-year interval.

of them were covered with a TNFi of at least 12 months. While receiving ≥12 months TNFi in the previous interval was associated with a lower progression of the sacroiliitis sum score compared to not receiving TNFi in the previous interval, this was not the case in patients who received TNFi ≥12 months in the current 2-year interval (Figure 1). The significant association between TNF ≥12 months in the previous interval and progression in the sacroiliitis sum score were confirmed in the adjusted multivariable longitudinal GEE analysis. In addition, a similar trend for the beneficial effects was observed in different models, which included other treatment definitions with TNFi in the previous 2-year interval (Table).

Conclusion: Treatment with TNFi was associated with retardation of radiographic

Total-Body ^{18}F-FDG PET/CT Imaging: A Tool for Diagnosis and Quantifying Inflammatory Burden of Psoriatic Arthritis

Siba Raychaudhuri[1], Yasser Abdelhafez[2], Smriti Kundu-Raychaudhuri[2] and Abhijit Chaudhari[2], [1]Sacramento Veterans Affairs Medical Center (VAMC)/University of California-Davis Health, Davis, CA, [2]UC Davis School of Medicine, Davis, CA

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Abstracts: Spondyloarthritis Including PsA – Diagnosis, Manifestations, & Outcomes I (0449–0452)

Session Type: Abstract Session

Session Time: 9:30AM–10:30AM

Background/Purpose: The underlying pathology in psoriatic arthritis (PsA) is systemic inflammation. The Total Body (TB)-PET/CT with the ^{18}F-FDG radiotracer captures glucose metabolism across the entire body, and provides standardized measures as surrogates for degree of inflammation such as SUVmax. So, we predicted that these TB-PET/CT indices will correlate with the existing outcome measures of the 5 clinical domains of PsA (DAPSA, Leeds Enthesitis Index, Leeds Dactylitis Index, BASDAI and NAPSI). The objective of this study is to validate TB-PET/CT imaging as a diagnostic tool and for describing systemic disease activity of PsA.

Methods: We have prospectively recruited 40 participants (30 male, 10 female), with PsA (n=15), RA (n=10), and OA (n=15). All subjects underwent a single-timepoint TB-PET/CT scan on the uEXPLORER scanner using the PET radiotracer ^{18}F-FDG. Qualitative findings and different patterns for these 3 conditions were evaluated. We quantified the degree of inflammation (SUVmax) and determined pathologic predilection for anatomical domains of bones/ligaments of in PsA, RA and OA.

Results: In PsA patients, large number of joints showed positive findings in all participants. Multiple sites of enthesitis were visualized in the majority of scans (n=14/15). Furthermore, nail matrix showed increased uptake in 9/15 participants. Less frequent features included spine involvement of the supra/interspinous ligaments/bursae (n=6), sacroiliac joint (n=2), and dactylitis (n=2).

The uptake patterns and intensity were significantly different in patients with PsA compared to those with OA and RA (Fig 1 A and 1B). Fig 1 A, shows in PsA, joints were affected asymmetrically. In the Fig 1 B PET-CT imaging of the hands in PsA compared to RA clearly had: (a) asymmetry (b) also other characteristic pathologies such as in PsA there is inflammation of the extensor tendon and DIP in the left index along with marked nail matrix inflammation. The relative maximum standardized uptake value (rSUV$_{max}$) was significantly higher in participants with PsA compared to OA. There was a fair (68%) agreement between the DAPSA score and the PET averaged SUV$_{max}$. Figure 2 demonstrates the significance of a single TB-PET/CT scan in identifying the extent and the nature of joint, entheses, and nail involvement in PsA.

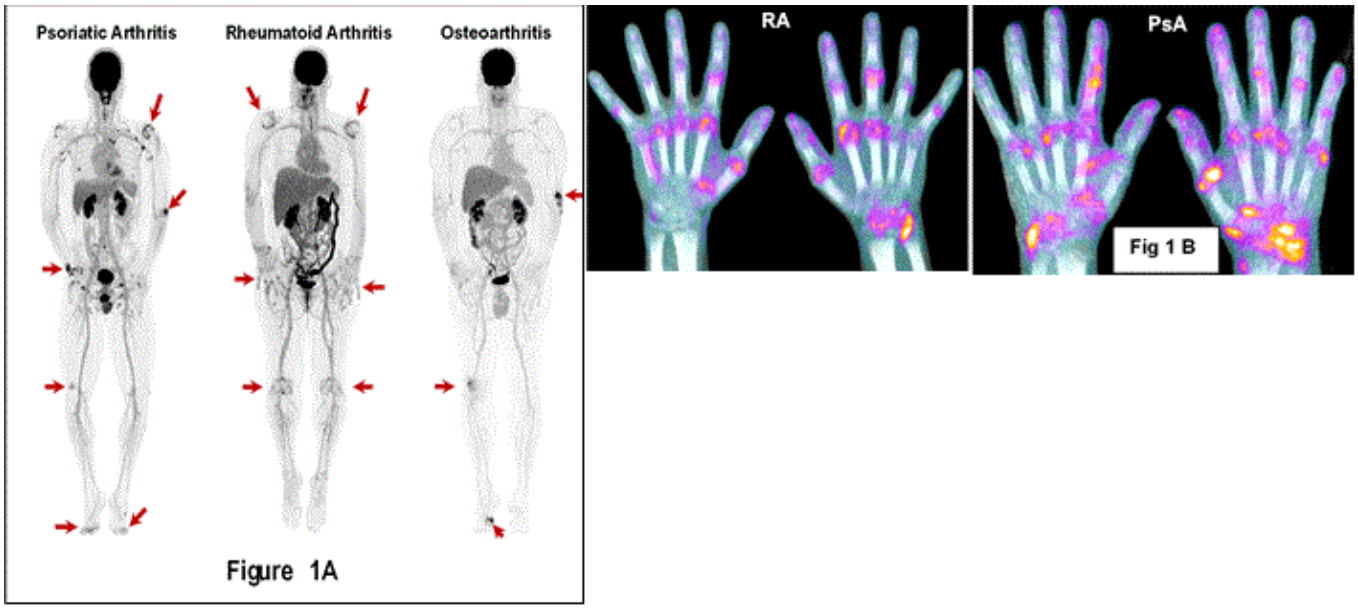

Figure 1. A. TB-PET/CT scans: Left: In PsA, showing multiple joints affected asymmetrically. Center: In RA: multiple joints affected, symmetric; including the shoulders, PIP joints of the hands and knees. Right: In OA, with few affected joints left elbow, right knee and right big toe. Figure 1: B. Compared to RA in PsA: (i) arthritis of small joints is asymmetric; evidenced by sparing of PIP/DIP of 3rd,4th,5th digits in the left hand (ii) there is inflammation of the extensor tendon and DIP in the left index finger and marked nail matrix inflammation in several fingers in both hands.

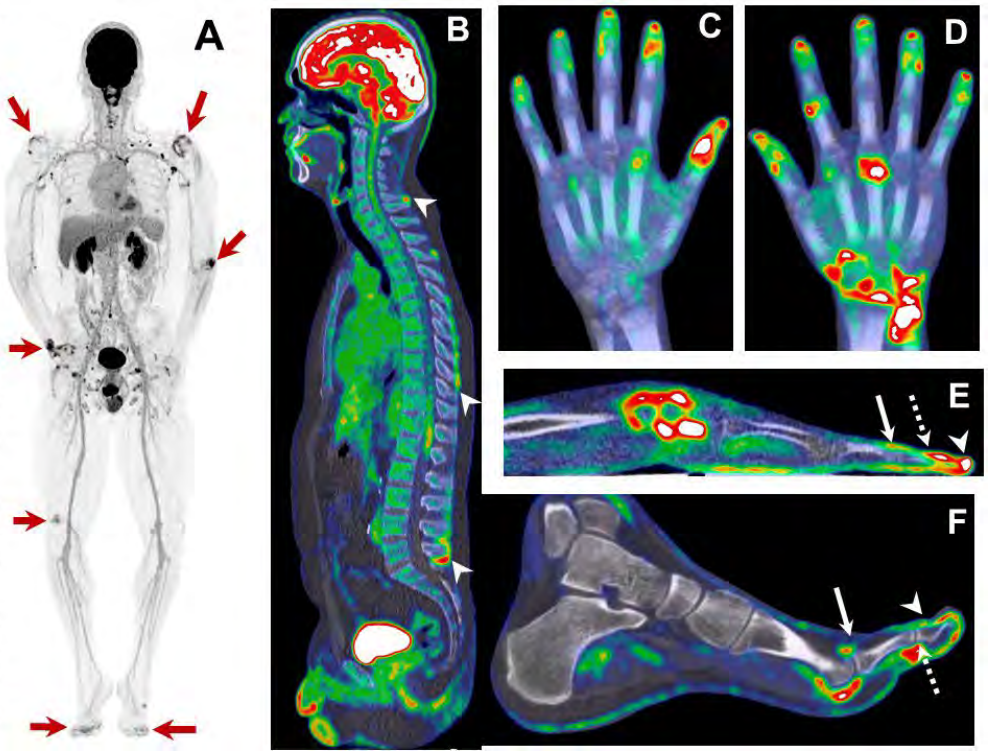

Fig 2: Total-Body evaluation of PsA:

(A) Maximum-intensity projection (MIP) of a Total-Body PET scan in a 40 y/o male demonstrating multiple asymmetric affection of the large and small joints (arrows).

(B) The spine entheses are involved at multiple levels and are well-visualized in the fused sagittal PET/CT image (arrowheads, B).

(C) and (D) Fused PET/CT images of the right and left hands demonstrating classic asymmetric arthritis of wrists, PIP and MCP joints and bilateral inflammation of the nail matrix.

E. Magnified fused sagittal view of the index finger (D), demonstrating nail matrix (arrowhead), DIP (dashed arrow) and PIP (solid arrow).

F. Magnified fused sagittal view of the right foot (F), demonstrating sausage digit of the right great toe along with inflammation of nail matrix (arrowhead), IP (dashed arrow) and MTP joints (solid arrow)

Figure 2. A single Total Body-PET/CT scan can identify the extent and the nature of joint, spine, entheses, and nail involvement in PsA.

Conclusion: Our results indicates that TB-PET/CT measures can identify unique pathologies of PsA (Fig 1 and Fig 2) compared to RA and OA such as (i) asymmetric synovitis of large and small joints, (ii) systemic generalized enthesitis (iii) DIP inflammation, (iv) inflammation of the extensor tendons of fingers and its association with its enthesitis and adjacent nail matrix inflammation, (v) nail matrix inflammation, (vi) dactylitis, (vii) spondyloarthritis with sacroiliitis and diffuse enthesitis of the spine.

These observations substantiate our proposal that TB-PET/CT identifies the pathologies unique for 5 clinical domains of PsA, differentiates from RA/PsA, provides a diagnosis, extent/severity of the disease with a quantitative measure of total inflammatory burden and identifies subclinical developing pathologies of PsA. Thus, a diagnostic tool for early disease at the point of transition from psoriasis.

Session Title: Plenary I (0453–0457)
Session Type: Plenary Session
Session Time: 10:30AM–12:00PM

Background/Purpose: Risankizumab (RZB) is a humanized immunoglobulin G1 monoclonal antibody that specifically inhibits interleukin 23 by binding to its p19 subunit. RZB is being investigated as a treatment for adults with psoriatic arthritis (PsA).

Methods: KEEPsAKE 1 and 2, double-blind, phase 3 trials, evaluated the efficacy and safety of RZB vs. placebo (PBO) for the treatment of active PsA. The trials enrolled adults with a diagnosis of active PsA, active plaque psoriasis or nail psoriasis, and ≥ 5 swollen joints and ≥ 5 tender joints. Both studies enrolled patients that had previously had an inadequate response or intolerance to ≥ 1 conventional synthetic disease modifying antirheumatic drug (csDMARD-IR). The KEEPsAKE 2 trial also enrolled patients that previously had an inadequate response or intolerance to 1 or 2 biologic therapies (Bio-IR).

In both trials, patients were randomized (1:1) to receive blinded subcutaneous RZB 150 mg or PBO at weeks 0, 4, and 16. The primary endpoint for this pooled analysis was the proportion of patients achieving 20% improvement

in American College of Rheumatology score (ACR20) at week 24. Non-responder imputation incorporating multiple imputations to handle missing data due to COVID-19 (NRI-C) was used for categorical efficacy data and Mixed-Effect Model Repeated Measurement (MMRM) analysis was used for continuous efficacy data. Safety was assessed throughout the study. Results reported here are from the 24-week double-blind period; the open-label period with all patients receiving RZB is ongoing.

Results: A total of 1407 patients (RZB, N = 707; PBO, N = 700) were initially enrolled and 1354 (RZB, N = 688; PBO, N = 666) completed the 24-week assessments. Demographics and baseline disease characteristics were similar between the two groups. Patients receiving RZB achieved higher rates of ACR20 than patients receiving PBO at Week 24 (**Table 1**, 55.5% vs 31.3%, $P < 0.001$). Patients receiving RZB showed greater improvements than patients receiving PBO in all secondary clinical and patient-reported outcome endpoints **(Table 1)**. RZB was well tolerated, and no new safety signals were observed **(Table 2)**.**Conclusion:** RZB resulted in statistically greater improvements in signs and symptoms of PsA compared with PBO and was well tolerated with no new safety signals.

Lupus Nephritis Mortality in the United States, 1999-2019: Profound Disparities by Race/Ethnicity and Place of Residence and a Recent Worsening Trend

Eric Yen[1], Snehin Rajkumar[1], Rohan Sharma[1] and **Ram Singh**[2], [1]University of California Los Angeles, Los Angeles, CA, [2]University of California Los Angeles David Geffen School of Medicine, Los Angeles, CA

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Plenary I (0453–0457)
Session Type: Plenary Session
Session Time: 10:30AM–12:00PM

Background/Purpose: Mortality from SLE has improved over the last two decades, but remains disproportionately high relative to general population mortality. Lupus nephritis (LN) occurs in 50-80% of childhood-onset and over 40% of adult-onset SLE patients. End-stage renal disease (ESRD) due to LN portends a high premature death burden compared to other manifestations of SLE – up to 26-times higher – and double the risk for hospital mortality compared with patients with all-cause ESRD. However, there have been no major population-based studies on mortality trends in LN over time across the U.S. We aimed to analyze mortality trends across the United States (U.S.) over two decades, 1999-2019, and to identify population characteristics associated with LN mortality.

Methods: We utilized the CDC's WONDER database that compiles mortality data from death certificates in all 50 states and District of Columbia. We obtained death counts attributed to SLE and LN, overall and by race/ethnicity and urbanization. Data on race/ethnicity were obtained for Hispanic, non-Hispanic (NH) White, NH Black, NH American-India/Alaska Native, and NH Asian/Pacific Islander. Urbanization was based off the 2006 urbanization data and is categorized based on population size – large central metropolitan (metro), large fringe metro, medium metro, small metro, micropolitan, and nonmetropolitan. Using these data, we calculated age-standardized mortality rate (ASMR) per 100,000 persons for LN deaths for each year from 1999 to 2019. We used joinpoint regression to fit piecewise-linear trends to yearly LN-ASMR, and for SLE-ASMR for comparison.

Results: From 1999 to 2019, there were 8,899 deaths attributed to LN and 25,973 deaths due to SLE. Overall, LN-ASMR decreased by 26.1% in 21 years. Joinpoint trend analysis showed that LN-ASMR decreased from 1999 to 2009, plateaued between 2009 and 2012, decreased again from 2012 to 2015, but significantly increased from 2015 to 2019. Such decrease-and-increase trend was not seen in all SLE-ASMR that continuously decreased from 1999 through 2019. Black persons were profoundly overrepresented in LN deaths (38%), while they account for only 12.8% of US population. On the other hand, white persons that represent 65.4% of US population accounted for 41.5% of all LN deaths. LN-ASMR in black persons was 6-fold higher than in white persons and >2-fold higher than in all other race/ethnic groups. LN-ASMR was also significantly higher in Hispanics, American-Indian/Alaska Natives, and Asian/Pacific Islanders than in white persons. Whereas 29.6% of US population lived in large central metro area, they accounted for 35.1% of LN deaths. LN-ASMR was highest in large central metro ($p < 0.05$ relative to all other areas), followed by medium metro that had higher LN-ASMR than in large fringe metro, small metro, micropolitan and nonmetro areas.

Conclusion: LN mortality rate has decreased since 1999, however, it showed an increasing trend from 2015 to 2019. LN mortality exhibited profound disparities by race/ethnicity and place of residence, with higher mortality in non-white persons and in those living in large central and medium metro. Studies are urgently needed to understand reasons underlying these disparities and the recent worsening trend.

P(numeric): Wilcoxon rank sum test (k=2 groups)

Background/Purpose: Rheumatoid arthritis (RA) has a preclinical phase that is characterized by the presence of antibodies against citrullinated proteins (ACPA), subclinical arthritis and pain. ACPA emerge years before the clinical onset of RA. In a subset of such individuals with ACPA (but not yet RA) imaging studies have revealed the presence of inflammatory and structural lesions. This subset of patients is at increased risk for the development of RA. As T cell mediated B cell activation is a key step for triggering the onset of autoimmune inflammatory diseases, such as RA, interventions that target this process may be useful for very early interventions, ultimately preventing the onset of RA. Abatacept appears to be an attractive approach in such task, as it interrupts the activation of T cells and has a well-known favourable safety profile in the treatment of RA.

To test whether abatacept, compared to placebo, reverses subclinical arthritis in patients with ACPA and MRI signs of inflammation, who have not yet developed RA.

Table 2

Primary Endpoint Analysis (Improvement in Inflammation Score) -ITT

P(categorial): Fishers exact test (2x2tables)

Primary Endpoint Analysis (Improvement in Inflammation Score) -ITT
*) composite of synovitis, tenosynovitis, and osteitis

Methods: ARIAA is a randomized double-blinded placebo-controlled multi-center study in RA-at risk individuals that ACPA positive and show MRI signs of inflammation. The study is composed by a 6 months treatment phase with either abatacept s.c. 125 mg weekly or placebo and 12 months follow up with no treatment. The primary analysis is done on the ITT population and missing values were rated as treatment failures. The primary endpoint was defined as an improvement in at least one of the MRI inflammation parameters (any change from baseline > 0 assessing synovitis, tenosynovitis and osteitis) according to the RAMRIS score.

Results: Between November 2014 and December 2019 a total of 139 patients were included into ARIAA by 14 study sites (11 in Germany, 1 in the Czech Republic and 2 in Spain). Of them, 100 patients were randomized to receive either abatacept or placebo. Two patients were excluded from the ITT population. As a result, 98 patients could be evaluated for efficacy and safety. The primary endpoint of ARIAA was reached: 61% of the patients in the abatacept group improved in at least one of the MRI parameters (synovitis, tenosynovitis, and osteitis) compared to only 31% in the placebo group (p=0.0043). Moreover, arthritis developed in 17 patients in the placebo group (34.7%) but only 4 patients (8.2%) in the abatacept group (p= 0.0025).

12 serious adverse events (1 gastritis, 1 cellulitis, 1 pneumonia, 1 tendinitis calcificans, 1 Rotator cuff syndrome, 1 Cholelithiasis, 1 x peripheral arterial occlusive disease, 1 x chronic idiopathic pain syndrom, 1 prostate cancer, 1 penile neoplasm; 1 trabeculectomy, 1 cataract operation) have been reported between 2014 - 2021, with only one (pneumonia) was assessed to have a causal relationship to study treatment.

Conclusion: These data show that abatacept significantly improves subclinical arthritis in patients at high risk to develop RA. In addition, the data also support the concept that early intervention may prevent or at least delay the development of RA.

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Plenary I (0453–0457)

Session Type: Plenary Session

Session Time: 10:30AM–12:00PM

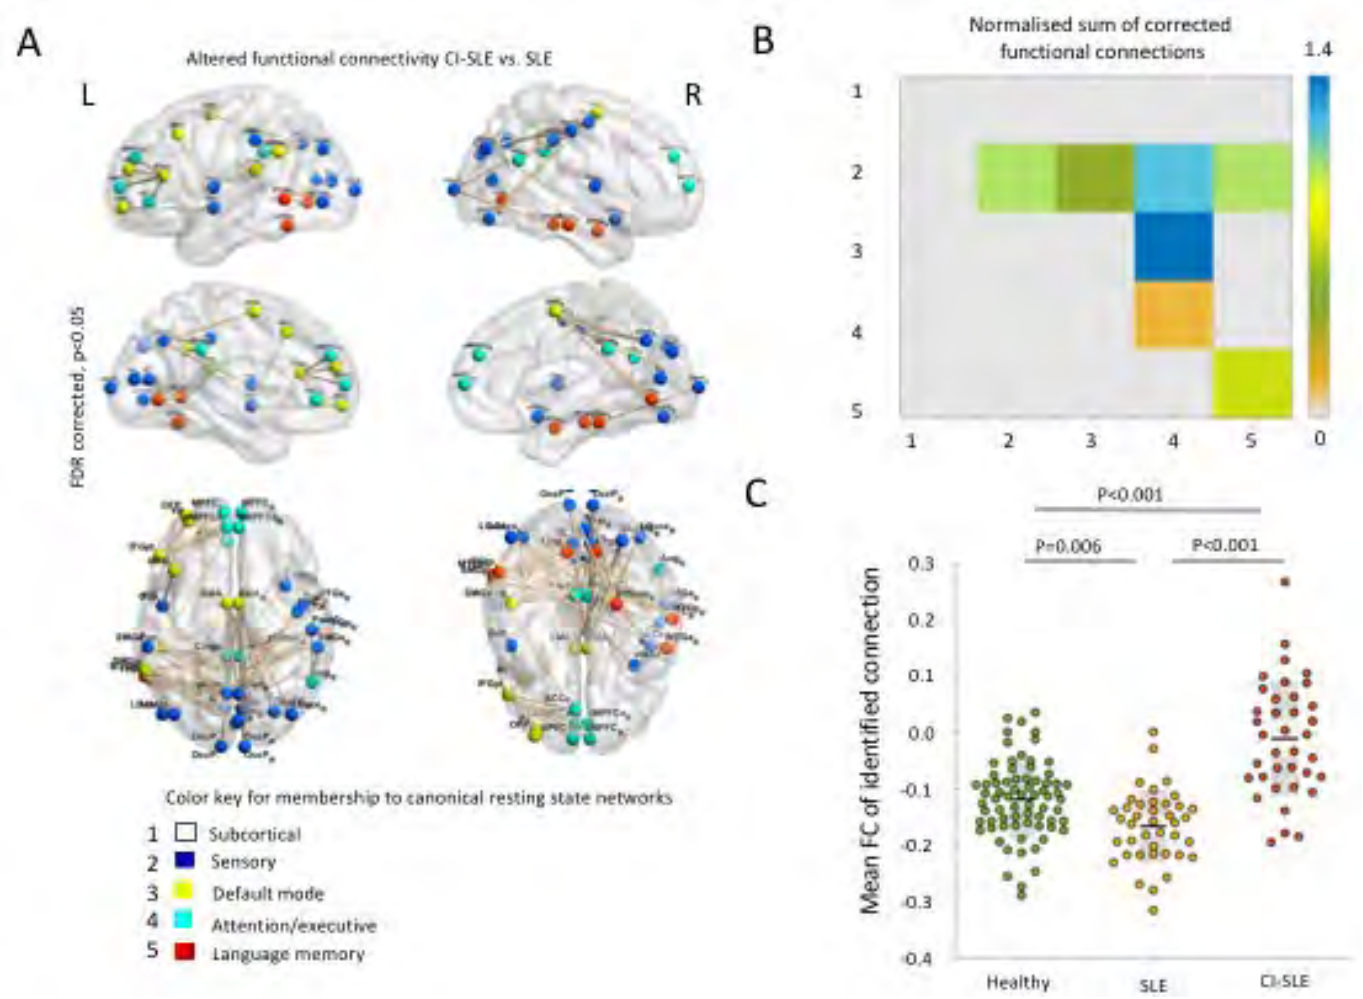

Figure 1. The association between resting state functional connectivity (rsFC) and cognitive impairment (CI) in patients with SLE. A. Contrast maps showing brain regions (colored nodes) with significant reductions in functional connections (yellow edges) in patients with SLE and CI (CI-SLE) compared to patients with SLE and normal cognition. Multiple comparisons were corrected using False Discovery Rate (FDR) at 0.05. Node colors represent membership in each of the five canonical resting state networks (color key legend at the left lower corner). B. Summed and normalized rsFC contrast matrix depicting the sum of corrected significant functional connections (CI-SLE < SLE). Color heat map (right) represents range of values; numbers represent resting-state networks as defined in the key below Panel A. C. Pearson correlation r-values reflecting the associations of all significant connections identified in Panels A & B were averaged and compared between patients with SLE and CI, patients with SLE and normal cognition, and healthy controls (see text for details). Data is presented as a scatter plot over a boxplot; the mean is shown as a black line.

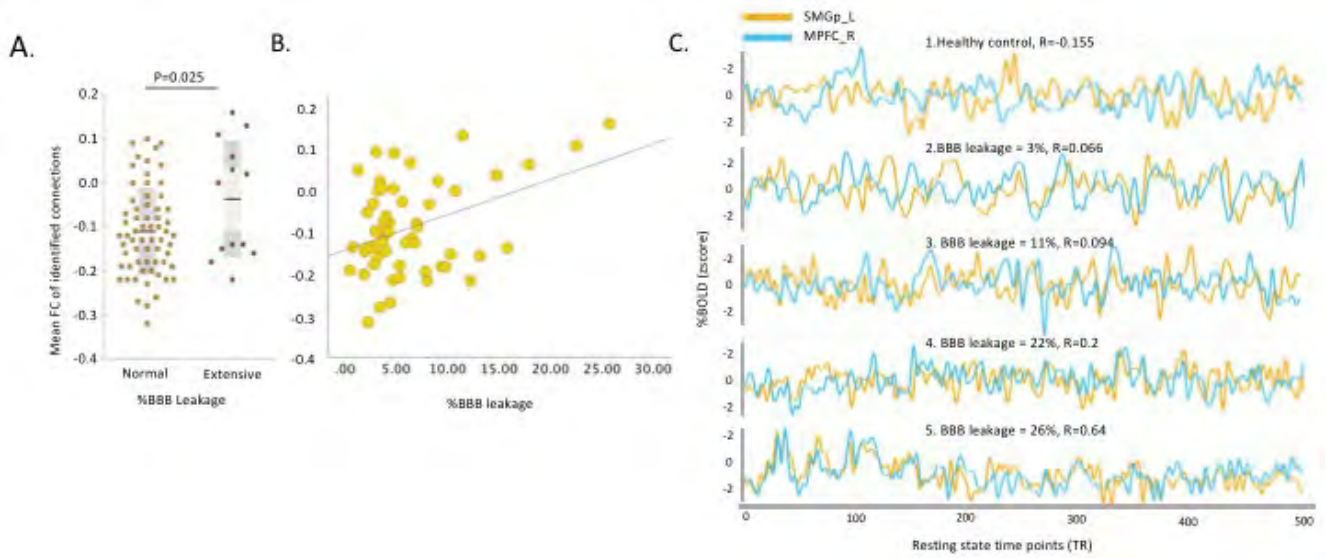

Figure 2. Altered rsFC in patients with SLE is associated with extensive blood-brain barrier leakage (BBB). A. In individual patients with SLE, the mean R-value of all significant functional connections was significantly higher in those with extensive BBB leakage. Data is presented as a scatter plot over a boxplot; the mean is shown as a black line. Significance is derived from the Spearman t-test. B. In individual patients with SLE, there was a trend in the association between the mean of all significant functional connections with %BBB disruption at p=0.082 (Kendal's Tau). C. %BOLD signal (z-scored) for two representative nodes are plotted for five different study participants in order of increasing %BBB disruption (#1 healthy control; #2 SLE with normal cognitive testing; #3-5 SLE with cognitive impairment). The plots show a shift from negative (#1) or no connectivity (#2) to positive connectivity (#3-5) between the two nodes with increase in %BBB leakage. SMGp_L (orange line): left supramarginal gyrus posterior; MPFC_R (blue line): right medial prefrontal cortex.

Background/Purpose: Cognitive impairment is the most frequent manifestation of neuropsychiatric systemic lupus erythematosus (NPSLE), yet the mechanisms underlying it remain poorly understood. We have previously reported an association between enhanced permeability of the blood-brain barrier (BBB), loss of grey matter volume and cognitive impairment in SLE patients. To further explore these associations and identify pathogenetic mechanisms the current study examined non-task based functional connectivity between brain regions using resting state functional magnetic resonance imaging (rsfMRI).

Methods: Adult patients with SLE (n=78, age 49.4 ± 14.3 years, 89.7% female) and healthy controls (n=71, age 38.9 ± 12.9 years, 69.0% female) were recruited at a single academic medical center. To identify cognitive impairment (CI) in SLE patients, global cognitive function and performance in five individual cognitive domains were assessed using standard neuropsychological tests. Quantitative assessment of BBB permeability was measured in SLE patients by dynamic contrast-enhanced magnetic resonance imaging (DCE-MRI). All study participants underwent rsfMRI, in which blood oxygen level dependent (BOLD) signals were collected as a proxy for neural activation. Mean BOLD signals were extracted from 131 regions across five canonical resting-state brain networks to analyze the resting-state functional connectivity (rsFC) between brain regions. The rsFC values were then compared between healthy controls, SLE patients with and without CI and between SLE patients with and without extensive BBB permeability.

Results: Fifty-one connections between functional brain regions were found to differ between SLE patients with CI and those without CI (P< 0.05, FDR corrected). Multivariate analysis of variance demonstrated differences between SLE patients with CI and healthy controls (P=0.006) (Figure 1A & 1C). In SLE patients with CI, within-network connectivity was significantly different for the sensory, attention/executive, and language memory networks (Figure 1B). The between-network connectivity differences occurred primarily between the sensory and attention/executive networks and between the default-mode and language-memory networks (Figure 1B). Mean functional connectivity of affect-

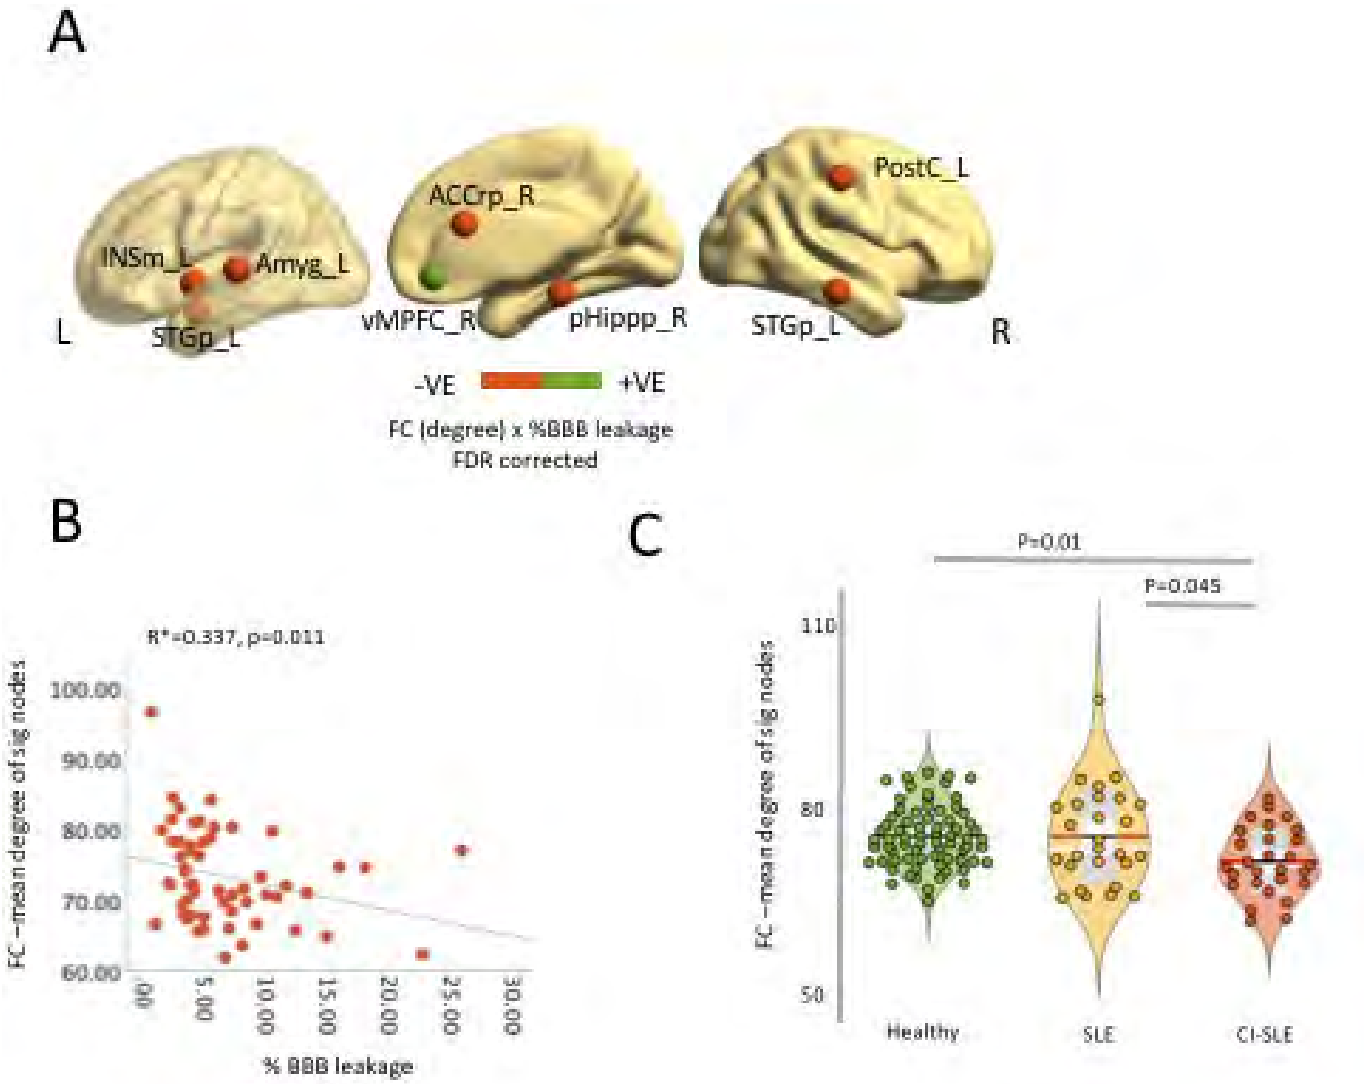

Figure 3. The total number of connections of specific brain regions (or nodal degree) is linked with %BBB leakage and cognitive impairment. A. Nodes in brain regions with decreased (red) or increased (green) connections (degree) were correlated with %BBB leakage (Spearman , corrected for multiple comparisons using False Discovery Rate). Abbreviations: INSm_L, left middle insula; STGp_L, left superior temporal gyrus; Amyg_L, left amygdala, ACCrp_R, right anterior cingulate cortex rostral posterior; pHippp_R, right parahippocampal gyrus posterior; PostC_L, left post central gyrus (S1); vMPFC_R, right ventral medial prefrontal cortex. B. Higher %BBB leakage is associated with lower average degree of the negatively affected nodes (Spearman). C. The average degree of affected nodes is significantly lower in patients with SLE and CI (CI-SLE) compared to patients with SLE with normal cognition (SLE) and healthy controls. Violin plot with scatter box plot with mean shown in red and median in white horizontal lines; p values computed with Kruskal Wallis test.

ed regions was different between SLE patients with normal BBB permeability and SLE patients with extensive BBB leakage (P=0.025) (Figure 2A & 2B). SLE patients with CI (Figure 1C) and those with extensive BBB leakage (Figure 2) had more positive functional connections compared to the other groups. Finally, the total number of brain-wide connections of specific brain regions decreased with higher BBB permeability (P=0.011) and was lower in SLE patients with CI than in SLE patients without CI (P=0.01, Figure 3).

Conclusion: SLE patients with CI demonstrated distinct differences in brain functional connectivity relative to SLE patients without CI and healthy controls. Within the SLE sample, these functional connectivity differences were also seen in those with extensive BBB leakage, suggesting an association between BBB leakage and neural pathology underlying CI in SLE patients.

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Plenary I (0453–0457)

Session Type: Plenary Session

Session Time: 10:30AM–12:00PM

Background/Purpose: Individuals with chronic inflammatory diseases (CID) are frequently treated with immunosuppressive medications that can increase their risk of severe COVID-19. While novel mRNA-based SARS-CoV-2 vaccination platforms provide robust protection in immunocompetent individuals, the immunogenicity in CID patients. Therefore, determining the effectiveness of SARS-CoV-2 vaccines in these patients is essential to risk-stratify them with impaired protection and provide clinical guidance regarding medication management.

Methods: We initiated the COVID-19 Vaccine Responses in Patients with Autoimmune Disease (COVaRiPAD) study, a prospective assessment of mRNA-based vaccine immunogenicity and reactogenicity in patients with CID. We collected blood from 197 adults with CIDs and 53 immunocompetent controls before initial immunization and 1-2 weeks after the second immunization. Serum anti-SARS-CoV-2 spike (S) IgG+ binding and neutralizing antibody titers were quantified to assess the magnitude and quality of the humoral response following vaccination.

Results: Compared to immunocompetent controls, a three-fold reduction in anti-S IgG titers (P=0.0046) and SARS-CoV-2 neutralization (P< 0.0001) to the D614G common variant were observed in CID patients. B cell depletion and glucocorticoids exerted the strongest effect with a 36- and 13-fold reduction in humoral responses, respectively (p< 0.0001). Janus kinase inhibitors and antimetabolites, including methotrexate, also blunted antibody titers in multivariate regression analyses (P< 0.0001, P=0.0023, respectively). Other targeted therapies, such as TNF inhibitors, IL-12/23 inhibitors, and integrin inhibitors, had only modest impacts on antibody formation and neutralization.

Conclusion: CID patients treated with immunosuppressive therapies exhibit impaired SARS-CoV-2 vaccine-induced immunity, with glucocorticoids and B cell depletion therapy more severely impeding optimal responses. We are currently determining cross-variant neutralization, long-term antibody and neutralization titers, and T cell responses in this cohort.

Table 1. Demographic and Clinical Characteristics of Participants with Chronic Inflammatory Diseases

Characteristics	Control (N=63)	CID (N=197)
Age, years		
Mean ± SD	43.4 ± 14.1	48.2 ± 16.1

Single Cell Profiling Reveals a Wnt-mediated Transcriptional Gradient That Drives Inflammation in Rheumatoid Arthritis Synovial Fibroblast Pathology

Alisa Mueller[1], Angela Zou[1], Emily Taylor[2], Triin Major[2], David Gardner[3], Adam Croft[4], Roche Fibroblast Network Consortium[5], Andrew Filer[2], Christopher Buckley[6], Kevin Wei[1], Ilya Korsunsky[1], Soumya Raychaudhuri[1] and Michael Brenner[7], [1]Brigham and Women's Hospital, Boston, MA, [2]University of Birmingham, Birmingham, United Kingdom, [3]University of Birmingham, College of Medical and Dental Sciences, Birmingham, United Kingdom, [4]University of Birmingham, Halesowen, United Kingdom, [5]Roche Innovation Center Basel, Basel, Switzerland, [6]University of Oxford, Oxford, United Kingdom, [7]Brigham and Women's Hospital, Harvard Medical School, Newton, MA

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Abstracts: RA – Etiology & Pathogenesis (0458–0461)

Session Type: Abstract Session

Session Time: 10:30AM–11:30AM

Background/Purpose: Synovial fibroblasts are key inflammatory aggressors in rheumatoid arthritis (RA) that mediate cartilage and bone destruction, yet therapies directly targeting these cells are lacking. Our previous single cell analy-

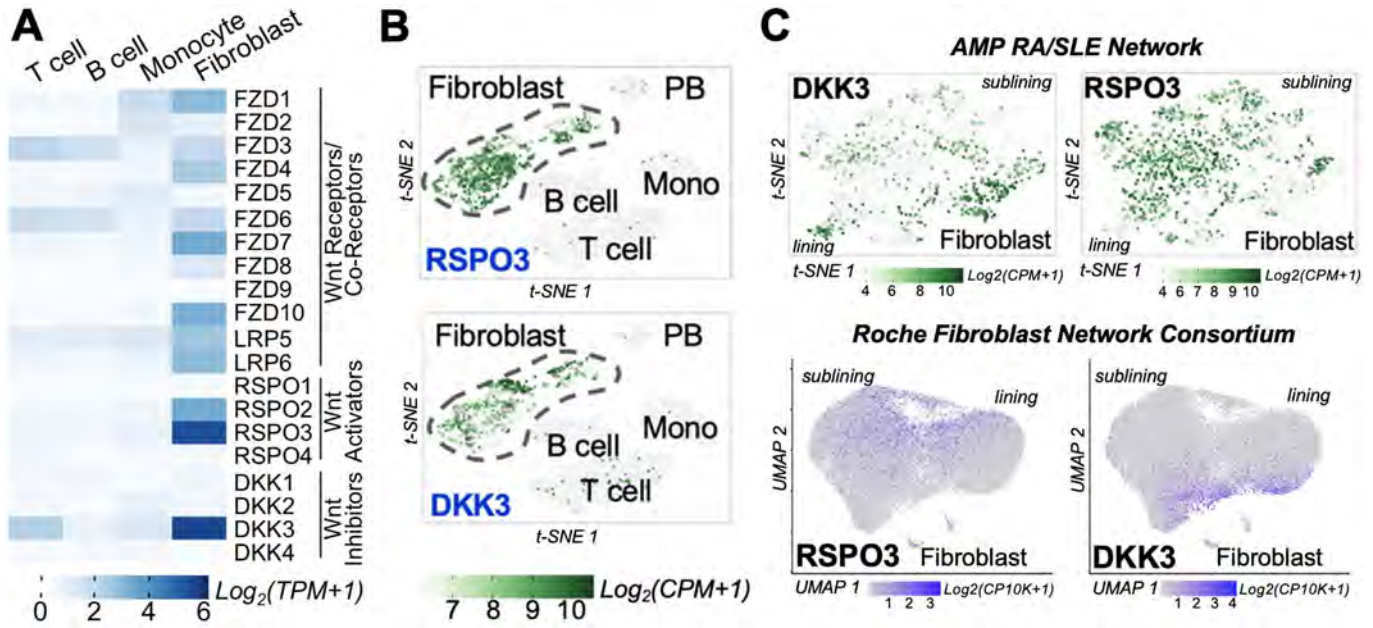

Figure 1. Synovial fibroblasts are poised for Wnt signaling, and expression of Wnt agonist RSPO3 is inversely correlated with Wnt antagonist DKK3 among fibroblast subpopulations. A) Expression of Wnt receptors, co-receptors, activators, and inhibitors from bulk RNA sequencing of synovial populations in OA and RA patients are predominantly expressed in fibroblasts. (B) Single-cell sequencing analyses of synovial cells from OA and RA patients confirms fibroblast-specific expression of a number of Wnt pathway members including DKK3 and RSPO3. (C) DKK3 and RSPO3 exhibit reciprocal patterns of expression within synovial fibroblast subpopulations in independent studies.

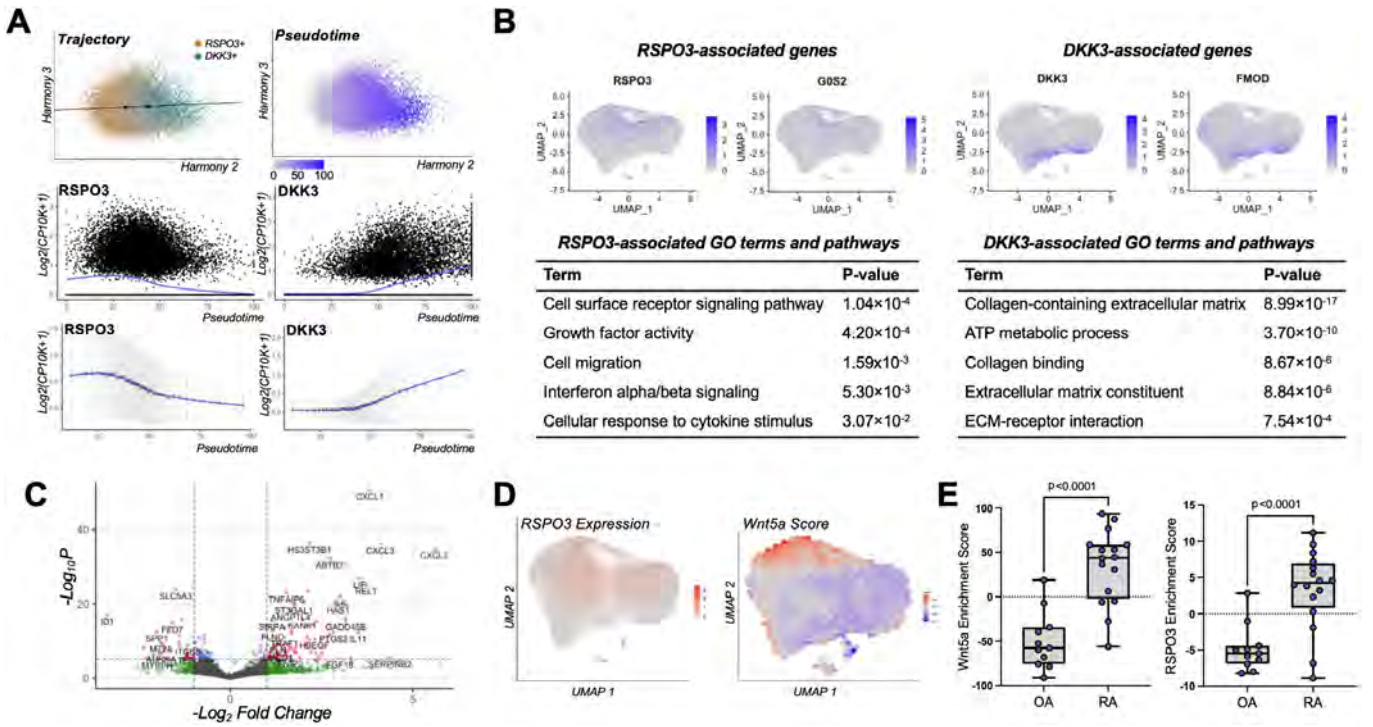

Figure 2. RSPO3 and DKK3 define a transcriptional gradient that is correlated with Wnt activity and inflammation. A) Trajectory analysis identifies genes that follow expression patterns that are similar to RSPO3 and DKK3 (B) Genes associated with RSPO3 show enrichment for cell growth, migration, and cytokine signaling while genes associated with DKK3 are linked to structural collagen components and extracellular matrix. (C) Differential expression analysis of synovial fibroblasts treated with Wnt5a compared with controls reveals that non-canonical Wnt signaling is associated with genes that drive inflammatory pathways. (D) RSPO3 expression is correlated with higher non-canonical Wnt activity. (E) Human fibroblasts isolated from leukocyte-rich RA synovial tissue show enhanced Wnt activity scores and RSPO3 enrichment scores compared with synovial fibroblasts isolated from OA samples.

ses revealed multiple clusters including a fibroblast subpopulation characterized by high expression of DKK3, a Wnt-associated gene. Wnt activation can promote cell proliferation, invasion, and differentiation, making it an attractive, potentially targetable pathway in RA. Here, we report that non-canonical Wnt signaling drives a strong inflammatory gene expression signature among synovial fibroblasts.

Methods: Bulk and single cell RNA sequencing data from the Accelerating Medicines Partnership (AMP) RA/SLE Network were used to analyze expression of Wnt pathway members among synovial populations in osteoarthritis (OA) and RA. To delineate fibroblast-specific patterns of Wnt signaling, we further utilized a comprehensive stromal cell-selected single cell dataset from the Roche Fibroblast Network Consortium that includes over 73,000 fibroblasts derived from OA and RA synovium as well as other chronic inflammatory diseases. Trajectory analysis was employed to identify a gradient of Wnt expression across fibroblast populations. We developed Wnt activation signatures using in vitro stimulation of human RA-derived synovial fibroblast lines treated with canonical and non-canonical Wnt ligands.

Results: Among all synovial cell populations, Wnt pathway members are predominantly expressed in fibroblast subsets. These molecules include Frizzed receptors, LRP5/6 co-receptors, R-spondin (RSPO) Wnt agonists, and Dickkopf (DKK) Wnt antagonists. Interestingly, non-canonical Wnt ligands dominate in expression as do RSPO3 and DKK3 (Figure 1A and 1B). Strikingly, RSPO3 and DKK3 are expressed reciprocally in distinct populations. Instead of being cluster-specific, RSPO3 and DKK3 form a strong gradient along both lining and sublining fibroblasts (Figure 1C). Using trajectory analysis, we demonstrate that RSPO3 and DKK3 correlate with genes that are differentially associated with inflammation and tissue repair, respectively (Figure 2A and 2B). To explore Wnt pathway activity along this gradient, we generated a non-canonical Wnt activation signature using synovial fibroblasts stimulated with Wnt5a. This signature reveals that non-canonical Wnt signaling drives fibroblast inflammation (Figure 2C) and is particularly active among cells expressing Wnt agonist RSPO3 (Figure 2D). The Wnt5a and RSPO3 gene signatures are also enhanced in fibroblasts derived from inflamed RA synovial tissue compared with those from OA synovial tissue while the DKK3 signature is reduced, suggesting increased Wnt activity in inflammatory RA (Figure 2E). Moreover, analyses show comparable Wnt-mediated gradients in Sjogren's syndrome and interstitial lung disease, indicating broader disease applicability.

Conclusion: We identify non-canonical Wnt signaling as a novel mechanism contributing to RA synovial fibroblast heterogeneity and inflammatory phenotype. This work provides a foundation for the development of Wnt-modulating pharmacologic strategies targeting synovial fibroblasts in RA.

CCN1: An Angiogenic Actor Implicated in the Structural Damages of Rheumatoid Arthritis

Jerome Avouac[1], Alexia Steelandt[2], Olivia Amiar[2], Agathe Leblond[2], Cindy Orvain[2], Anne Cauvet[2], Virginie Gonzalez[2] and Yannick Allanore[1], [1]Université de Paris, Service de Rhumatologie, Hôpital Cochin, AP-HP.CUP, Paris, France, [2]INSERM U1016, Institut Cochin, Paris, France

SESSION INFORMATION

Session Date: Saturday, November 6, 2021
Session Title: Abstracts: RA – Etiology & Pathogenesis (0458–0461)
Session Type: Abstract Session
Session Time: 10:30AM–11:30AM

Background/Purpose: We have previously shown that decreased expression of the deacetylase sirtuin-1 (SIRT1) contributes to the proliferative, activated and proangiogenic profile of endothelial cells (EC) in rheumatoid arthritis (RA). The matricellular protein CCN1, characterized by proangiogenic and immunomodulatory properties, may be directly implicated in these processes, since its expression is negatively regulated by SIRT1.Our objective was to study the implication of CCN1 in RA pathogenesis.

Methods: CCN1 expression was assessed in ECs (25 RA and 10 controls) by quantitative RT-PCR, western blot and ELISA, in the synovial tissue (5 RA and 5 controls) by immunohistochemistry and immunofluorescence, and in the serum (205 RA and 20 controls) by ELISA. Invalidation of CCN1 in RA ECs was achieved through the use of shRNA and neutralizing monoclonal antibodies. The functional consequences of CCN1 invalidation in RA ECs were studied i) *in vitro* by the analysis of proliferation (cell impedance), tube formation in Matrigel and migration in Boyden chambers; and ii) *in vivo*in the murine model of tumor neoangiogenesis. Conditional invalidation of CCN1 in ECs was analyzed in the mouse model of methyl-BSA-induced arthritis.

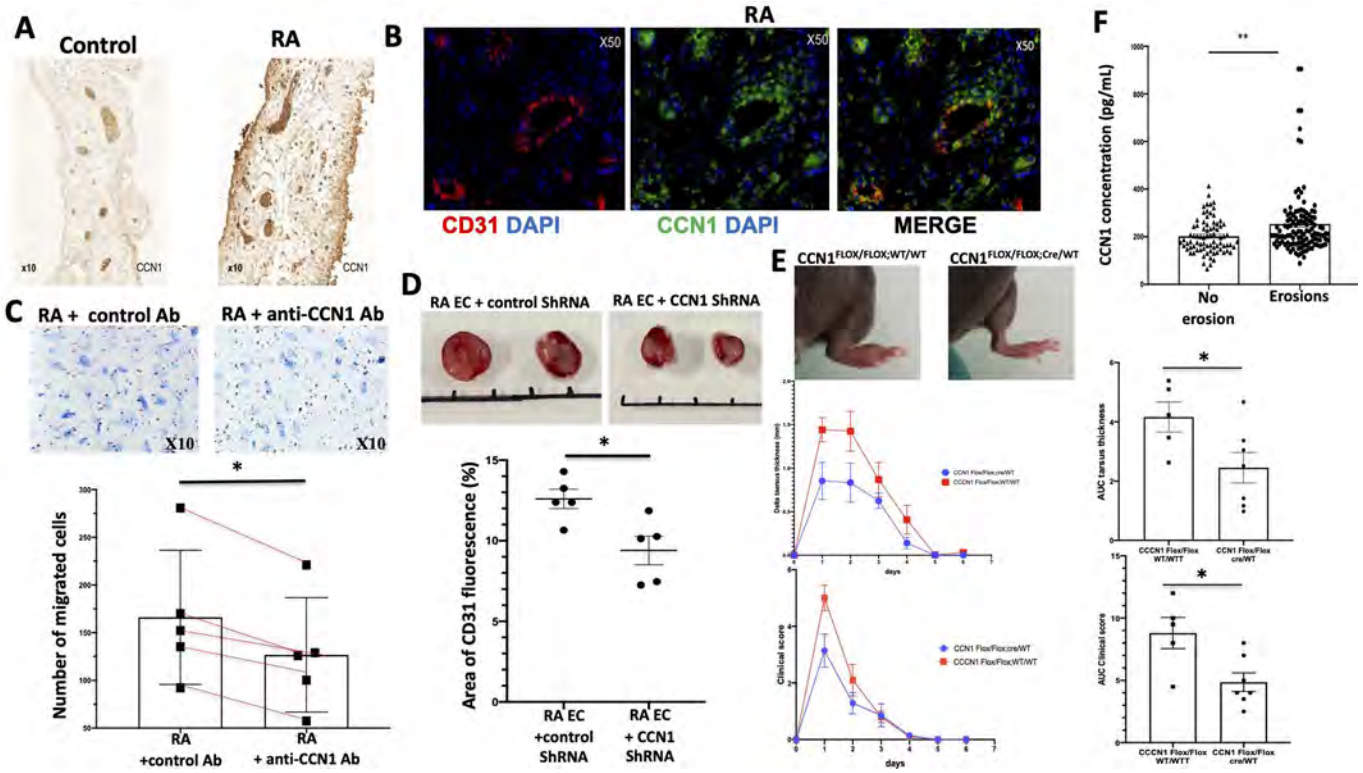

Figure 1. Implication of CCN1 in the pathogenesis of rheumatoid arthritis (RA). A, Representative immunohistochemistry staining for CCN1. B, Representative confocal microscopy analyses. p<0.01. C, Representative images of RA endothelial cell (EC) migration; Y-axis shows the number of migrated cells, statistical test: Wilcoxon test, * p<0.05. D, Representative subcutaneous tumors, Y-axis shows the fluorescence area in %, statistical test: Wilcoxon test, * p<0.05. E, mBSA-induced arthritis in littermates of CCN1 Flox/Flox; WT/WT mice (n=5) and SCCN1 Flox/Flox; Cre/WT mice (n=7); Y-axis shows tarsus thickness and clinical score, as well as the area under the curve (AUC) of tarsus thickness (C) and the clinical score (D). statistical test: Student t test, * p<0.05. F, CCN1 serum concentrations; statistical test: Student t test, ** p<0.01.

Results: CCN1 mRNA and protein expression were increased by 1.72- (p = 0.012) and 7.2-fold (p=0.008) in RA ECs compared to controls, respectively. CCN1 concentrations were significantly increased in RA EC culture supernatants (930±153 vs. 359±199 pg/mL, p=0.007). CCN1 was overexpressed in the synovial tissue of RA patients (Figure 1A) and confocal microscopy analyses revealed a prominent CCN1 expression in the vascular endothelium (CD31 +) and T cells (CD3 +) (Figure 1B). *In vitro*, recombinant TNF-α and IL-17 induced the mRNA and protein expression of CCN1 in RA ECs. CCN1 invalidation was associated with reduced proliferative capacities, delayed capillary tube formation, and decreased migration (Figure 1C) of RA ECs. *In vivo*, subcutaneous transplantation of CT26 tumor cells combined with RA ECs transfected with CCN1 shRNA to CB17 SCID mice was associated with a 51% reduction in tumor volume (p=0.008) and a 27% reduction in tumoral vascular density (p=0.032) compared with mice transplanted with MOCK transfected RA-ECs (Figure 1D). Conditional deletion of CCN1 in ECs through a Cre-LoxP recombination system alleviated signs of methyl-BSA-induced arthritis (Figure 1E). Serum CCN1 concentrations were significantly higher in the presence of bone erosions (253±139 vs. 202±7 pg/mL, p=0.002) (Figure 1F) and correlated with radiographic Larsen score (r=0.3, p=0.001) and HAQ (r=0.25, p=0.012).

Conclusion: CCN1 is overexpressed in ECs and the synovial tissue of patients with RA. CCN1 also regulate the functional properties of RA ECs and their angiogenic potential *in vivo.* Moreover, endothelial inactivation of CCN1 alleviate experimental arthritis. CCN1 could represent a new therapeutic target, which is being evaluated in experimental models of erosive arthritis. CCN1 may also be a reliable biomarker of structural damages given the association between its serum concentrations and the extent of radiographic lesions. The performance of CCN1 serum levels to predict structural progression is under investigation.

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Abstracts: RA – Etiology & Pathogenesis (0458–0461)
Session Type: Abstract Session
Session Time: 10:30AM–11:30AM

Background/Purpose: B cell and T cell activation pathways in the synovium are an incompletely understood feature of rheumatoid arthritis. In this study, utilizing single cell RNA sequencing coupled with B and T cell repertoire sequencing to characterize B and T cell states that may play a role in immune activation within the synovium, we define potential developmental relationships and identify key signaling pathways that support local immune cell activation and development of autoreactive plasma cells.

Methods: B and T cells were sorted by flow cytometry from RA synovial tissue (n=13) and matched peripheral blood (PBL) (n=10) as part of the AMP Network Phase 2. Single cell RNA sequencing was performed on the 10x Genomics platform with poly-A selected, 5' initiated expression and BCR or TCR libraries generated from each single cell. Quality control criteria (# of genes detected and % mitochondria gene) were applied to the sequencing data. Clustering analysis using gene expression was performed to identify B cell and T cell subsets. In B cells, we analyzed somatic hypermutation (SHM), immunoglobulin isotype and clonality. Diversity was assessed by looking at V(D)J segment usage frequencies and CDR3 properties. In T cells, we assessed the extent of oligoclonality in different T cell subsets and the overlap in repertoires across T cell subsets.

Results: After applying QC, over 50,000 lymphocytes were available for downstream analysis (36,000 from PBL and 20,600 cells from synovial tissue). Clustering identified various naive and activated B cell populations, plasma cells, and naive CD4 and CD8, Treg and effector T cell states. We observed synovial enrichment of clusters including activated B cells, Tph cells, and granzyme K-expressing CD8 T cells. Activated synovial B cells had significantly higher SHM compared to PBL. In every subject, we observed substantial clonal expansion in both the synovium and peripheral blood, as well as clones shared between these tissues. Naïve B and T cells exhibited fewer expanded clonotypes than non-naïve populations. In both B cells and T cells, there was clonal sharing across synovial sub-populations, including between IgG and IgA plasma cells, activated B cell and plasma cells, and between memory and effector T cells. Together, our findings suggest in situ differentiation of selected B and T cell clones and trafficking of these expanded clones between blood and synovium.

Conclusion: Our data demonstrate the value of integrating gene expression and repertoire data for the study of T and B cell responses in RA synovial tissue and provide evidence of in situ selection.

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Abstracts: RA – Etiology & Pathogenesis (0458–0461)
Session Type: Abstract Session
Session Time: 10:30AM–11:30AM

Background/Purpose: Circulating autoantibodies like ACPA frequently develop years before symptoms of RA, during which the individual is at-risk for disease. Several lines of evidence suggest that these autoantibodies may be driven by microbial-mucosal interactions. We hypothesized that discrete gut-derived bacteria drive autoantibody generation.

Methods: Dual IgA/IgG family plasmablasts (n=94) were isolated from 4 individuals at-risk for RA, defined as serum anti-CCP+ (75%) and/or RF+ (75%), and from 2 anti-CCP+ individuals with early RA. Fab domains from the plasmablast-derived mAbs (PB-mAbs), selected for binding of RA-relevant antigens on a protein microarray, were expressed in a mouse IgG2a scaffold. The PB-mAbs were used to identify targeted fecal bacteria, and *Ruminococcaceae(Rumino)* strains were isolated from the feces of a human at-risk for RA. 16S sequencing identified seven *Rumino* family strains of interest, and through whole genome sequencing we identified an as yet unnamed species within genus *Subdoligranulum (Sbg)*. Human PBMC were isolated and exposed to individual strains of *Sbg* to gauge memory responses by assessing *in vitro* CD154+ upregulation on CD4+ T cells. Germ free DBA/1 mice were colonized with each *Sbg* strain, as well as *Prevotella copri* and PBS as controls, and were monitored for stable colonization, autoantibody development, and joint swelling. Serum collected from arthritogenic *Sbg* monocolonized mice was injected into naive germ-free DBA/1 mice, and mice were monitored for joint swelling.

Results: All PB-mAbs bound RA-relevant antigens and 58/94 (62%) targeted families *Lachno(spiraceae)/Rumino* from a pool of fecal bacteria (derived from 5 healthy controls, 8 at-risk individuals, and 5 RA cases) at a disproportionately elevated level (56.31 ± 12.85% of all bacteria bound) compared to other taxa, suggesting cross-reactivity between bacterial and host antigens. We verified PB-mAb binding of *Lachno/Rumino* using our generated *Sbg* strains. We then observed an MHC class II-dependent memory T cell response in PBMCs against a subset of the *Sbg* strains in individuals with RA that was nearly absent in controls. To determine if *Sbg* could induce autoantibodies *in vivo*, germ-free mice were stably colonized with the *Sbg* strains, *P. copri*, or sterile PBS; within 14 days, joint swelling was observed only in mice monocolonized with a subset of the *Sbg* strains. Joint swelling was associated with an expansion of

antibodies to RA-relevant antigens. Transfer of serum from affected *Sbg* strain colonized mice, but not *P. copri* or PBS controls, to naïve mice resulted in joint swelling.

Conclusion: A subset of circulating dual IgA/IgG PB-mAbs isolated from individuals at-risk for RA target both RA-relevant antigens and bacteria within families *Lachno/Rumino*. A specific strain from the genus *Sbg* established from an at-risk individual were recognized by T cells from RA cases. When germ-free mice were monocolonized with the specific *Sbg* strain, they developed joint swelling and serum autoantibodies capable of transferring the joint swelling phenotype. Our data suggests one model in which a strain of bacteria is capable of stimulating the development of pathogenic autoantibodies.

Session Type: Abstract Session
Session Time: 10:30AM–11:30AM

Background/Purpose: Inflammatory rheumatic disease (IRD) related fatigue is pervasive and disabling, even in otherwise stable disease. Although cognitive-behavioural approaches (CBAs) and personalised exercise programmes (PEP) are considered effective treatments, rheumatology services encounter significant implementation barriers: 1) existing interventions have not been standardised and tested across the range of IRDs managed by rheumatology 2) the requisite specialist expertise does not commonly exist within rheumatology multi-disciplinary teams (MDT) 3) regular face to face sessions are often undesirable for patients, especially during a pandemic.

This is the first study to test remotely delivered CBA and PEP, by the rheumatology MDT, across IRDs.

Table 1 Baseline characteristics of study participants

Variable	PEP (n 124)	CBA (n 121)	Usual Care (n 122)
Age [years]#	56.4 (12.3)	59.3 (13.0)	56.8 (12.7)

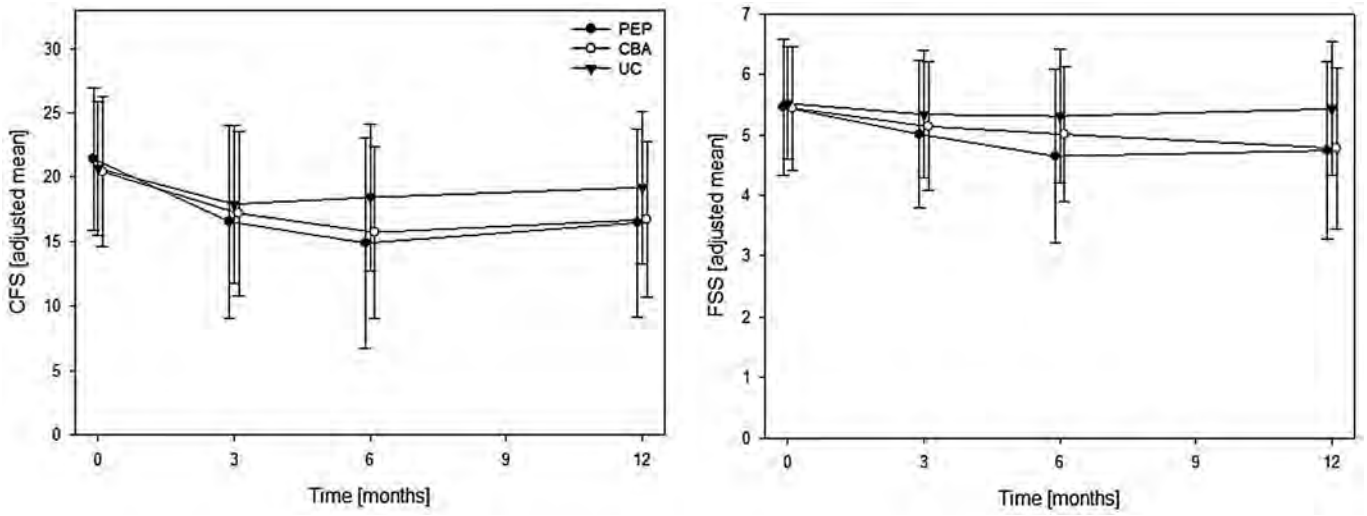

Figure 1. Fatigue severity (CFS) and fatigue impact (FSS) over time by treatment group Data are shown as adjusted means (sd). All models adjusted for their baseline outcome measure, HADS depression subscale >10 at baseline as fixed effects fixed effect with Centre clustering and individuals nested within Centre's as random effects. PEP, personalised exercise programme; CBA, cognitive-behavioural approach; UC, usual care; HADS, Hospital Anxiety and Depression Scale.

Table 2 Secondary outcomes at 12 months

Outcome	PEP	CBA	UC	PEP vs UC	CBA vs UC
HADS Anxiety	7.8 (4.9); 73	7.8 (4.4); 86	7.8 (4.6); 85	-0.7 [-1.6, 0.1]; 0.100	-0.4 [-1.3, 0.5]; 0.358
HADS Depression	5.4 (3.6); 75	6.0 (3.4); 88	6.3 (3.5); 85	-1.0 [-1.7, -0.2]; 0.009	-0.4 [-1.1, 0.3]; 0.303
Pain	5.2 (2.7); 79	5.3 (2.4); 93	5.3 (2.7); 92	-0.3 [-0.9, 0.3]; 0.401	0.1 [-0.4, 0.7]; 0.630
Sleep	11.6 (5.9); 75	10.8 (5.8); 89	12.9 (5.7); 81	-1.3 [-2.6, -0.1]; 0.033	-1.8 [-3.0, -0.6]; 0.003
Work (WPAI)	31.0 (21.6); 21	42.7 (23.9); 29	49.0 (25.6); 31	-14.1 [-26.7, -1.4]; 0.029	-6.3 [-17.8, 5.3]; 0.287

Methods: A multicentre, three-arm randomised controlled trial of usual care (UC) alongside telephone delivered CBA or PEP were tested against UC alone. UC typically comprised a fatigue self-management education booklet. Patients with any stable (unaltered immunomodulatory therapy for ≥3 months), physician diagnosed IRD were considered eligible if they reported significant (≥6 on numeric rating 0-10 scale, NRS) and persisting (≥3 months) fatigue. CBA and PEP was delivered by members of the rheumatology MDT, who received specialist training and supervision. Patients received up to 7 sessions across 14 weeks with a booster session at 6 months. Primary outcomes were fatigue severity (Chalder Fatigue Scale, CFS) and impact (Fatigue Severity Scale, FSS) at 12 months. Secondary outcomes included depression (Hospital Anxiety and Depression Scale), pain (NRS), sleep disturbance (Jenkins) and Work Productivity and Activity Impairment (WPA-I), also at 12 months. Generalized linear mixed models were used to compare the effectiveness of active therapies versus UC following an Intention-To-Treat approach. Results are expressed as mean difference (md) with 95% confidence intervals (95% CI).

Results: 368 IRD patients (55% rheumatoid arthritis, 21% connective tissue disease, 19% spondyloarthritis, 5% other IRD) were randomised. Baseline characteristics were similarly distributed across the trial arms (table 1). 73% and 85% completed PEP and CBA respectively and primary outcome data was available for 77% of all patients. PEP and CBA significantly improved fatigue severity (CFS md -2.9, 95% CI [-4.6, -1.2], p=0.001 and md -2.5, 95% CI [-4.01, -0.8], p=0.003, respectively) and fatigue impact (FSS md -0.6, 95% CI [-0.9, -0.3], p< 0.001 and md -0.6, 95% CI [-0.8, -0.3], p< 0.001, respectively) compared to UC alone at 12 months (figure 1). Both PEP and CBA also improved sleep (Jenkins md -1.3, 95% CI [-2.56, -0.1] and -1.8, 95% CI [-3.0, -0.6], respectively), while PEP further improved depression (HADS md -1.0, 95% CI [-1.7, -0.2]) and overall work impairment (WPAI md -14.1, 95% CI [-26.7, -1.4]) (table 2).

Conclusion: Telephone delivered CBA and PEP provided statistically and clinically significant reductions in fatigue severity and impact for a wide range of stable IRD patients. The benefit was maintained for 6 months following treatment completion and was successfully delivered by members of the rheumatology MDT after specialist training.

Data are shown as adjusted means (sd); n. Results are expressed as mean difference (md) with 95% confidence intervals (95% CI) and p-value. All models adjusted for their baseline outcome measure, HADS depression subscale >10 at baseline as fixed effects fixed effect with Centre clustering and individuals nested within Centre's as random effects. PEP, personalised exercise programme; CBA, cognitive-behavioural approach; UC, usual care; HADS, Hospital Anxiety and Depression Scale; WPAI, Work Productivity and Activity Impairment (overall work impairment domain);

Treatment Persistence Among Medicare Beneficiaries with Seropositive Rheumatoid Arthritis Initiating Biologic or Targeted Synthetic DMARDs

Sang Hee Park[1], Taylor Schwartz[2], Xue Han[1], Scott Robinson[2], Sumie Kakehi[1], Keith Wittstock[1], Kris Norris[2], Anne Murunga[2], Alison Silverstein[2] and Jeffrey Sparks[3], [1]Bristol Myers Squibb, Princeton, NJ, [2]Avalere Health, Washington, DC, [3]Brigham and Women's Hospital and Harvard Medical School, Boston, MA

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Abstracts: Health Services Research (0462–0465)
Session Type: Abstract Session
Session Time: 10:30AM–11:30AM

Background/Purpose: Recent exploratory clinical trial and retrospective studies[1] suggest that patients with seropositive RA (rheumatoid factor [RF]+ and/or anti-cyclic citrullinated peptide [anti-CCP]+) treated with abatacept experience increased clinical efficacy compared to those treated with other biologic or targeted synthetic (b/ts) DMARDs. This biomarker-defined patient group may also demonstrate increased treatment durability. The objective of this study was to describe treatment persistence to abatacept and 2 comparison treatment groups (tumor necrosis factor inhibitors [TNFi] and Janus kinase inhibitors [JAKi]) among Medicare patients with seropositive RA.

Figure 1. Time to Treatment Discontinuation

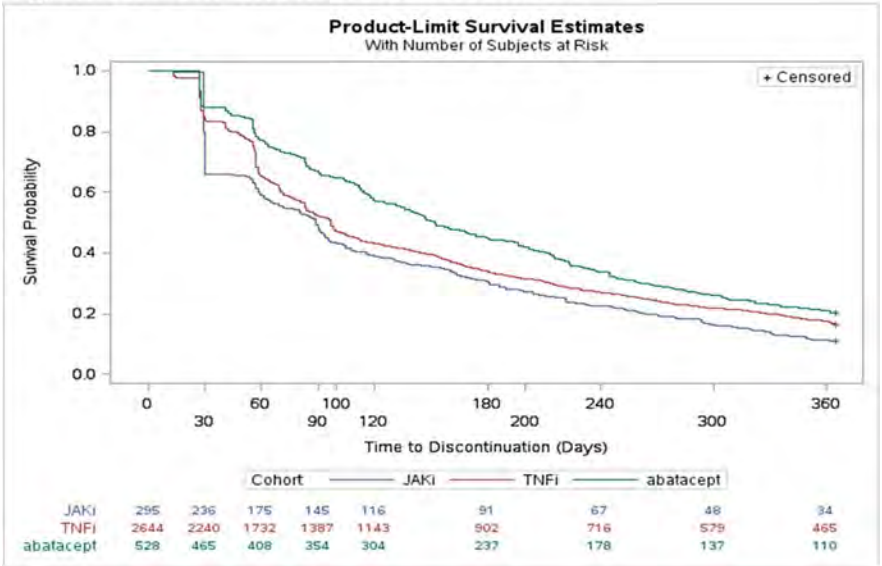

Table 1. Cox Proportional Hazards Model for Time to Treatment Discontinuation

Covariate	DF	Coefficient	SE	P-value	HR	95% CI	
						Lower	Upper
Abatacept vs. TNFi	1	0.183	0.049	0.000	1.201	1.091	1.322
Abatacept vs. JAKi	1	0.309	0.075	0.000	1.362	1.175	1.578

SE = standard error; HR = hazard ratio; CI = confidence interval; TNFi = tumor necrosis factor inhibitors; JAKi = Janus kinase inhibitors

Covariates also included age, gender, race/ethnicity, region, dual Medicare/Medicaid eligibility, low income subsidy status, baseline Charlson Comorbidity Index score, glucocorticoid use at baseline, serious infection at baseline, prior csDMARD at baseline, and prior biologic use at baseline

Methods: This retrospective cohort study utilized 100% Medicare Fee-for-Service Parts A/B/D claims linked to Prognos laboratory data January 1, 2012-December 31, 2019. Patients included had ≥2 claims in any setting, on separate days, ≥7 days apart, with an ICD-9-CM or ICD-10-CM diagnosis code for RA and RF+ and anti-CCP+ test results. The index date was the date of RA treatment initiation. Patients were placed into 3 mutually exclusive treatment groups based on index treatment: 1) abatacept, 2) a TNFi, or 3) a JAKi. Other treatment classes were excluded due to low sample size. Patients were required to have 1 year of continuous pre- and post-index enrollment. Baseline demographic and clinical characteristics were reported and persistence during follow up was evaluated. Treatment persistence was calculated for each patient from the index date until the earliest of treatment gap >15 days, switch in therapy, or end of follow up. Risk of time to treatment discontinuation over 1 year by index treatment was estimated using Kaplan Meier curves and Cox proportional hazard model, adjusting for baseline patient characteristics.

Results: A total of 3,468 seropositive RA patients (abatacept: 528 [15.2%]; TNFi: 2,654 [76.5%); JAKi: 295 [8.5%]) were included in the study sample. The population had mean (SD) age of 66.4 (10.0) years, was 78.3% female, and 73.9% White. Approximately 90% of patients were biologic naïve prior to index. Within each index treatment group, 21.4%, 18.2%, and 12.5% of patients utilizing abatacept, TNFi, and JAKi, respectively, had persistence to the index medication for 1 year. After drug initiation, patients spent a median (IQR) of 269 (140-332) days on abatacept, 206 (111-322) days on a TNFi, and 218 (90-316) days on a JAKi. Patients on abatacept had longer time to treatment discontinuation (median 152 days) compared to patients on TNFi (97) and JAKi (89), before adjustment (Figure 1) and after adjustment (HR vs. TNFi: 1.3; 95% CI: 1.1–1.4; HR vs. JAKi: 1.4; 95% CI: 1.2–1.7; Table 1).

Conclusion: Among Medicare beneficiaries with seropositive RA, those on abatacept were more often persistent to their index treatment and had longer time to treatment discontinuation at 1 year compared to patients on TNFi or JAKi which may be reflective of treatment efficacy.

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Abstracts: Health Services Research (0462–0465)

Session Type: Abstract Session

Session Time: 10:30AM–11:30AM

Background/Purpose: Systemic lupus erythematosus (SLE) has the 6th highest hospital readmission rate of all US chronic diseases with significant health disparities and costs. Transitional care management with higher reimbursement for post-discharge care within 14 days has been shown to decrease 30-day hospital readmissions in other chronic diseases. However, the impact of timely follow-up care (within 14 days) on readmission has not been evaluated among SLE patients. Our objectives were to (1) examine predictors of timely post-discharge follow-up and (2) compare all-cause 30-day readmissions after hospitalization with and without timely ambulatory follow-up among SLE patients.

Methods: We conducted a retrospective cohort study using a 20% random sample of all US Medicare hospitalizations in 2014. Hospitalized patients in the study had an SLE diagnosis code, age ≥18 years, alive at discharge, discharged to home, and not receiving hospice. Baseline characteristics of patients with inpatient stays with and without follow-up with a primary care provider or rheumatologist within 14 days of index hospital discharge were compared. Multivariate general estimating equation (GEE) models clustered by patient were used to determine the predictors and the effects of timely follow-up on 30-day rehospitalization risk.

Results: Compared to SLE admissions with timely (within 14 days) post-hospitalization follow-up (n=3118, 36%), those without timely follow-up (n=5530, 64%) were more likely to be younger, non-White, and living in the most disadvantaged neighborhoods (Table 1). Patients without timely follow-up were more likely to have comorbidities such as renal failure, depression, and tobacco, drug, or opioid use disorders. Observed thirty-day readmission rates were higher among those without timely follow-up (26% vs 20%), and only 11% of follow-up within 14 days was with rheumatology. Young adults had 10% lower timely follow-up (27 vs 37%) and 15% higher readmissions (37 vs 22%; Tables 2 & 3). Multivariable predictors of timely follow-up showed higher odds per year of age (aOR 1.01 (1.01,1.02); Table 2), but lower odds for those with renal failure (aOR 0.74 (0.65,0.84)), and those residing in the most disadvantaged neighborhoods (aOR 0.87 (0.76,0.99)) and rural areas (aOR 0.72 (0.58,0.88)). Timely post-discharge follow-up predicted 21% lower odds of readmission (aOR 0.79 (0.70,0.89); Table 3). Unlike younger age, race/ethnicity, rurality, and neighborhood disadvantage did not predict readmission risk after considering timely follow-up.

Conclusion: Hospitalized Medicare beneficiaries with SLE were 20% less likely to be readmitted within 30 days if they received post discharge follow-up within 14 days with either rheumatology or primary care, even after adjusting for comorbidities. Adjusted risk factors for lack of timely follow-up care included younger age, living in the most disadvantaged neighborhoods or in a rural area, and renal failure. To overcome limitations in this study our next analysis will explore whether immortal time bias influences outcomes. Other future studies should investigate targeted interventions to increase timely post-discharge follow-up care to reduce SLE readmissions and health disparities.

Cost-effectiveness of Treatment Strategies Involving Arthroscopic Partial Meniscectomy and Physical Therapy for Degenerative Meniscal Tear

Emma Williams[1], Valia Leifer[1], Jamie Collins[2], Tuhina Neogi[3], Lisa Suter[4], Jeffrey Katz[5] and Elena Losina[2], [1]The Orthopaedic and Arthritis Center for Outcomes Research (OrACORe) at Brigham and Women's Hospital, Boston, MA, [2]Brigham and Women's Hospital, Boston, MA, [3]Boston University School of Medicine, Boston, MA, [4]Yale School of Medicine, New Haven, CT, [5]Brigham and Women's Hospital, Brookline, MA

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Abstracts: Health Services Research (0462–0465)

Session Type: Abstract Session

Session Time: 10:30AM–11:30AM

Background/Purpose: Knee osteoarthritis (KOA) and meniscal tear (MT) are highly prevalent and often concomitant. Treatments for MT in the presence of KOA include physical therapy (PT; non-surgical) and arthroscopic partial meniscectomy (APM; surgical). Several randomized controlled trials (RCTs) suggest APM yields similar or only slightly better outcomes than PT for MT patients, but many of these trials have ~30% crossover from PT to APM, limiting their ability to isolate treatment benefits. Whether APM is cost-effective for those with KOA and MT has received little study.

Methods: We evaluated quality-adjusted life-years (QALYs), cumulative medical costs over five and 10 years, and incremental cost-effectiveness ratios (ICERs) of three treatment strategies: (1) PT Only, (2) PT + Optional APM, for those whose pain persists after a 3-month PT program, and (3) APM Only. Subjects whose pain persisted were offered total knee replacement (TKR) as a final treatment. We used the OAPol Model, a validated Monte Carlo state-transition simulation of KOA. We used a cohort with baseline KOA, MT, and demographics derived from the Meniscal Tear in Osteoarthritis Research (MeTeOR) RCT of APM vs. PT (mean age: 58; KOOS pain: 47 (0-100); KL1: 45%, KL2: 26%, KL3: 29%). We used previously published estimates of quality-of-life utilities and background medical costs based on pain, comorbidities, age, and BMI. Using published data, we estimated the risks and costs of APM complications and modeled KOA progression, with heightened progression among subjects treated with APM (relative risk: 1.62). We used MeTeOR data to estimate mean reductions in pain for subjects with low or high baseline pain (PT, low pain: 8 points; PT, high pain: 17; APM, low pain: 15; APM, high pain: 30), treatment costs (PT: $804; APM: $4,301), and utilization rates of Optional APM over one year (35%) and TKR over five years (2% for subjects treated non-surgically; 10% for those treated surgically). In sensitivity analyses we varied: indirect costs from productivity losses, Optional APM and TKR uptake rates, baseline pain, relative risk of KOA progression post-APM, duration of crossover period when subjects who failed PT are eligible for Optional APM, and efficacy of Optional APM. We discounted costs and QALYs at 3%/year and calculated ICERs as ratios of change in medical costs (2019 USD) to change in QALYs between strategies.

Table. Cost-effectiveness of treatment strategies involving APM and PT in patients with KOA and MT over a five-year time frame

Strategy	Cost	QALY	ICER
PT Only	$31,279	3.4044	--
PT + Optional APM	$33,280	3.4694	$30,800/QALY
APM Only	$36,351	3.4760	$465,300/QALY

Results: Relative to PT Only, PT + Optional APM added 0.065 QALYs and $2,001 in costs over five years (ICER: $30,800/QALY). Relative to PT + Optional APM, APM Only added 0.0066 QALYs and $3,071 (ICER: $465,300/QALY). The 10-year analysis produced similar ICERs. Results were sensitive to reducing the efficacy of APM in the PT + Optional APM strategy compared to the APM Only strategy.

Conclusion: At a willingness-to-pay threshold of $50,000/QALY, PT followed by APM, if pain persists post-PT, is a cost-effective treatment for those with KOA and MT. Immediate APM is not cost-effective. These findings are robust despite base case assumptions that favor non-surgical approaches but are sensitive to reductions in Optional APM efficacy.

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Abstracts: Imaging of Rheumatic Diseases (0466–0469)
Session Type: Abstract Session
Session Time: 10:30AM–11:30AM

Background/Purpose: Polymyalgia rheumatica (PMR) and giant cell arteritis (GCA) are closely related diseases. PMR occurs in approximately 50 % of GCA patients[1], however the frequency of subclinical GCA in PMR has not been widely studied. Furthermore risk factors for the clinical expression of GCA in PMR have not been clearly established. The aim of our multicenter, prospective study was to determine the prevalence of subclinical GCA in newly diagnosed PMR, using vascular ultrasound (US) as a diagnostic modality.

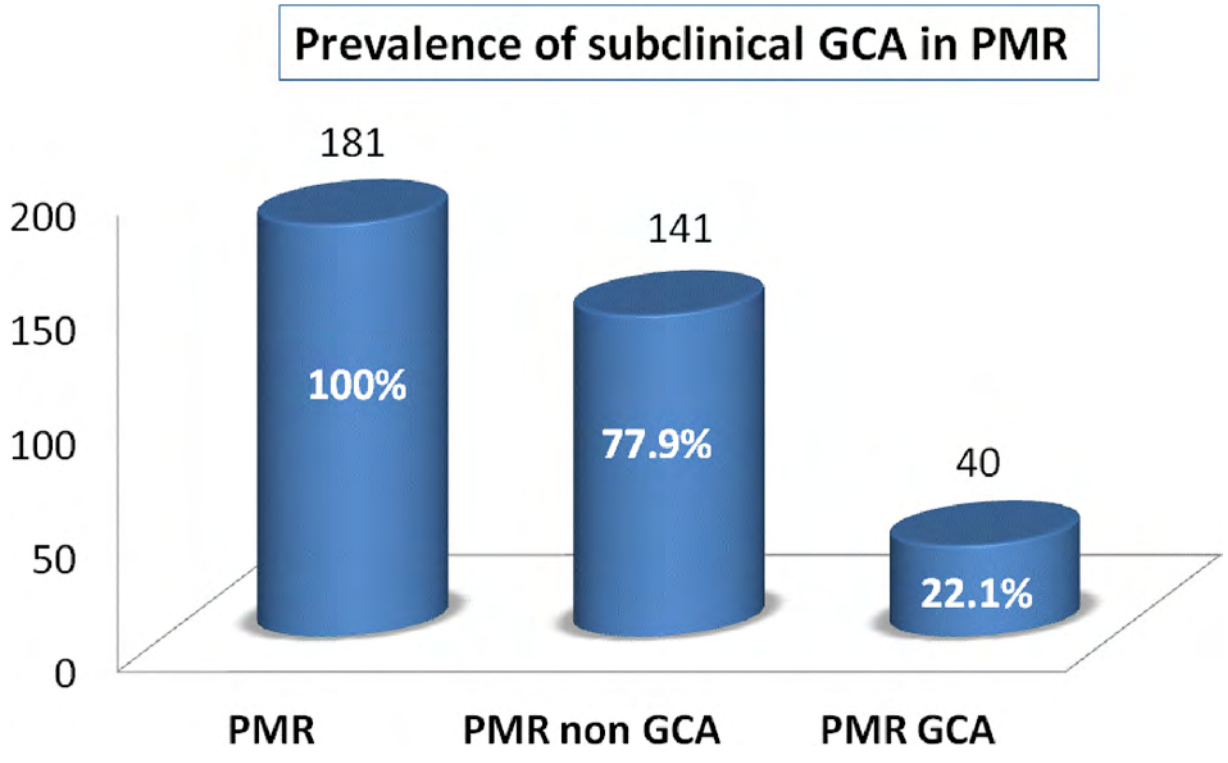
Methods: Six rheumatology centers participated in the study. The studied cohort represented consecutive newly diagnosed PMR patients who fulfilled 2012 EULAR/ACR Provisional Classification Criteria for Polymyalgia Rheumatica[2] and had no symptoms or signs suggestive for GCA. Besides hip and shoulder ultrasound all studied patients underwent detailed US examination of 5 vessel territories, bilaterally (i.e. temporal, carotid, subclavian, axillary and femoral arteries). The halo sing was considered as positive US finding[3]. In addition intima-media thickness of arteries was measured, with a cut-off of 0.34 mm for temporal arteries (TA) frontal and parietal, 0.42mm for common TA, and 1 mm for common carotid, axillary and subclavian arteries for positive result. Clinical characteristics of PMR patients were recorded and the frequency of subclinical GCA determined.

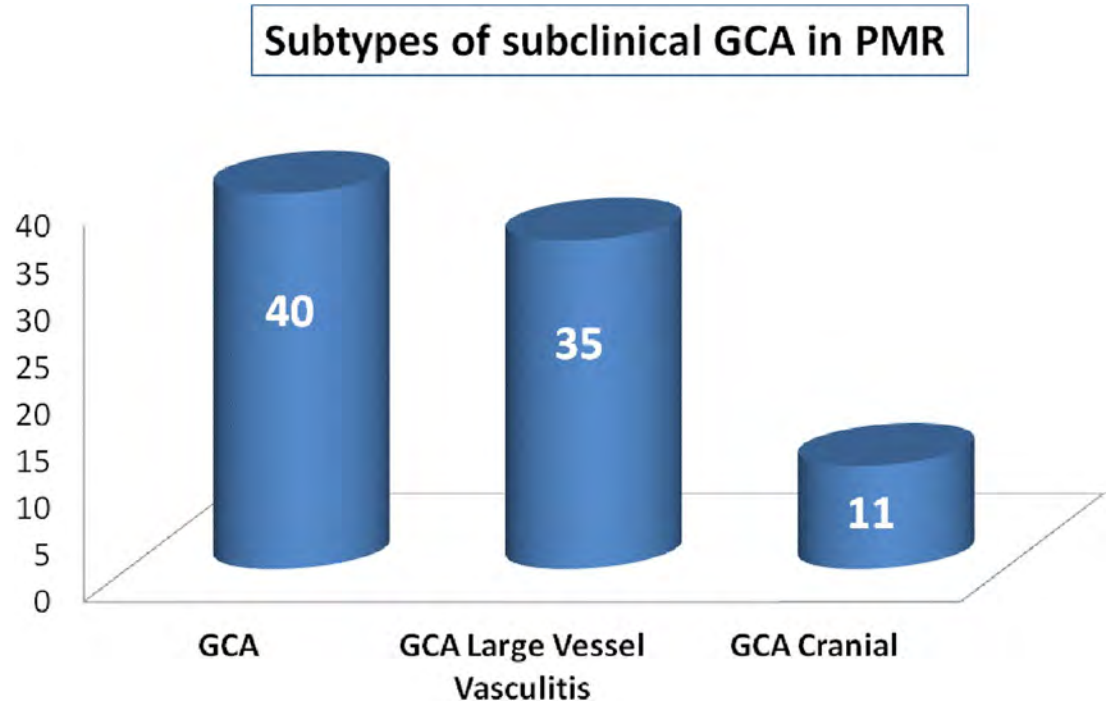
Results: US examinations were performed in 181 patients, 97 (53.6%) females with a mean age of 72.63±7.99 years. A halo sign was found on at least one of the examined arteries in 40 patients (22.1%). Cranial artery involvement was found in 11/120 patients, and 35/181 patients (19.3%) had extracranial large artery involvement (Figure 1 and 2). Table 1 shows the characteristics of studied population. Except of patient age that was significantly higher in PMR with GCA, there were no other specific PMR signs or symptoms predictive for subclinical US proven vasculitis.

Clinical and demographic characteristics

	PMR study n=181	PMR without GCA n=141	PMR with GCA n=40
Age (mean±SD)*	72.63±7.99	71.82±7.94	75.63±7.03
Sex (female/male)	97/84	74/67	23/17
Shoulder pain	173	135 (95.7%)	38 (95.0%)
Hip pain	145	113 (80.1%)	32 (80.0%)
Neck pain	99	76 (53.9%)	23 (57.5%)
Morning stiffness	153	122 (86.5%)	31 (77.5%)
Weight loss	43	34 (24.1)	9 (22.5%)
Fever	20	17 (12.1%)	3 (7.5%)
Peripheral arthritis	42	36 (25.5%)	8 (20%)
Pitting edema	22	18 (12.8%)	4 (10%)
Headache	20	13 (9.2%)	7 ((17.5%)
Duration symptoms (weeks)	8.82±6.76	8.70±6.91	9.37±6.07
CRP mg/l	55.62±45.77	58.00±47.64	43.85±33.57
ESR mm/h	59±27	59 ±28	61±27

PMR= Polymyalgia rheumatica; GCA= giant cell arteritis; SD= standard deviation.
*p<0.01 between PMR with and without GCA





Conclusion: The prevalence of subclinical GCA in patients with PMR was 22.1%. Increasing age emerged as a risk factor for subclinical GCA .

Abstract Number: 0467

Assessing the Extent of Lumbosacral Spinal Urate Deposition in Patients with Tophaceous and Nontophaceous Gout Compared with Non-gout Controls Using Dual-Energy CT (DECT)

Michael Toprover[1], Michael Mechlin[1], Anastasia Slobodnick[1], Virginia Pike[1], Cheongeun Oh[1], Claudine Davis[1], Theodore Fields[2], Fabio Becce[3] and Michael Pillinger[4], [1]NYU Langone Health, New York, NY, [2]Hospital for Special Surgery, New York, NY, [3]Lausanne University Hospital, Lausanne, Switzerland, [4]New York University Grossman School of Medicine, New York, NY

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Abstracts: Imaging of Rheumatic Diseases (0466–0469)
Session Type: Abstract Session
Session Time: 10:30AM–11:30AM

Background/Purpose: Axial gout involvement was first reported in 1950 (1). Over 100 cases have subsequently been published. Reported cases have presented as acute back pain, cord compression, and/or neurologic symptoms, with diagnosis made by invasive procedure (surgical excision or biopsy). However, the true extent of MSU deposition in the spine of gout patients, including asymptomatic patients or those with non-specific symptoms, is unknown and likely higher. *We used DECT to determine the extent of MSU deposition in the lumbosacral spines of patients with gout, with and without tophi, compared to controls without gout*.

Methods: We recruited controls, nontophaceous, and tophaceous gout patients, age 45-80. Individuals with CPPD disease, RA, spondyloarthropathy, active spinal malignancy, or on urate lowering treatment (ULT) ≥ 6 months were excluded. Gout subjects met 2015 ACR gout classification criteria, with entry serum urate (sU) of >6.8 mg/dL (>6.0 mg/dL if on ULT for < 6 months). Demographics, gout history, Aberdeen back pain scale, sU, ESR, and CRP were collected. Subjects underwent DECT of the lumbosacral spine (LS) to assess for MSU deposition.

Results: 75 subjects were enrolled, and 72 completed the study (1 nontophaceous gout patient lost to follow-up prior to DECT, 2 tophaceous excluded after sU at time of DECT found to be < 6.0mg/dL). All groups were similar in age in years (controls 61.8±3.8, nontophaceous 64.0±6.1, tophaceous 60.4±11.0, p=0.81) but differed in BMI (controls 28.3±6.5 kg/m^2, nontophaceous 34.1±7.2 kg/m^2, tophaceous 29.5±4.5 kg/m^2, p=0.03) and creatinine (controls 1.0±0.2 mg/dL, nontophaceous 1.4±0.7 mg/dL, tophaceous 1.4±0.6 mg/dL, p< 0.05). Mean sU and ESR were higher in gout subjects (sU-controls 5.3±1 mg/dL, nontophaceous 8.5±1.7 mg/dL, tophaceous 8.5±1.6 mg/dL, p< 0.05; ESR-controls 13.7±13.8 mm/h, nontophaceous 26.5±19.4 mm/h, tophaceous 25.1±15.7 mm/h, p< 0.05). Using standard DECT settings for MSU visualization, gout patients had larger MSU volumes than controls (controls 2.2±1.2 cm^3, all gout 5.23±6.9 cm^3; p =0.03). Tophaceous patients had numerically greater MSU deposition compared with nontophaceous (6.0±8.9 cm^{3,} vs 4.4±4.3 cm^3, ns). Reanalysis of a subset of scans using highly specific settings to eliminate artifact reduced the number of subjects with MSU signal but confirmed greater prevalence of deposition among gout patients (n=29; controls with deposition 0/9, nontophaceous with deposition 1/11, tophaceous with deposition 2/9). Back pain was also more common among gout patients. No subject had frank tophi on spinal DECT.

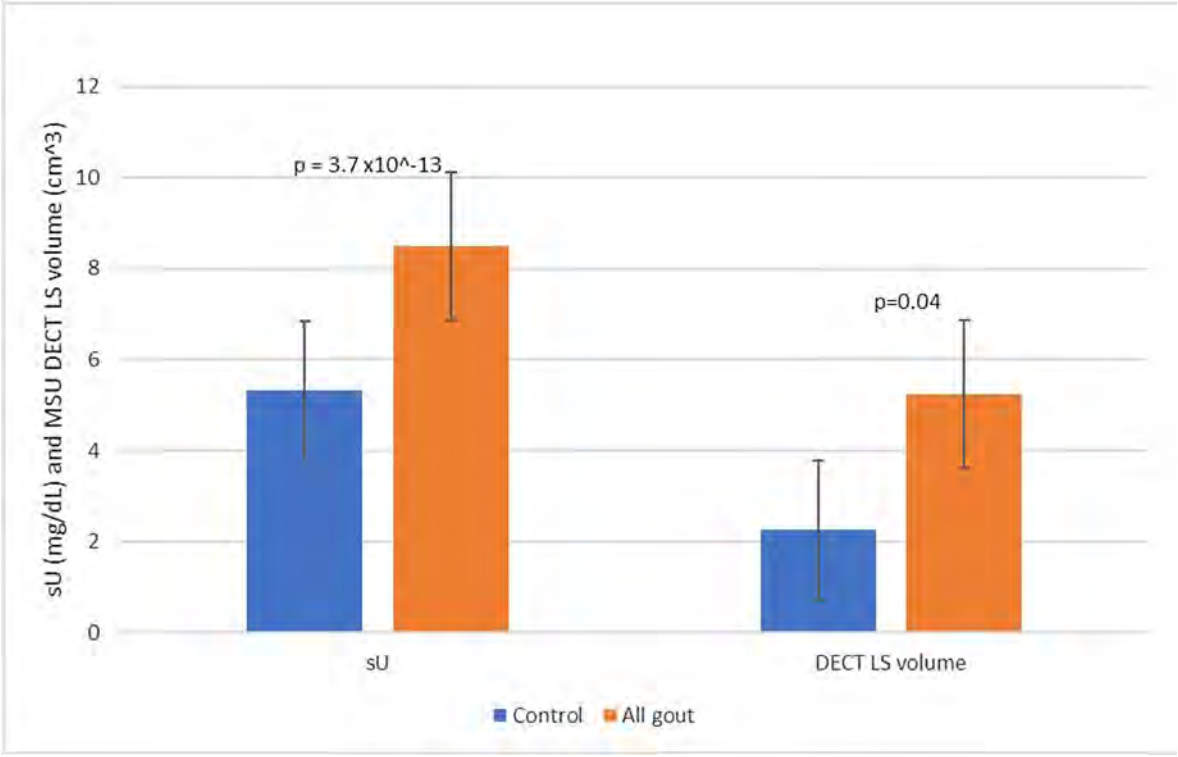

Figure 1. Mean sU and DECT LS volume (control vs all gout).

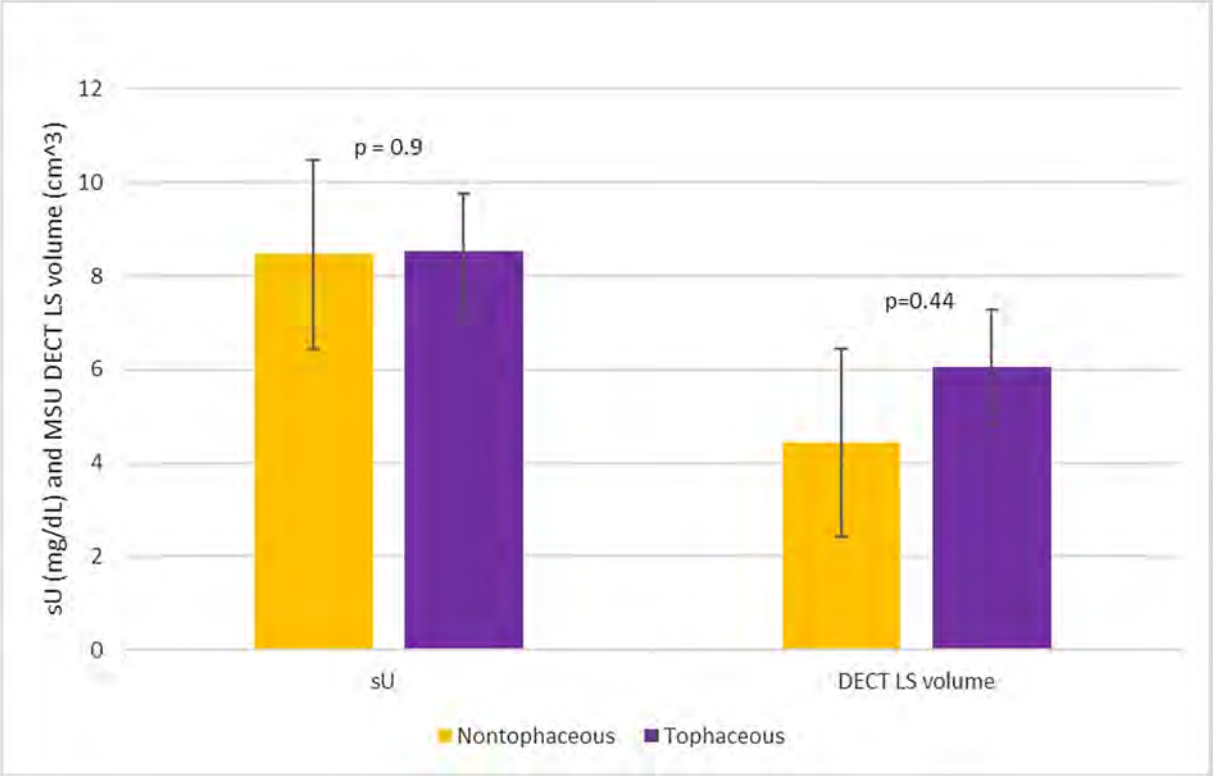

Figure 2. Mean sU and DECT LS volume (nontophaceous gout vs tophaceous gout).

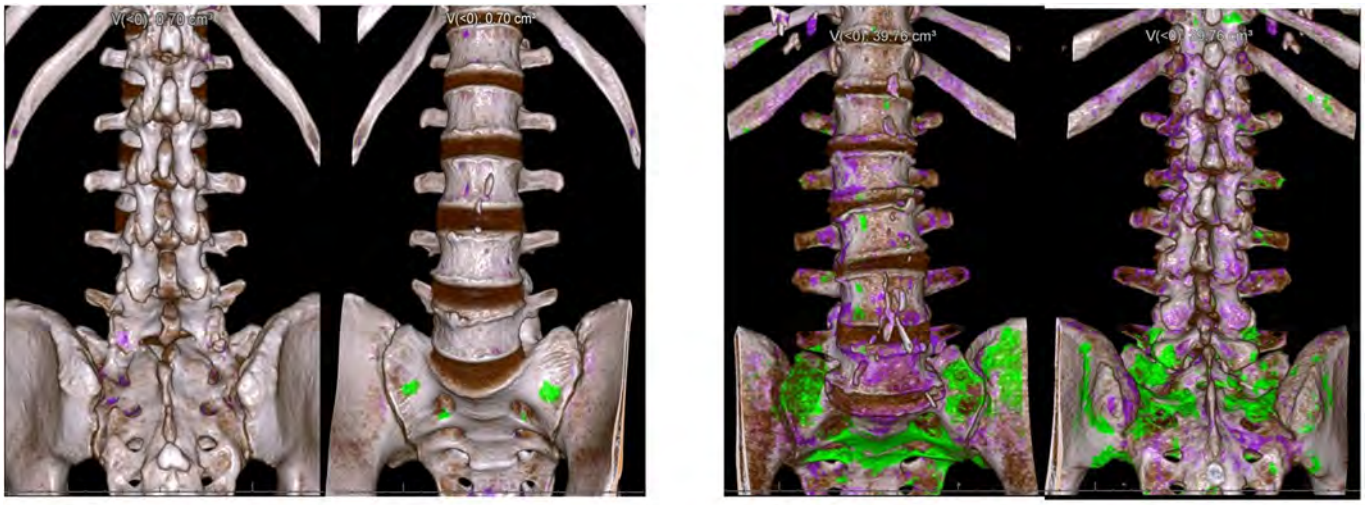

Figure 3. Comparison of Control vs Tophaceous Gout Patient LS DECT, green represents MSU deposition.

Conclusion: Gout patients have significantly greater intercritical inflammation and LS MSU deposition than controls, and trend toward greater deposition among patients with tophi. Preliminary results using the most stringent DECT threshold settings suggests MSU differences are not artifact. The complete data set is currently undergoing evaluation and the full results will be presented.

During Development of Rheumatoid Arthritis, Intermetatarsal Bursitis May Occur Before Clinical Joint Swelling: A Large MRI Study in Patients with Clinically Suspect Arthralgia

Bastiaan van Dijk[1], Fenne Wouters[1], Elise van Mulligen[2], Monique Reijnierse[1] and Annette H.M van der Helm-van Mil[1], [1]Leiden University Medical Center, Leiden, Netherlands, [2]Erasmus Medical Center, Rotterdam, Netherlands

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Abstracts: Imaging of Rheumatic Diseases (0466–0469)
Session Type: Abstract Session
Session Time: 10:30AM–11:30AM

Background/Purpose: Inflammation of the synovial lining is a hallmark of rheumatoid arthritis (RA). A synovial lining is not only present at synovial joints and tendon sheaths but also at bursae. Inflammation of the synovium-lined intermetatarsal bursae in the forefoot, intermetatarsal bursitis (IMB), was recently identified with MRI. It is specific for early RA and present in 69% of RA patients at diagnosis. During development of RA, MRI-detectable subclinical synovitis and tenosynovitis often occur before clinical arthritis presents. Whether IMB is also present in a pre-arthritis stage is unknown. Therefore, a large MRI-study in patients with clinically suspect arthralgia (CSA) was performed to assess the occurrence of IMB and its association with progression to clinical arthritis.

Methods: We studied 577 consecutive patients presenting with CSA. CSA was defined as recent-onset arthralgia of small joints that is likely to progress to RA based on the clinical expertise of the rheumatologist. Participants underwent unilateral contrast-enhanced 1.5T MRI of the forefoot, metacarpophalangeal (MCP) joints and wrist at baseline. Thereafter patients were followed for detection of clinical arthritis, as identified at physical joint examination by the rheumatologist. Baseline MRIs were evaluated for IMB-presence and -size in dorsoplantar direction at all 4 intermetatarsal spaces. Also synovitis, tenosynovitis and osteitis were assessed in line with the RA MRI scoring system (summed as RAMRIS-inflammation). IMB and RAMRIS-inflammation features were considered positive if uncommon in the general population (i.e. scored above the 95th-percentile of age-matched symptom-free controls). Cox regression analysed the association of IMB with progression to clinical arthritis; multivariable analyses adjusted for RAMRIS-inflammation which is known to associate with progression to clinical arthritis. Analyses were repeated stratified for ACPA-status, since ACPA-positive and ACPA-negative RA harbor differences in pathophysiology.

Results: 23% of CSA-patients had IMB (i.e., dorsoplantar size above the reference in symptom-free controls). IMB was more frequent in ACPA-positive than ACPA-negative CSA-patients (56% versus 19%, $p< 0.001$). Patients with IMB were more likely to also have subclinical synovitis (OR 2.4 (95%CI 1.2–4.8)) and tenosynovitis (11.5 (5.1–26.2)) on forefoot MRI, but not osteitis (0.8 (0.4–1.7)). Median follow-up was 25 months. Patients with IMB developed clinical arthritis more

often than patients without IMB (HR 3.3 (2.1-5.1)). This association was independent of synovitis-, tenosynovitis- and osteitis-presence at the forefoot, MCPs or wrist (adjusted HR 1.7 (1.03–2.7)). IMB predicted clinical arthritis development in ACPA-positive CSA (adjusted HR 2.2 (1.0–5.0)) but not in ACPA-negative CSA patients (0.8 (0.4–1.6)).

Conclusion: A quarter of CSA patients have IMB, which is frequently accompanied by subclinical synovitis and tenosynovitis. IMB precedes the development of clinical arthritis, and in particular the development of ACPA-positive RA. These results reinforce the notion that not only intra- but also juxta-articular synovial inflammation is involved in the development of RA.

Imaging Characteristics in Patients with Spondyloarthritis Using a Novel Heel Enthesitis Magnetic Resonance Imaging Scoring (HEMRIS) System: Post-hoc Analysis of a Phase 3 Secukinumab Trial

Xenofon Baraliakos[1], Philipp Sewerin[2], Eugenio De Miguel[3], Effie Pournara[4], Christine Kleinmond[5], Ankita Shekhawat[6], Annette Wiedon[7] and Frank Behrens[8], [1]Rheumazentrum Ruhrgebiet Herne, Ruhr-Universität Bochum, Herne, Germany, [2]Department and Hiller Research Unit of Rheumatology, Heinrich Heine University Duesseldorf, Duesseldorf, Germany, [3]Hospital Universitario La Paz, Madrid, Spain, [4]Novartis Pharma AG, Basel, Switzerland, [5]ClinProject GmbH, Eurasburg, Germany, [6]Novartis Healthcare Private Limited, Hyderabad, India, [7]Novartis Pharma GmbH, Nürnberg, Germany, [8]Rheumatology & Fraunhofer Institute for Translational Medicine and Pharmacology ITMP, Fraunhofer Cluster Immune-Mediated Diseases (CIMD), Fraunhofer Cluster Immune-Mediated Diseases (CIMD), Frankfurt/Main, Germany

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Abstracts: Imaging of Rheumatic Diseases (0466–0469)
Session Type: Abstract Session
Session Time: 10:30AM–11:30AM

Background/Purpose: The heel is a frequently affected anatomical site for enthesitis in spondyloarthritis (SpA).[1] Recently, the Outcome Measures in Rheumatology (OMERACT) group developed and validated the Heel Enthesitis MRI Scoring system (HEMRIS) that takes both inflammatory and structural features of enthesitis into account.[2] ACHILLES (NCT02771210) is a prospective randomized controlled trial, investigating both clinical and imaging endpoints in patients (pts) with SpA and heel enthesitis.[3] Here, we report a post hoc analysis applying HEMRIS system in blinded and centrally read MRI data of the heel from the ACHILLES trial (N=204).

Methods: ACHILLES included pts (≥18 years) with active psoriatic arthritis or axial SpA, with clinical and MRI-positive heel enthesitis, refractory to standard treatment (either Non-steroidal anti-inflammatory drugs or Tumor necrosis factor-inhibitors). Pts were randomized to receive s.c. secukinumab (SEC) 150 mg, 300 mg or placebo (PBO) at baseline, Weeks (Wks) 1, 2, 3, and 4, followed by once every 4 wks. At Wk 24, pts on PBO were switched to SEC 150 or 300 mg. MRI-positive heel enthesitis was confirmed in all pts by local investigators and was defined as tendinitis and/or bone marrow edema (BME) in the area of the Achilles' tendon and/or the plantar aponeurosis. MRIs were performed at three time points: screening (SCR), Wks 24, and 52. In the present analysis, all MRIs were re-evaluated by two blinded central readers in a consensus read fashion for a priori defined MRI parameters based on HEMRIS system.

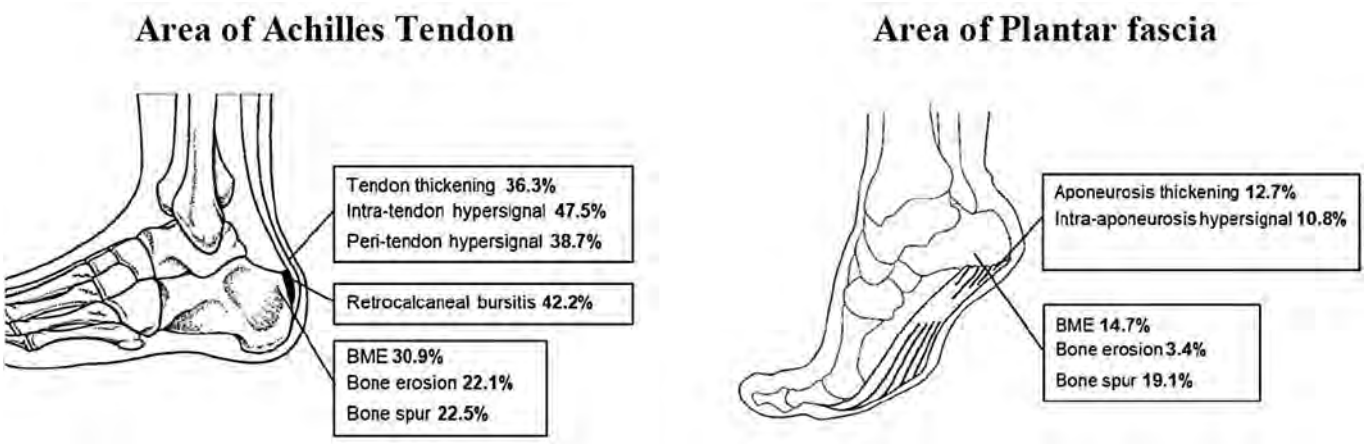

Figure. Inflammatory and structural pathologies at screening.

Results: Structural and inflammatory parameters at SCR are shown in **Figure**. At SCR, 156/204 (76.5%) pts presented with total entheseal inflammation score >0, 131/204 (64.2%) with total structural damage score >0, and 171/204 (83.8 %) with any entheseal inflammation and/or structural damage, considering both Achilles tendon and plantar fascia. The mean total entheseal inflammation score at SCR was 3.58 (N=204) and the mean change (SD) from SCR to Wk 24 and to Wk 52 was -1.05 (2.11) and -1.26 (2.28) in the SEC group vs -0.74 (2.21) and -1.17 (2.73) in the placebo group, respectively. The mean total structural damage score at SCR was 1.85 (N=204) and the mean change (SD) from SCR to Wk 24 and to Wk 52 was -0.01 (0.71) and -0.09 (0.66) in the SEC group vs 0.12 (0.56) and 0.06 (0.83) in the PBO-SEC group, respectively. Mean scores at SCR and mean change over time for individual parameters are given in **Table 1 and Table 2**, respectively.

Table 1. Inflammatory and structural pathologies – Mean score at screening

Mean score (SD)	Secukinumab N = 102	Placebo N = 102
Intra-tendon/aponeurosis hypersignal	0.90 (1.09)	0.96 (1.18)
Peri-tendon/aponeurosis hypersignal	0.86 (1.13)	0.96 (1.27)
Retro calcaneal bursitis at Achilles tendon	0.90 (1.19)	0.84 (1.14)
BME	0.92 (1.38)	0.80 (1.26)
Tendon/aponeurosis thickening	0.85 (1.16)	0.89 (1.13)
Bone erosion	0.37 (0.70)	0.25 (0.57)
Bone spur	0.70 (1.19)	0.63 (1.19)
Data presented are as observed. Pathologies reported for the area of Achilles tendon and plantar fascia, except bursitis (Achilles tendon only). N represents number of patients included in the analysis at screening.		

Table 2. Inflammatory and structural pathologies – Mean change from screening to Wk 24

Mean change (SD); 95% CI	Secukinumab N = 91	Placebo N = 90
Intra-tendon/aponeurosis hypersignal	–0.12 (–0.03); –0.11, –0.13	–0.20 (–0.17); –0.16, –0.24
Peri-tendon/aponeurosis hypersignal	–0.32 (–0.27); –0.26, –0.37	–0.19 (–0.20); –0.15, –0.23
Retro calcaneal bursitis at Achilles tendon	–0.35 (–0.22); –0.31, –0.40	–0.08 (–0.16); –0.04, –0.11
BME	–0.26 (–0.26); –0.21, –0.32	–0.28 (–0.16); –0.24, –0.31
Tendon/aponeurosis thickening	–0.01 (–0.01); –0.01, –0.01	0.02 (–0.01); 0.02, 0.02
Bone erosion	–0.02 (0); –0.02, –0.02	0.08 (0.10); 0.06, 0.10
Bone spur	0.02 (0.04); 0.01, 0.03	0.02 (–0.01); 0.02, 0.02
Data presented are as observed. Pathologies reported for the area of Achilles tendon and plantar fascia, except bursitis (Achilles tendon only). N represents number of patients included in the analysis at Wk 24.		

Conclusion: Based on the newly developed HEMRIS system, entheseal inflammation and/or structural damage was not confirmed for 16.2% of pts with SpA enrolled in the ACHILLES trial. The mean improvements in total inflammation and total structural damage scores were higher in the SEC-treated pts compared to placebo. The observed magnitude of improvement for the SEC-treated pts was more pronounced for the peri-tendon/aponeurosis hypersignal, bursitis and bone erosion.

Abstract Number: 0470

Inhibition of Toll-Like Receptor 7 (TLR7) with the Potent and Selective Inhibitor of Human TLR7 and TLR8 BMS-986256 Provides Robust Efficacy in Murine Lupus Models, Reversing Established Disease

Shailesh Dudhgaonkar[1], Anjuman Rudra[1], Sourabh Ranade[1], Siva Subramani[1], Jignesh Nagar[1], Preethi Karunanithi[1], Priyadeep Bhutani[1], Vishwanath Kurawattimath[1], Rosemary Zhang[2], Hongchen Qiu[2], ALARIC DYCKMAN[2] and Gary Schieven[2], [1]Biocon Bristol Myers Squibb Research Center, Bangalore, India, [2]Bristol Myers Squibb, Lawrenceville, NJ

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Abstracts: SLE – Animal Models (0470–0473)
Session Type: Abstract Session
Session Time: 11:00AM–12:00PM

Background/Purpose: TLR7, a member of the Toll-Like Receptor family, recognizes ssRNA and is primarily expressed in plasmacytoid dendritic cells and B cells. TLR7 has been implicated in systemic lupus erythematosus (SLE) in knockout mouse studies, but effects of inhibition at disease onset or in established disease are not well understood. Mouse TLR7 carries out human TLR7 functions, whereas mouse TLR8 does not carry out human TLR8 responses. BMS-986256 is a potent and selective inhibitor of TLR7 and TLR8 currently in clinical development for immune-mediated diseases. BMS-986256 has similar human and mouse TLR7 potency and was used in murine lupus models to investigate the role of TLR7 in disease onset and in established disease.

Methods: MRL/lpr mice and NZB/W mice were treated orally, once daily with vehicle or selected doses of BMS-986256 and/or prednisolone after anti-dsDNA antibodies developed but before onset of proteinuria. Alternatively, NZB/W mice were treated therapeutically in established disease (proteinuria at levels of 60–100 mg/dL) or advanced disease (proteinuria >100 mg/dL). Human blood was treated with BMS-986256 and prednisolone, stimulated with the TLR7 agonist gardiquimod or the TLR8 agonist TL8-506, and IL-6 production was measured to determine synergy.

Results: BMS-986256 treatment for 8 weeks in the MRL/lpr model provided robust inhibition of proteinuria onset and inhibition of IgG deposition in the kidney, with inhibition of autoantibody production. BMS-986256 treatment for 24 weeks in the NZB/W model resulted in nearly complete inhibition of proteinuria onset and IgG deposition in the kidney. Treatment of NZB/W mice with proteinuria of 60–100 mg/dL for 14 weeks and mice with proteinuria of >100 mg/dL for 10 weeks resulted in reversal of proteinuria, IgG deposition in the kidney, and kidney tissue damage, while markedly increasing survival in both established and advanced disease models. Production of anti-dsDNA, anti-SmRNP and anti-Ro autoantibody titers and cytokine production were inhibited in preventative, therapeutic and established models. BMS-986256 displayed steroid-sparing activity in all the disease models, when single agent and combination treatments with prednisolone were compared. BMS-986256 acted synergistically with steroid treatment to inhibit TLR7 and 8 responses in human blood.

Conclusion: The potent and selective TLR7/8 inhibitor BMS-986256 displayed robust efficacy in the MRL/lpr and NZB/W models of lupus. Therapeutic treatment with BMS-986256 reversed proteinuria, immune complex deposition, and kidney tissue damage in established and advanced disease NZB/W models. Treatment reduced titers of autoantibodies implicated in lupus as well as cytokine responses. BMS-986256 displayed steroid-sparing activity in the disease models and acted synergistically with steroid treatment in human blood. These results indicate that TLR7 plays an important role in both the initiation and progression of disease and support the potential of BMS-986256 in

the treatment of SLE. Given the robust pharmacological efficacy observed in this study, BMS-986256, currently under investigation in patients with cutaneous lupus (CLE), was advanced to a Phase 2 trial in SLE patients.

Abstract Number: 0471

Therapeutic Efficacy of BT-104, an Oral LANCL2 Agonist, for the Treatment of Systemic Lupus Erythematosus

Andrew Leber, Raquel Hontecillas, Nuria Tubau-Juni, Sarah Fitch, Jyoti Chauhan and Josep Bassaganya-Riera, Landos Biopharma, Blacksburg, VA

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Abstracts: SLE – Animal Models (0470–0473)
Session Type: Abstract Session
Session Time: 11:00AM–12:00PM

Background/Purpose: Systemic lupus erythematosus is a complex disease in which the immune system is dysfunctional at multiple levels including impaired regulatory responses, altered self-antigen processing and increased autoantibody production. LANCL2 is a novel anti-inflammatory target that has been first targeted by a gut-restricted compound, omilancor (BT-11), currently in Phase II/III clinical development for inflammatory bowel diseases. BT-104 functions through similar immunometabolic mechanisms, increasing the suppressive capacity and stability of regulatory CD4+ T cells while also supporting the metabolic demands of autophagy in phagocytes.

Methods: Based on these immunological effects, we evaluated oral BT-104 in three mouse models of lupus: the NZB/W F1 model, the MRL/lpr model and the bm12 adoptive transfer model. Mice were treated daily with oral BT-104 from ages 24 to 36 wk in the NZB/W F1 model, from ages 12 to 18 wk in the MRL/lpr model and from 1 to 2 wk post-transfer in the bm12 model. Therapeutic efficacy was evaluated by proteinuria, anti-nuclear antibody titers, immune cell changes in the blood and spleen, and histological inflammatory changes in the kidney. Further, the MRL/lpr model was used to identify global transcriptional signatures of BT-104 in blood and spleen after oral treatment. The translational efficacy of BT-104 was evaluated in PBMCs from SLE patients *in vitro*.

Results: In the NZB/W F1 and MRL/lpr models, BT-104 protected against worsening from baseline in proteinuria grade in greater than 90% of mice, improved proteinuria grade in roughly half of mice, and reduced anti-nuclear antibody levels by three-fold. BT-104 reduced overall histological score in the kidneys, including improvement in interstitial inflammation, glomerular proliferation, and cellular crescents. Immunologically, across all three models, BT-104 significantly reduced IL17+ and IL21+ CD4+ T cells in the spleen while significantly increasing CD25+ FOXP3+ regulatory CD4+ T cells (Treg). BT-104 significantly reduces the production of interferon alpha in human PBMCs from SLE patients in response to general (PMA and ionomycin), TLR7 (gardiquimod) and CpG oligonucleotide (ODN2395) stimuli.

Conclusion: Based on the preclinical data generated, BT-104 is a promising therapeutic for systemic lupus erythematosus and other rheumatic conditions. BT-104 is expected to enter Phase I clinical testing in normal healthy volunteers in Q4 2021.

An Atlas of Human and Mouse Intrarenal Immune Cells in Lupus Nephritis Reveals Homologous Immune Populations Across Common Mouse Strains and Species

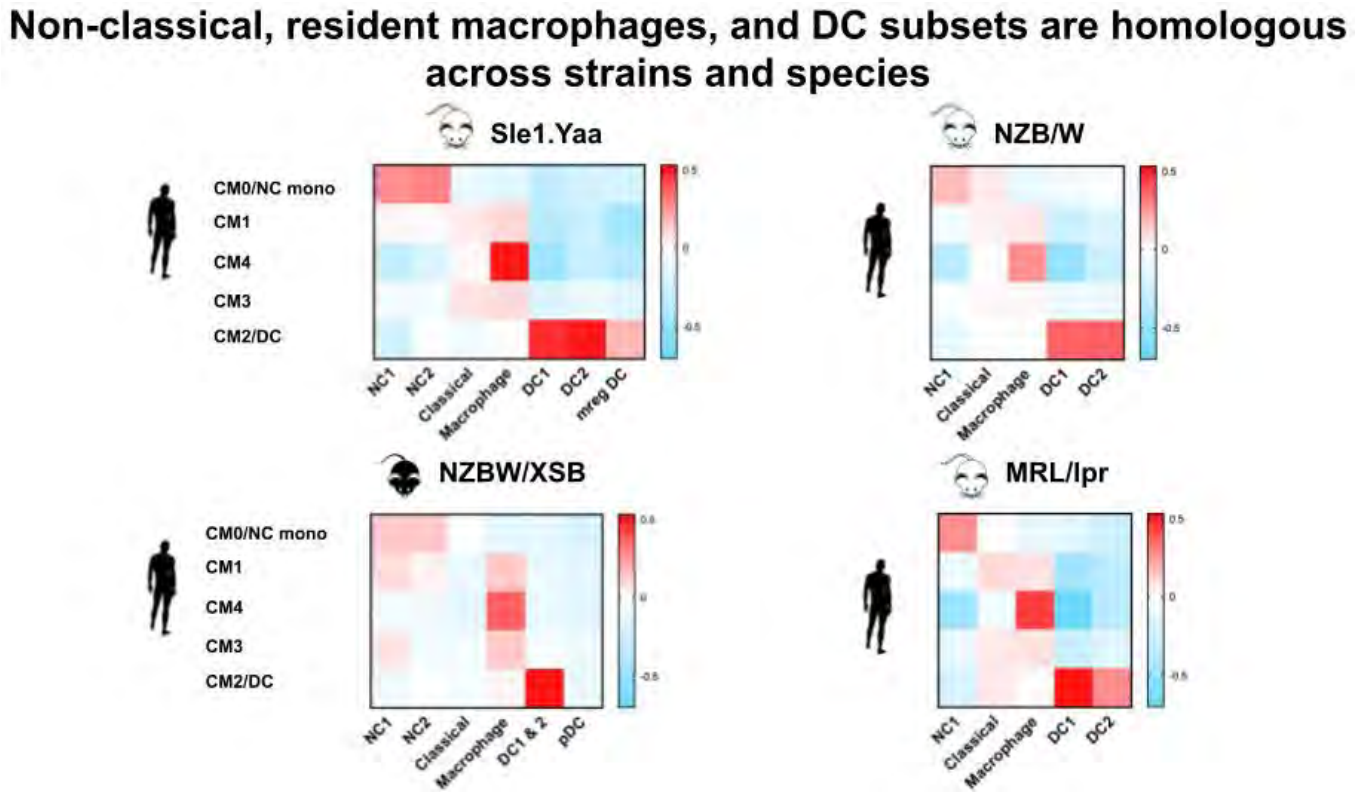
Paul Hoover[1], Michael Peters[2], David Lieb[2], Runci Wang[3], Garett Dunlap[4], Deepak Rao[1], Nir Hacohen[2] and Anne Davidson[5], [1]Brigham and Women's Hospital, Boston, MA, [2]Broad Institute, Cambridge, MA, [3]Brigham and Women's Hospital, Boston, MA, [4]Harvard University, Somerville, MA, [5]Institute of Molecular Medicine, Feinstein Institutes for Medical Research, Manhasset, NY

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Abstracts: SLE – Animal Models (0470–0473)
Session Type: Abstract Session
Session Time: 11:00AM–12:00PM

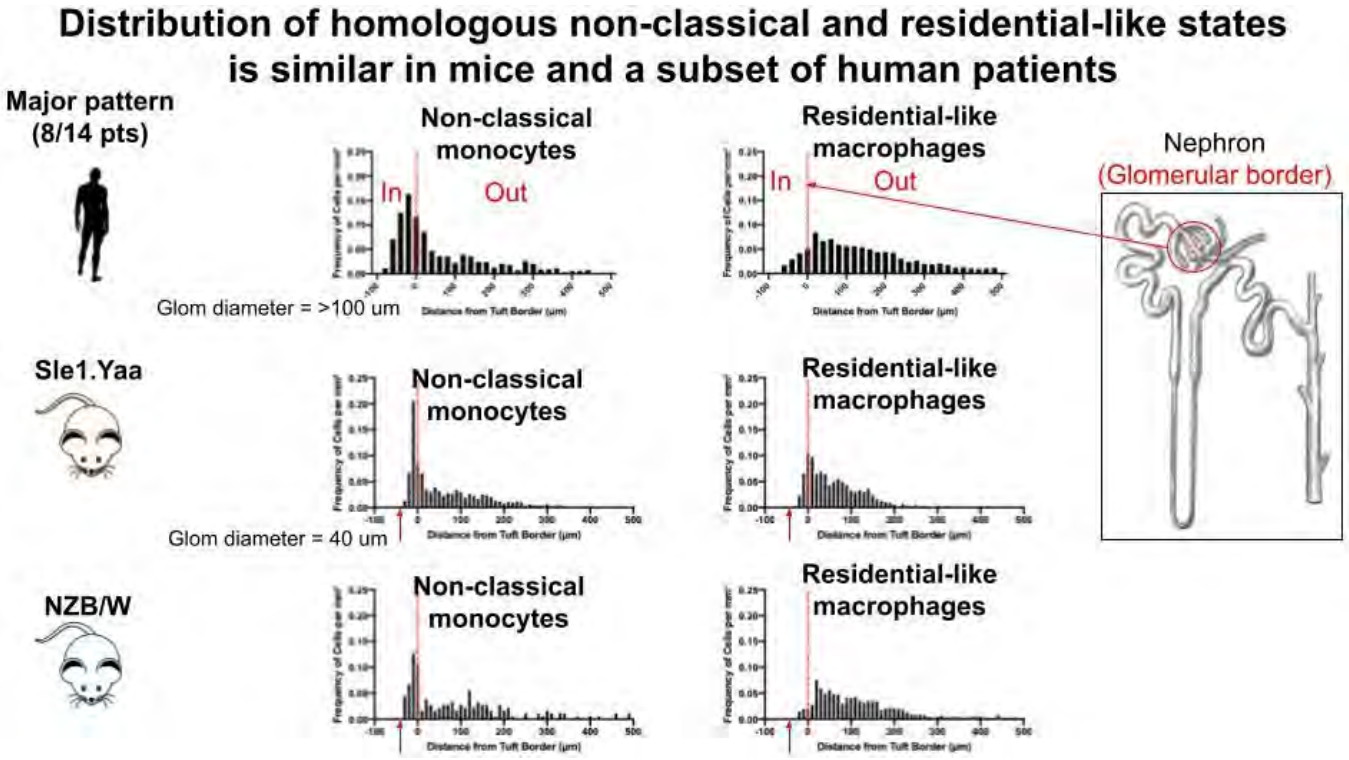
Background/Purpose: We discovered 21 immune cell-types in lupus nephritis kidney biopsies as part of the Accelerating Medicines Partnership (AMP) consortium. These immune cells are the basis of new hypotheses about the drivers of disease. However, we cannot feasibly collect immune cells from human kidney biopsies for mechanistic testing. Mouse lupus models and humans share important clinical features including autoantibody development and kidney injury that progresses to failure. How mice recapitulate human lupus nephritis remains an open question. Here, we used single cell RNA sequencing to identify homologous intrarenal immune cell subsets and conserved gene programs from humans and four common lupus strains.

Methods: Using AMP protocols we sorted CD45+ cells from dissociated mouse kidneys with spontaneous adaptive-driven autoimmunity (NZB/W and MRL/lpr) and TLR7-overexpression innate-driven autoimmunity (Sle1.Yaa and NZW/BXSB) in early and nephritic disease. We profiled single cell transcriptomes using 10x Genomics and analyzed droplets that contained >500 genes and UMIs after doublet removal using Seurat 3.0. We analyzed the top 2000 variable genes for clustering and differential gene expression. We compared transcriptomes of intrarenal immune cells collected from mice at early and peak clinical disease to those from humans at peak clinical disease.

Results: We identified intrarenal myeloid, T-, and B-cell subsets from >75,000 cells passing QC. Many subsets were shared among strains and homologous to human subsets. In particular, the myeloid compartment in mice and humans contained: i) non-classical monocytes that expressed TNF and fate related transcription factors (Spi1, Nr4a1); ii) a novel Fcrl5+ non-classical monocyte unique to TLR7-overexpression strains that emerged in nephritic mouse kidneys and expressed Nr1h3 known to regulate lipids and inflammation; iii) resident-like macrophages that expressed genes for tissue repair (Igf1, Pdgfrb), immunomodulation (Creb5, Dab2), and phagocytosis (Mertk, Gas6); resident-like macrophages in adaptive-driven lupus strains shifted gene expression from anti-fibrotic to remodeling that correlated with proteinuria. We spatially mapped these homologous cells in kidney sections and found they localized to similar compartments in mice and in most human patients.



Conclusion: Most intrarenal myeloid, T-, and B-cell subsets in early and nephritic disease were common to mouse strains; unique subsets correlated with genetic susceptibility. TLR7-overexpression strains contained a novel and unique Fcrl5+ non-classical monocyte. Spontaneous strains contained a population of residential-like macrophages that shifted gene expression from anti-fibrotic to remodeling in nephritic mice. Both non-classical and residential-



like macrophages in mice and humans shared genes critical for tissue repair, immunomodulation, and immune cell recruitment. Further, each of these cell-types localized to similar locations in kidney sections in mice and a subset of human patients. These findings support shared roles of these cells in lupus nephritis. We hope our work opens a new path using mouse models to more precisely study aspects of human disease.

Heatmaps representing how well intrarenal mouse myeloid clusters from each lupus strain expressed gene signatures from human myeloid subsets from lupus nephritis biopsies. The warmer colors represent higher expression of human signatures in corresponding mouse clusters. Mouse NC1 and NC2 (non-classical 1 and 2) highly expressed the signature from human CM0/NC1 (non-classical); mouse macrophage expressed the signature from human CM4; mouse DC1 and DC2 (dendritic cell 1 and 2) expressed the signature from human CM2/DC2.

Homologous subsets were spatially mapped across kidney sections and plotted as function of distance relative to the glomerular border. This location was chosen because significant histopathologic tissue changes occur here that influence disease classification. Homologous human and mouse non-classical monocytes (left panel of histograms) are both enriched inside glomerular structures and form a gradient toward the borders outside the glomerulus. Homologous human and mouse residential-like macrophages (right panel) both localize to the glomerulus to a lesser extent, and form a gradient toward the glomerular edge. This spatial phenotype is conserved in mice and in the majority but not all of the patients we interrogated. Thus, the distribution of these homologous cells is similar in mice and a subset of human patients. These data suggest homologous cells carry out conserved effector functions in the same anatomic compartments in mice and a subset of humans.

Disease-Associated Microglia Are Implicated in Neuropsychiatric Manifestations of Systemic Lupus Erythematosus

Hadijat Makinde[1], Shang-Yang Chen[1], Elise Mike[2], Chaim Putterman[2], Deborah Winter[3] and **Carla Cuda**[1], [1]Northwestern University, Chicago, IL, [2]Albert Einstein College of Medicine, Bronx, NY, [3]Northwestern University Division of Rheumatology, Chicago, IL

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Abstracts: SLE – Animal Models (0470–0473)
Session Type: Abstract Session
Session Time: 11:00AM–12:00PM

Background/Purpose: Systemic lupus erythematosus (SLE) is a complex autoimmune syndrome affecting multiple organs, including the brain. Though 50% of patients may experience neuropsychiatric symptoms (NPSLE), underlying disease mechanisms remain largely unknown. Microglia, the tissue-resident macrophage of the brain, are heterogenous and may be associated with a homeostatic microglia ($CD11c^{lo}$) or disease-associated microglia (DAM; $CD11c^{hi}$) state, a subset common to Alzheimer's disease (AD). In AD, DAM co-localize with amyloid-b (Ab) plaques, are enriched for genes involved in lysosomal, lipid metabolism and phagocytic pathways and may play a protective role in the early stages of AD by reducing Ab plaque burden. Our group was the first to show that expression of DAM-associated genes correlates with the severity of hippocampal- and cerebellar-associated behavioral deficits in microglia isolated from two NP-SLE models prior to overt systemic disease. While DAM have been extensively studied in AD, to date no studies have specifically examined DAM in NPSLE.

Methods: FACS-purified CD45$^{dim/+}$CD11b^{+} cells from whole brain of 11-12-month-old female WT and NPSLE-prone CReCOM mice (n=1) were analyzed by single-cell RNA-seq (scRNA-seq; 10X Genomics 3' v3.0). NPSLE-prone MRL$^{lpr/lpr}$ female mice were intraperitoneally injected at 10 weeks of age with fingolimod, a sphingosine-1-phosphate receptor modulator that reduces microglia activation and improves blood brain barrier integrity, or vehicle control 3 times/week for 4 weeks and underwent behavioral testing. FACSorted bulk CD11c^{lo} homeostatic microglia and DAM were subjected to the Quantseq 3' RNA-seq. GO analysis (GOrilla) of treatment-unique genes determined enriched processes.

Results: SingleR designated microglia from merged scRNA-seq data, with cluster-specific genes identifying DAM and a CD11c^{lo} homeostatic subset in control and CReCOM mice. CReCOM DAM are enriched for genes associated with antigen presentation but depleted for genes associated with phagocytosis, which is in contrast to DAM in AD that are critical for phagocytic functions. Moreover, CReCOM CD11c^{lo} microglia upregulate genes linked to synapse pruning and phagocytosis, consistent with exacerbated synaptic pruning by microglia in NPSLE models. Fingolimod treatment improved depression and spatial memory issues in MRL$^{lpr/lpr}$ mice. DAM transition from a CD11c^{lo} homeostatic microglia state; thus, MRL$^{lpr/lpr}$ DAM are enriched for DAM-associated genes compared to CD11c^{lo} microglial counterparts. However, fingolimod treatment restricted expression of DAM-associated genes in DAM and induced a unique signature in DAM enriched for genes linked to behavior- and synapse-related processes.

Conclusion: We find that DAM appear to lack typical functions in NPSLE-like disease and restricted expression of the DAM transcriptional program in NPSLE DAM corresponds to improved behavioral outcomes. Together, these discoveries mark the first to implicate DAM as a potentially pathogenic microglia subset in NPSLE. In future studies, we will explore whether DAM actively participate in the initiation of NPSLE-like disease.

Correlation of Fibromyalgia Survey Questionnaire and Quantitative Sensory Testing Among Patients with Active Rheumatoid Arthritis

Meriah Moore[1], Beth Wallace[2], Jing Song[3], Lutfiyya Muhammad[4], Andrew Heisler[5], Daniel Clauw[1], Marcy Bolster[6], Wendy Marder[1], Tuhina Neogi[7], Alyssa Wohlfahrt[8], Dorothy Dunlop[9] and Yvonne Lee[9], [1]University of Michigan, Ann Arbor, MI, [2]Michigan Medicine, VA Ann Arbor Healthcare System, Ann Arbor, MI, [3]Northwestern University, Worthington, IL, [4]Northwestern University Feinberg School of Medicine, Chicago, IL, [5]Bronson Rheumatology Specialists, Kalamazoo, MI, [6]Massachusetts General Hospital, Boston, MA, [7]Boston University School of Medicine, Boston, MA, [8]Tufts University School of Medicine, Boston, MA, [9]Northwestern University, Chicago, IL

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Abstracts: Fibromyalgia & Other Clinical Pain Syndromes (0474–0477)
Session Type: Abstract Session
Session Time: 11:00AM–12:00PM

Background/Purpose: Patients with rheumatoid arthritis (RA) commonly demonstrate disordered pain processing, termed central sensitization (CS). CS is typically measured using quantitative sensory testing (QST), which is burdensome to patients. The self-administered fibromyalgia survey questionnaire (FSQ) has been proposed as a low-burden surrogate measure of CS. We examine the correlation between FSQ and QST in a population with active RA.

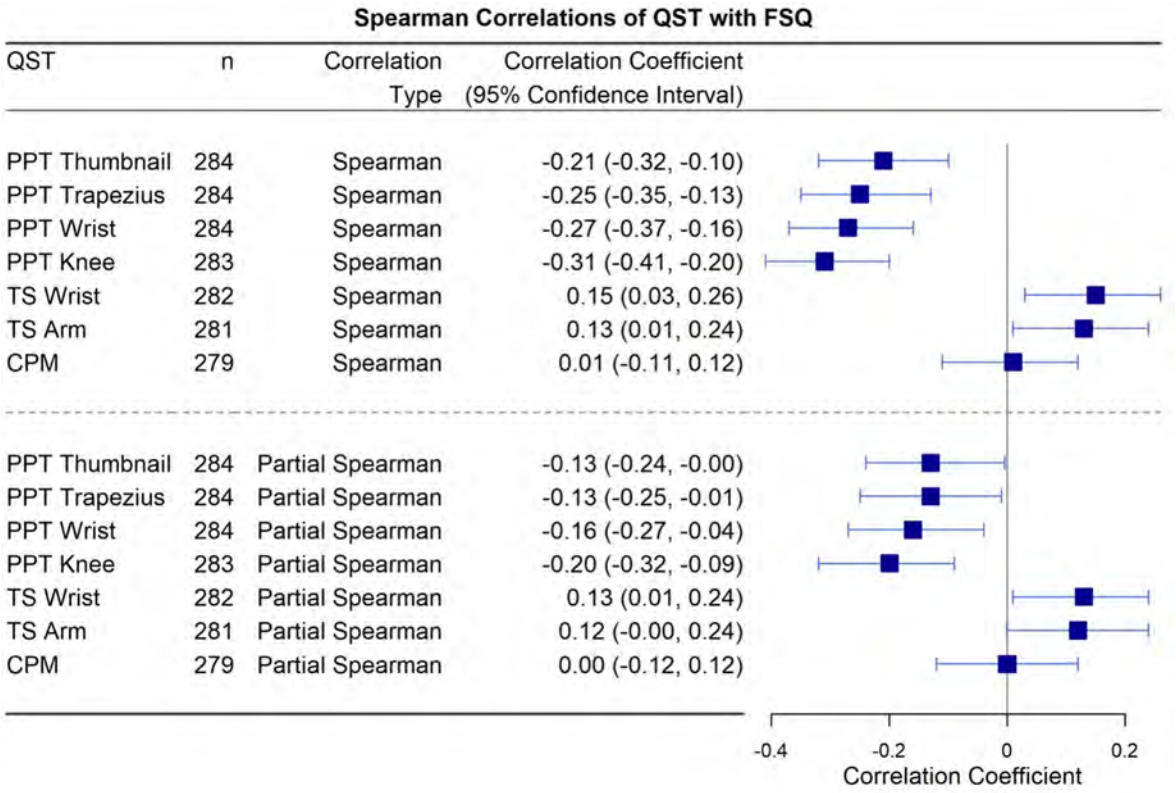

Figure 1. Unadjusted and adjusted correlations between QST measures and FSQ. Adjusted for age, sex, race, BMI, seropositivity, swollen joint count, CRP, pain catastrophizing, and site. PPT = pressure pain threshold; TS = temporal summation; CPM = conditioned pain modulation.

Methods: RA patients in the multicenter Central Pain in Rheumatoid Arthritis cohort underwent FSQ and QST evaluation at enrollment. QST measures included pressure pain threshold (PPT) at thumb, trapezius, wrist and knee, temporal summation (TS) at wrist and arm, and conditioned pain modulation (CPM). Spearman correlation was assessed between FSQ and each QST measure, adjusted for age, sex, race, body mass index, sero-status, swollen joint count, C-reactive protein, pain catastrophizing, and study site. We performed sensitivity analyses stratified by a) patient sex and b) sub-components of the FSQ (widespread pain index [WPI], and symptom severity scale [SSS]).

Results: Among 285 RA patients with high RA activity (mean baseline Clinical Disease Activity Index score of 24.56), FSQ was weakly but statistically significantly correlated with PPT (r = -0.21 to -0.31), and TS (r = 0.13 to 0.15) at all sites in unadjusted analyses (Figure 1). After adjustment for the covariates above, statistically significant correlations persisted for PPT at all sites except the thumb, and for TS at the wrist. Sensitivity analyses did not identify any differences in association based on sex or differences in associations with the components of the FSQ (WPI or SSS).

Conclusion: FSQ and QST were correlated among patients with active RA, but the strength of association was weak. These results do not support the use of FSQ as a proxy measurement for QST-assessed central sensitization among patients with active RA.

Quantitative Analysis of Gender and Racial Disparities in Randomized Controlled Trials of Fibromyalgia

Rami Diab[1], Ali Malik[2], Mahmoud Al Rifai[3] and Dennis Ang[4], [1]Wake Forest Baptist Health/Wake Forest School of Medicine, Winston-Salem, NC, [2]Wake Forest Baptist Health / Wake Forest School of Medicine, Winston-Salem, NC, [3]Baylor College of Medicine, Houston, TX, [4]Wake Forest School of Medicine, Winston-Salem, NC

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Abstracts: Fibromyalgia & Other Clinical Pain Syndromes (0474–0477)
Session Type: Abstract Session
Session Time: 11:00AM–12:00PM

Background/Purpose: Fibromyalgia is a chronic pain syndrome characterized by widespread musculoskeletal pain, mood disorders, fatigue, and cognitive and sleep disturbance. Mainstay treatments include tricyclic antidepressants, selective serotonin/serotonin norepinephrine reuptake inhibitors, and antiepileptic drugs. The purpose of this study was to examine whether or not gender and racial disparities exist in the context of research subjects recruited for clinical studies performed on the only three FDA approved medications for fibromyalgia.

Methods: The PubMed database was searched for clinical trials studying duloxetine (DLX), milnacipran (MLN), or pregabalin (PRG) for the treatment of fibromyalgia. Studies with randomized, double blind, placebo controlled design involving any of the above medications as monotherapy and reporting on gender and ethnic demographic parameters published over the last 10 years were included. Ethnic backgrounds were grouped into Caucasian or White, African American, Hispanic, Asian, and Other respectively.

Results: A total of 28 studies met inclusion criteria. Paired t-tests demonstrated a female gender preponderance of research participants for all of the DLX, MLN, and PRG treatment groups analyzed separately ($p < 0.05$ each) and collectively ($p < 0.001$). White or Caucasian was the predominant ethnic group across all treatment groups analyzed

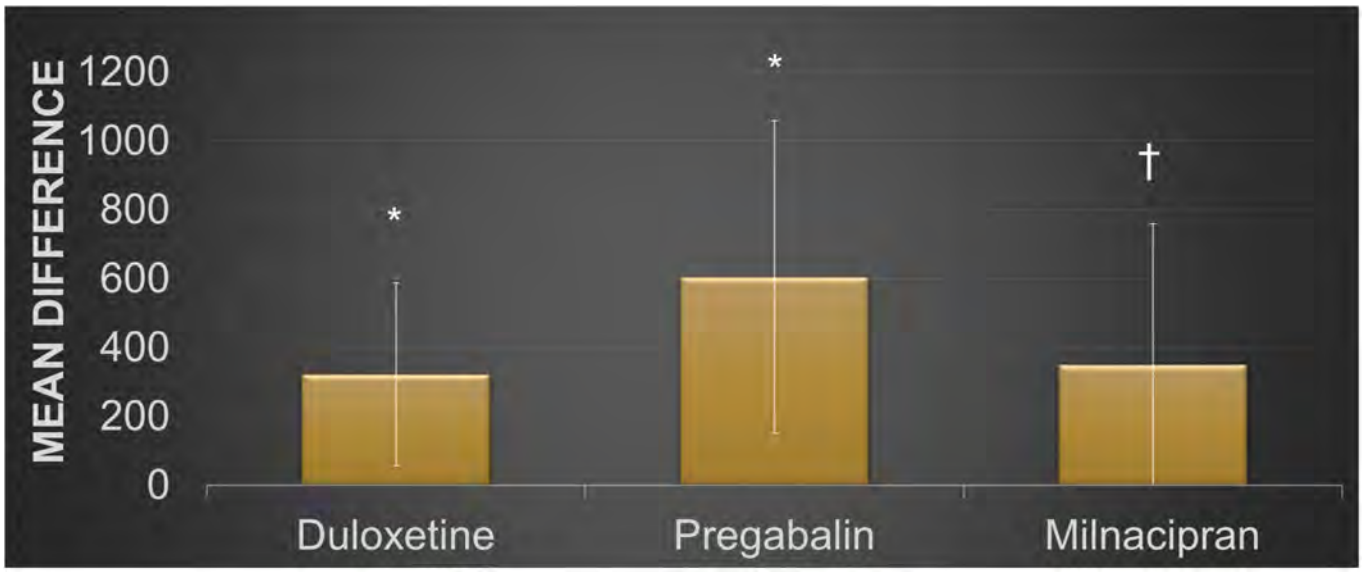

Figure 1. Statistically significant overrepresentation of Caucasian or White research subjects in comparison to all other ethnic groups as determined by paired t-tests (* denotes $p<0.005$, † denotes $p<0.05$).

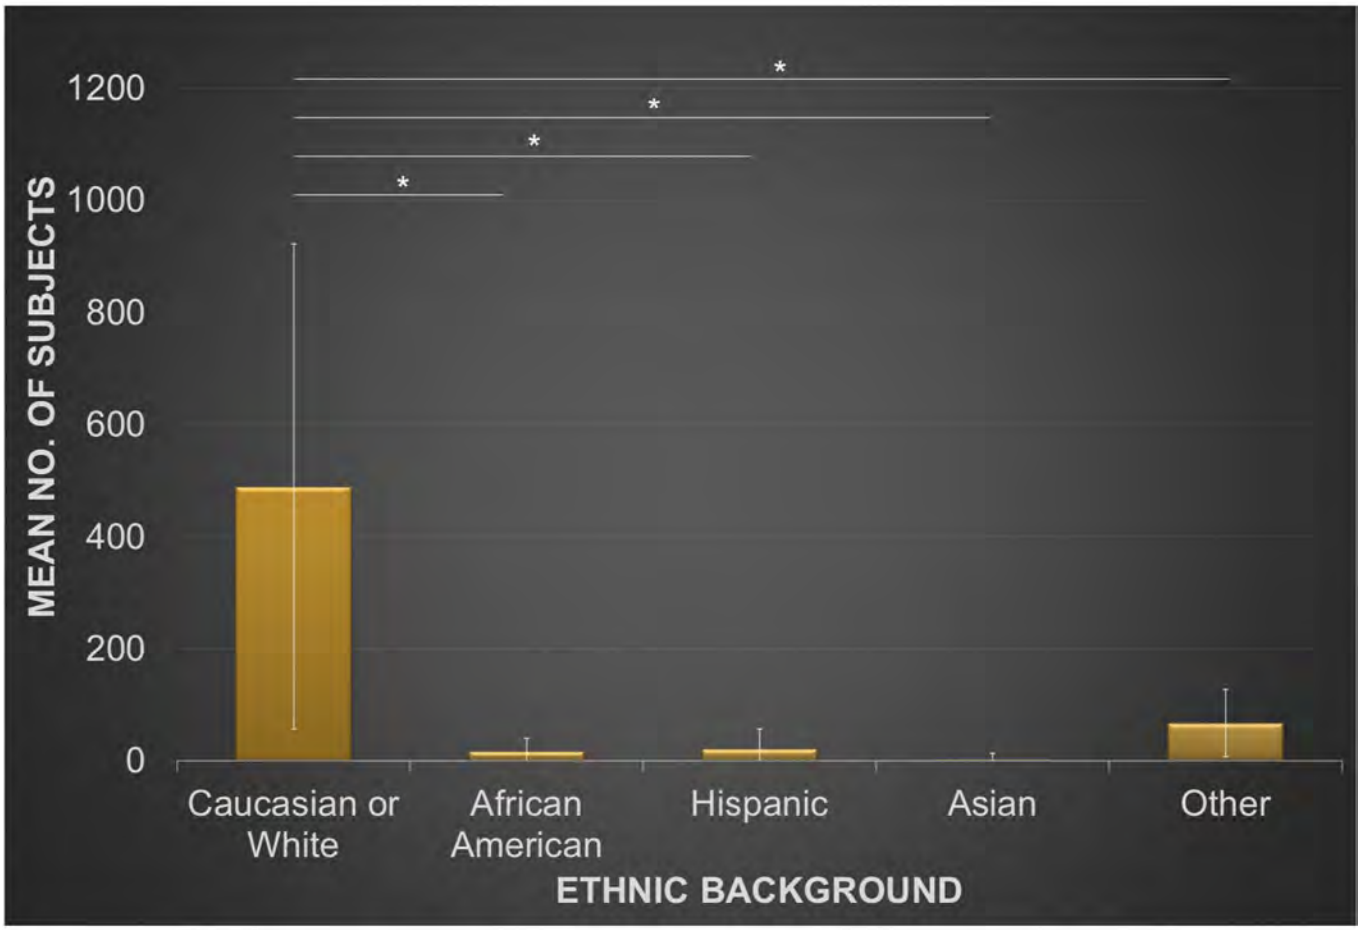

Figure 2. Statistically significant overrepresentation of Caucasian or White research subjects in comparison to African American, Hispanic, Asian, and all other ethnic groups remaining as determined by paired t-tests (* denotes p<0.001).

separately (86.4±6.1% DLX, 89.2±6.2% PRG, and 87.3±8.1% MLN) or collectively (87.6±6.7%). There were no statistically significant differences between group means across all treatment groups as determined by one-way ANOVA for White or Caucasian (F(2,25)=1.57, p=0.23), African American (F(2,25)=2.71, p=0.09), Asian (F(2,25)=0.64, p=0.54), or all ethnic groups combined (F(2,25)=1.6, p=0.22); as was the case for studies conducted within (F(2,22)=1.79, p=0.19) or outside (F(1,3)=0.1, p=0.77) the USA. Nonetheless, a statistically significant difference was observed by

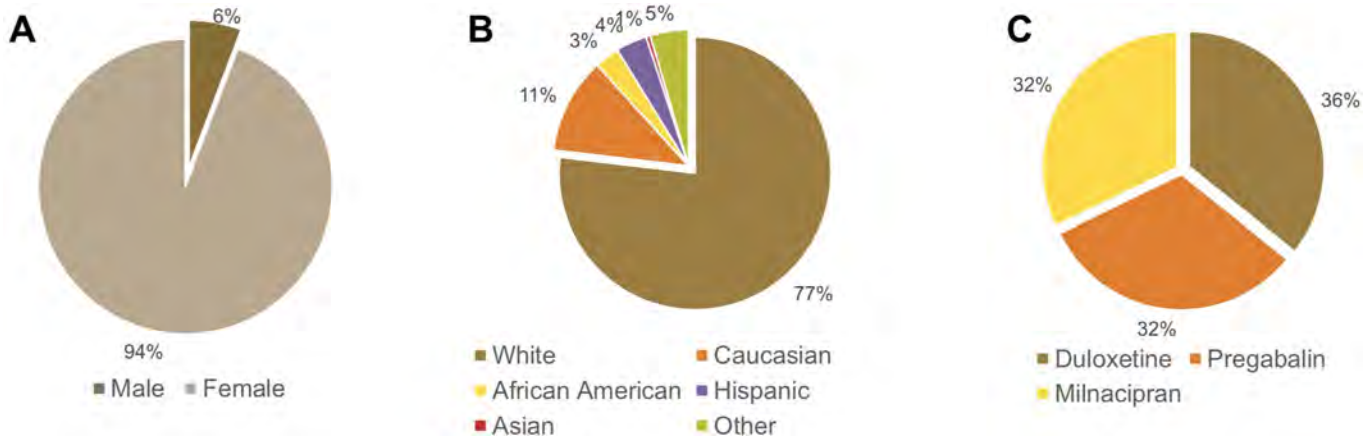

Figure 3. Demographic representation of research participants by gender (A) and ethnic background (B); and classification of included studies by medication.

one-way ANOVA for the Hispanic ethnic group ($F(2,25)=5.19$, $p< 0.05$). Paired t-tests revealed a statistically significant overrepresentation of Caucasian or White research subjects (489.25±432.70) in comparison to African American (17±23.39, $t(27)=6.06$, $p< 0.001$), Hispanic (21.29±35.43, $t(27)=5.78$, $p< 0.001$), Asian (2.93±10.51, $t(27)=5.95$, $p< 0.001$), or all other ethnic groups examined (67.32±60.03, $t(27)=5.76$, $p< 0.001$). A similar pattern of Caucasian or White subject overrepresentation in comparison to all other ethnic groups was found on subgroup analysis for all of the DLX (mean(diff)=322.20±265.27, $t(9)=3.83$, $p< 0.005$), PRG (mean(diff)=604.56±453.60, $t(8)=3.40$, $p< 0.005$), and MLN (mean(diff)=350.11±408.85, $t(8)=2.57$, $p< 0.05$) treatment groups respectively.

Conclusion: Evidence of widespread gender and racial disparities amongst subjects recruited for clinical trials of various pharmacologic agents for fibromyalgia exist. Whereas female preponderance for fibromyalgia is believed to reflect a true gender predilection of this disorder more research is needed to determine whether or not racial disparities observed indeed reflect on the nature of the disease.

Factors Associated with Pain Reduction and Improved Well-Being Among Fibromyalgia Patients Using Medical Cannabis

Marc Martel[1], Lilach Eyal Waldman[1], Romina Sotoodeh[1], Antonio Vigano[1], Yola Moride[2], Michelle Canac-Marquis[3], Rihab Gamaoun[3], Maja Kalaba[4], Pierre Beaulieu[2], Julie Desroches[2], Mark A. Ware[4], Jordi Perez[3], Yoram Shir[3] and Mary-Ann Fitzcharles[1], [1]McGill University, Montréal, QC, Canada, [2]Université de Montréal, Montréal, QC, Canada, [3]McGill University Health Centre, Montréal, QC, Canada, [4]Canopy Growth Corporation, Montréal, QC, Canada

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Abstracts: Fibromyalgia & Other Clinical Pain Syndromes (0474–0477)
Session Type: Abstract Session
Session Time: 11:00AM–12:00PM

Background/Purpose: Fibromyalgia (FM) is characterized by a constellation of symptoms that are often poorly responsive to current treatments, and patients are increasingly turning to medical cannabis (MC) as a strategy to improve pain and well-being. To date, little is known about the factors that may contribute to the perceived benefits of medical cannabis in patients with FM. Given that negative affect (i.e., anxiety, depression) and sleep problems contribute to heightened pain intensity and poor well-being, improvements in these variables might indirectly contribute to MC treatment benefits. Factors contributing to continuation of MC treatment, a surrogate for treatment satisfaction, are also largely unknown. The objectives of the present analyses were: 1) to examine whether changes in negative affect and sleep problems contributed to changes in pain intensity and well-being following initiation of MC; 2) to examine the factors contributing to MC treatment continuation.

Methods: Patients included in this study were part of a prospective, observational, non-comparative registry of adult patients who initiated MC under the supervision of a physician between 2015 and 2018 in Quebec, Canada. Sociodemographic and clinical characteristics were recorded at baseline. MC treatment characteristics (MC products, routes, doses) and symptom variables were assessed during in-clinic visits at baseline and every three months for a period of one year.

Results: Of the 2068 chronic non-cancer pain patients enrolled in this registry, 308 (14.9 %) had FM. The FM sample included 87 % women (mean age: 52.3 ± 12.9 years) and most patients (54.3 %) were using a combination of THC

and CBD. Results revealed significant improvements in pain intensity and well-being following initiation of MC (both ps < .05). A multilevel mediation analysis subsequently revealed that reductions in pain intensity were mediated by reductions in negative affect (p < .001) and sleep problems (p < .001). Improvements in well-being were mediated by reductions in negative affect (p < .001) and pain intensity (p < .05). MC was continued by 74%, 58.8%, 39.6%, and 23.1% of FM patients at the 3, 6, 9, and 12-month time points, respectively. The likelihood of treatment discontinuation was higher among patients with higher levels of pain and negative affect (both ps < .05), but was unrelated to the degree of improvement in these symptoms over the course of MC treatment (all ps > .05).

Conclusion: Our findings suggest that reductions in negative affect and sleep problems are important contributors to improvements in pain intensity and well-being among FM patients using MC. Discontinuation of MC was more common among those with higher levels of pain and negative affect but was not related to symptom improvement. These findings are a move towards precision medicine in MC recommendations for treatment of FM.

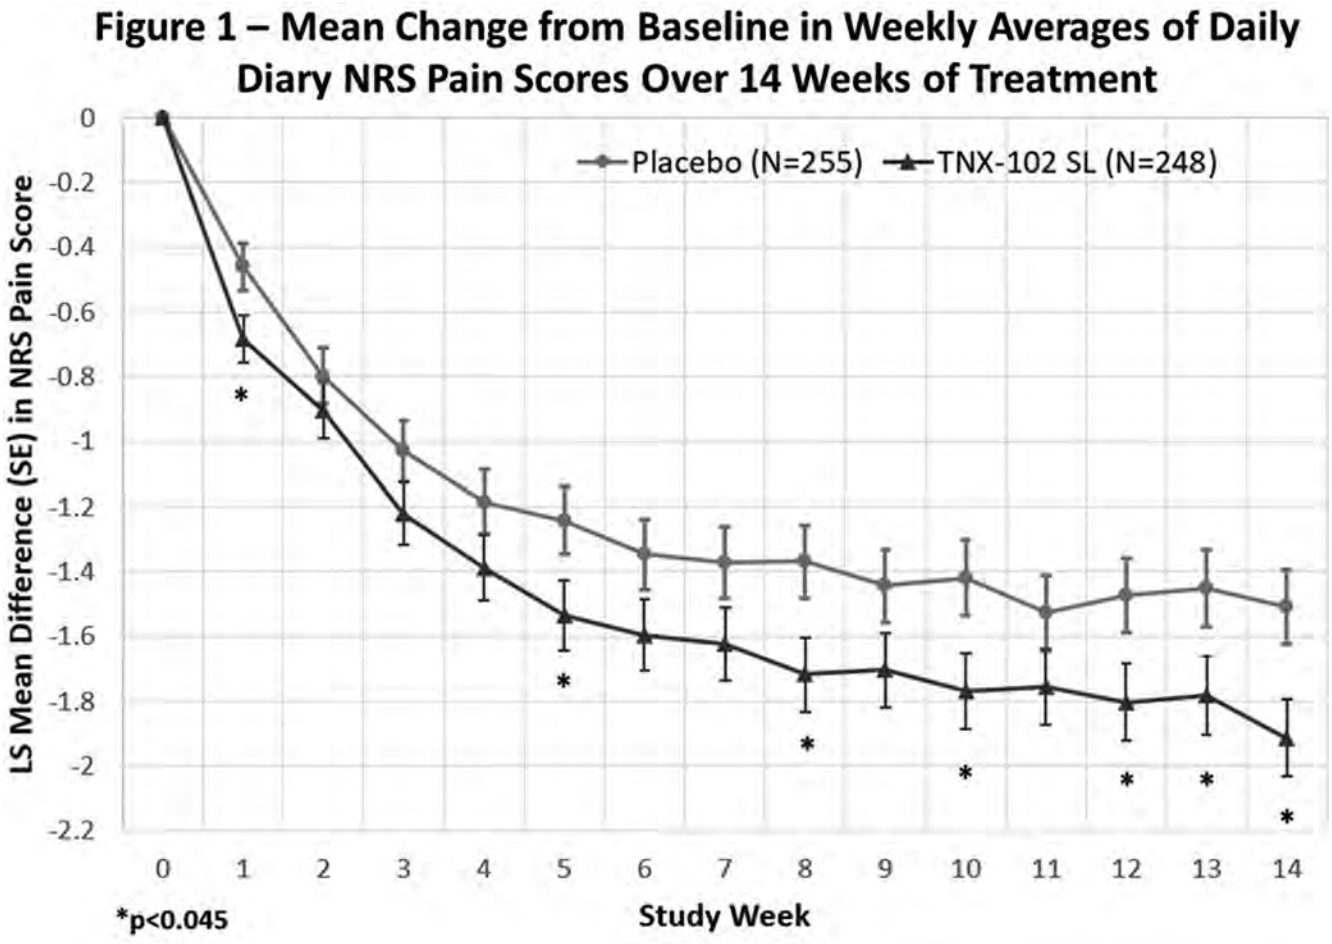
TNX-102 SL (Sublingual Cyclobenzaprine) for the Treatment of Fibromyalgia in the RELIEF Study: Positive Results of a Phase 3 Randomized, Double-Blind, Placebo-Controlled Multicenter Efficacy and Safety Trial

Gregory Sullivan[1], Mary Kelley[2], Annabelle Iserson[1], Perry Peters[2], Ashild Peters[2], Candace Flint[1], Judy Gendreau[3], Herb Harris[1], Ben Vaughn[4] and Seth Lederman[5], [1]Tonix Pharmaceuticals, Inc., Chatham, NJ, [2]Tonix Pharmaceuticals, Inc., San Diego, CA, [3]Gendreau Consulting, LLC, Poway, CA, [4]Rho, Inc., Cary, NC, [5]Tonix Pharmaceuticals, Inc., South Dartmouth, MA

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Abstracts: Fibromyalgia & Other Clinical Pain Syndromes (0474–0477)
Session Type: Abstract Session
Session Time: 11:00AM–12:00PM

Background/Purpose: Fibromyalgia (FM) is characterized by chronic widespread pain, fatigue, and nonrestorative sleep, a symptom constellation suggestive of a pathological disturbance in central pain processing known as central sensitization. TNX-102 SL* (cyclobenzaprine HCl sublingual tablets, 'TNX') targets improvement in sleep quality in order to reverse central sensitization. Prior studies of TNX at a 2.8 mg dose in FM showed signals for broad efficacy but narrowly missed significance on primary outcome of daily diary pain reduction. This Phase 3 trial ('RELIEF'#) evaluated efficacy and safety of TNX for FM at twice the dose, 5.6 mg.

Methods: The Intent-to-treat sample of 503 patients meeting 2016 FM diagnostic criteria were enrolled at 39 U.S. sites and received TNX 2.8 mg or placebo for 2 weeks followed by TNX 5.6 mg or placebo for 12 weeks. Primary outcome measure was change from baseline in weekly average of daily diary pain scores (0-10 NRS) at Week 14, analyzed by mixed model repeated measures with multiple imputation (MMRM-MI). The 1st key secondary analysis was Patient Global Impression of Change (PGIC) responders by logistic regression. Remaining key secondaries (by



MMRM-MI) included: Fibromyalgia Impact Questionnaire-Revised (FIQ-R) symptom domain; FIQ-R function domain; Patient Reported Outcomes Measurement Information System (PROMIS) Sleep Disturbance; PROMIS Fatigue; and daily diary NRS of sleep quality. To adjust for multiplicity, a sequential, ordered test procedure was applied to each (at $p < 0.045$ to account for an interim analysis α-spend).

Results: TNX was effective in decreasing daily diary pain compared to placebo (p=0.010; **Fig. 1**). A ≥30% pain reduction responder analysis indicated 46.8% TNX responders vs. 34.9% on placebo (p=0.006). By PGIC, 37.5% on TNX were responders, which was numerically but not significantly greater than 29.4% on placebo (p=0.058). TNX also provided greater separation from placebo on: FIQ-R Symptoms (p=0.007), Function (p=0.009); PROMIS Sleep Disturbance ($p < 0.001$) and Fatigue (p=0.018); and daily diary sleep quality ($p < 0.001$; **Fig. 2**).

In the TNX group, 82.3% completed vs. 83.5% on placebo. Systemic adverse events (AEs) were infrequent, with somnolence/sedation the only category at a rate of ≥ 5% on TNX (5.6% TNX; 1.2% placebo). The most common local administration site reaction was oral numbness (17.3% TNX; 0.8% placebo) which was episodic and typically temporally related to dosing, resolving in < 60 min in most occurrences. AEs led to premature study discontinuation in 8.9% on TNX vs. 3.9% on placebo.

Conclusion: Bedtime TNX at the 5.6 mg dose significantly reduced daily pain, provided a larger rate of ≥30% pain responders. It showed activity in improving sleep, fatigue, and other FM symptoms and measures of function. In addition, nightly TNX 5.6 mg was well tolerated. Taken together, these findings indicate TNX-102 SL primarily targets sleep quality and may thereby reduce central sensitization, leading to improvement at the syndromal level, manifesting as broad-spectrum activity across symptoms of FM.

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Abstracts: Osteoarthritis – Clinical (0478–0483)
Session Type: Abstract Session
Session Time: 2:00PM–3:30PM

Background/Purpose: Hand osteoarthritis (OA) is an heterogenous disease in terms of risk factors, localization and severity. This heterogeneity also applies to the clinical presentation and to the symptoms and is still poorly investigated. Our objective was to delineate the symptom-based phenotypes in a hand OA population using integrative analyses based on the cardinal symptoms of hand OA (pain, functional limitation, stiffness, esthetic discomfort).

Methods: We used the baseline data from the hospital-based hand OA cohort DIGICOD (PMID: 33689840). Clustering segregation was performed on AUSCAN subscores (0-100) of pain, function, stiffness separately, and the visual analog scale (0-100 mm) of esthetic discomfort. Hierarchical agglomerative clustering analyses were performed on 389 patients based on the Euclidean distance and the Ward D2 agglomeration method. Differences between cluster's characteristics were assessed by Kruskal-Wallis, Wilcoxon and Fisher exact tests. The Bonferroni method was applied on adjusted p-values to correct for multiple testing.

Results: Among the 389 patients analyzed, the AUSCAN subscores and the visual analog scale of esthetic discomfort enabled to identify 5 distinct clinical clusters by hierarchical clustering (Figure 1). We further characterized the composition of these clusters (Figure 2). Cluster 1 (N=88) is mainly composed of low symptomatic patients, cluster 2 (N = 91) of patients with mild symptoms (pain, stiffness and functional limitation), cluster 3 (N=80) of patients displaying esthetic discomfort mainly (without pain), cluster 4 (N =42) of high level of pain, stiffness and functional disability but without esthetic discomfort and cluster 5 (N=88) of the combined features of cluster 4 plus high level of esthetic discomfort. Age and hand OA duration were significantly different amongst clusters and higher in clusters 4 and 5 (p=0.06 and p=0.0002). Men were mostly present in low and mild-symptomatic cluster 1 and 2 (p=0.002). The clusters did not differ significantly for BMI, metabolic syndrome and CRP level, although metabolic syndrome represented 45.4 % of the highly symptomatic cluster 5 vs 26.1 % of low symptomatic cluster 1 (p= 0.01). The esthetic discomfort (corresponding to clusters 3 and 4) was associated with higher number of articular nodes (p=0.0003) and with radiographic erosive hand OA (p=0.04). Clusters 3, 4 and 5 were composed with patients more severe joint structure

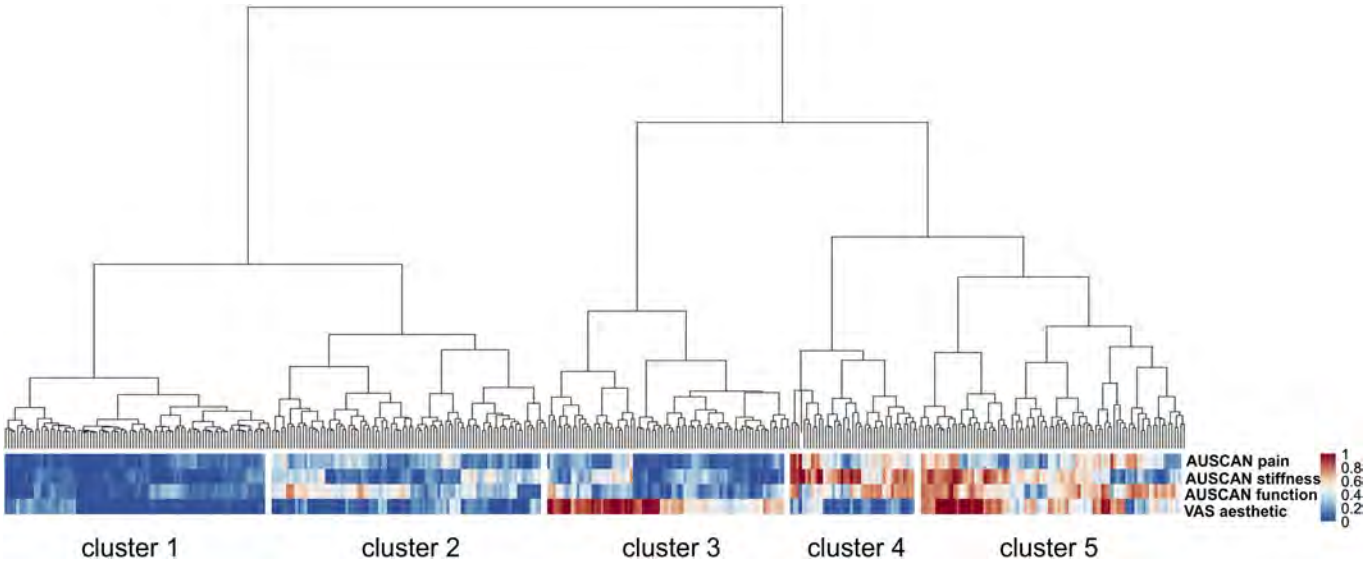

Figure 1. identification by clusters of hand OA phenotypes. The heatmap represents the results of hierarchical agglomerative clustering performed on AUSCAN pain, function and stiffness, and VAS esthetic data collected on 389 patients from the DIGICOD cohort.

expectation of improvement in all clusters was function, except pain for the highly symptomatic cluster 5. Only cluster 4 and 5 which represented one third of our cohort (N=130) had a mean AUSCAN pain score ≥ 40 mm.

Conclusion: The identification of these 5 clinical symptomatic phenotypes through hierarchical clustering illustrates the heterogeneity of the clinical presentation of hand OA. This opens toward a tailored therapeutic management according to each cluster and may help rationalizing patient recruitment in clinical trials evaluating symptomatic drugs.

A Novel Semi-automated Classifier of Radiographic Hip Osteoarthritis on DXA Scans Is Strongly Predictive of Pain, Clinical Diagnosis and Joint Replacement: Findings from 40,000 Participants in UK Biobank

Benjamin Faber[1], Raja Ebsim[2], Fiona Saunders[3], Monika Frysz[1], Claudia Lindner[2], Jennifer Gregory[3], Richard Aspden[3], Nicholas Harvey[4], George Davey Smith[1], Timothy Cootes[2] and Jon Tobias[1], [1]University of Bristol, Bristol, United Kingdom, [2]University of Manchester, Manchester, United Kingdom, [3]University of Aberdeen, Aberdeen, United Kingdom, [4]University of Southampton, Southampton, United Kingdom

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Abstracts: Osteoarthritis – Clinical (0478–0483)
Session Type: Abstract Session
Session Time: 2:00PM–3:30PM

Background/Purpose: Radiographic hip osteoarthritis (rHOA) is traditionally defined on hip or pelvic radiographs, using subjective methods such as Kellgren-Lawrence scoring. Associations between subjective rHOA measures and clinical outcomes such as hip pain are inconsistent. Applying digital analytical tools to high-resolution dual-energy X-ray absorptiometry (DXA) scans, we aimed to (1) develop a novel semi-automated classifier for rHOA, (2) apply this to available hip DXAs from UK Biobank (UKB), and (3) evaluate face validity of the classifier based on prevalence data and relationships with hip pain, hospital diagnosed OA, and risk of total hip replacement (THR).

Methods: Osteophyte area was manually measured (in mm^2) at the lateral acetabulum, superior-lateral and inferior-medial femoral head on left hip DXAs obtained from individuals in UKB (Figure 1). Osteophyte area thresholds were defined and subsequently applied to categorise each osteophyte into grades 0-3. Minimum joint space width (mJSW) was automatically measured (in mm) over the superior joint space using outline points placed by a machine learning based approach. Thresholds of mJSW were used to categorise individuals into joint space narrowing (JSN) grades 0-3. Osteophyte and JSN grades were summated for each individual to give a rHOA score of 0-12. Hips were then categorised into rHOA grades 0-4 based on rHOA score. Logistic regression was used to examine associations between rHOA grade and hip pain derived from a questionnaire, and hospital diagnosed OA and THR from electronic health record national linkage (HES). Our adjusted model included age, sex, height and weight as covariates.

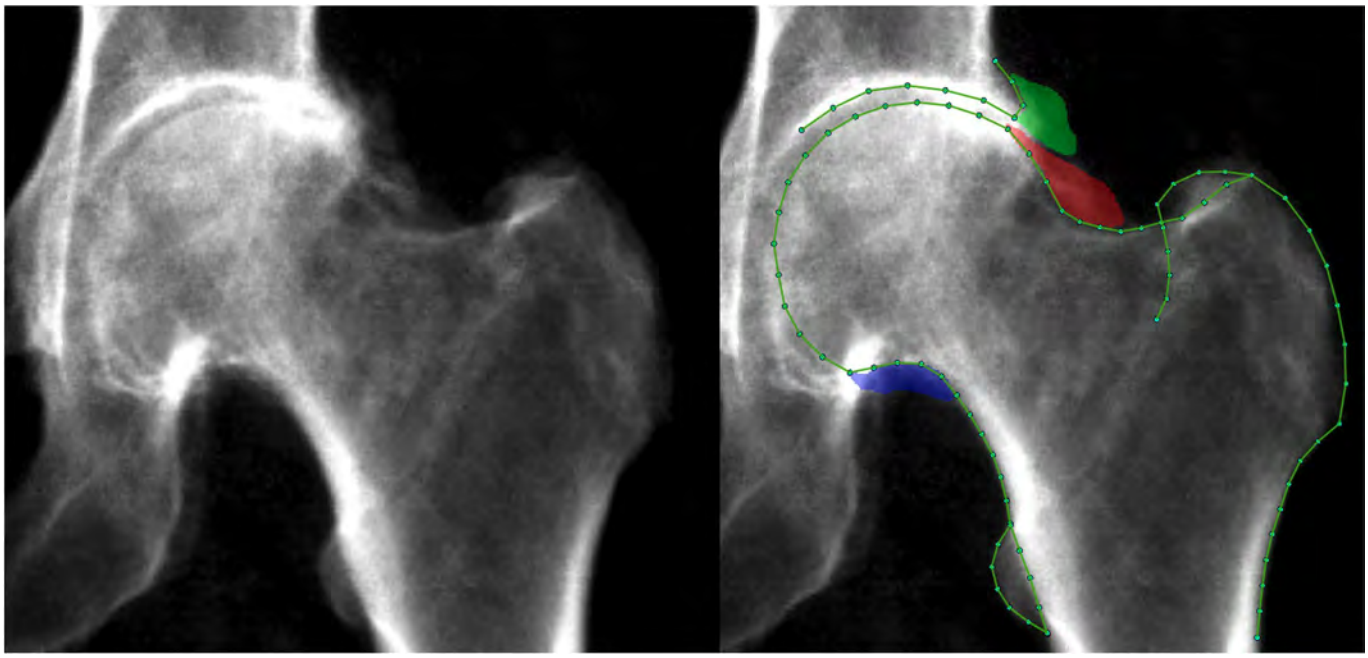

Figure 1. The left image shows a DXA scan from UK Biobank. The right image shows the same DXA scan with osteophytes and outline points marked.

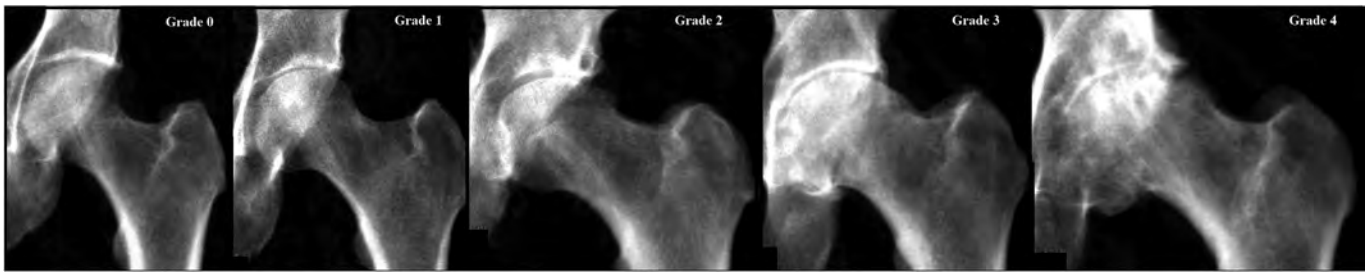

Figure 2. Example DXAs of each rHOA grade.

Results: 40,340 individuals were included in the study [mean age 63.7 (range 44-82), 19294/21046 male/female]. 32758 (81.2%) had rHOA grade 0, 4565 (11.3%) grade 1, 2317 (5.7%) grade 2, 543 (1.3%) grade 3, 157 (0.4%) grade 4 (Figure 2), with all features of rHOA being more common in males than females. rHOA grades ≥2 were associated with all three clinical outcomes in both unadjusted and adjusted models, a clear dose-response relationship was seen with each increase in grade showing a large rise in odds ratio (Figure 3).

Conclusion: Having developed a semi-automated classifier for rHOA on hip DXA scans, we successfully applied this to over 40,000 individuals from UKB, yielding expected findings for OA prevalence including higher rates in males compared with females. The validity of our classifier was further supported by the strong and progressive relationships observed between rHOA and hip pain, and risks of hospital diagnosed hip OA and THR. We conclude that hip DXA scans provide a promising means of objectively defining rHOA, with potential application in the clinic and as a research tool.

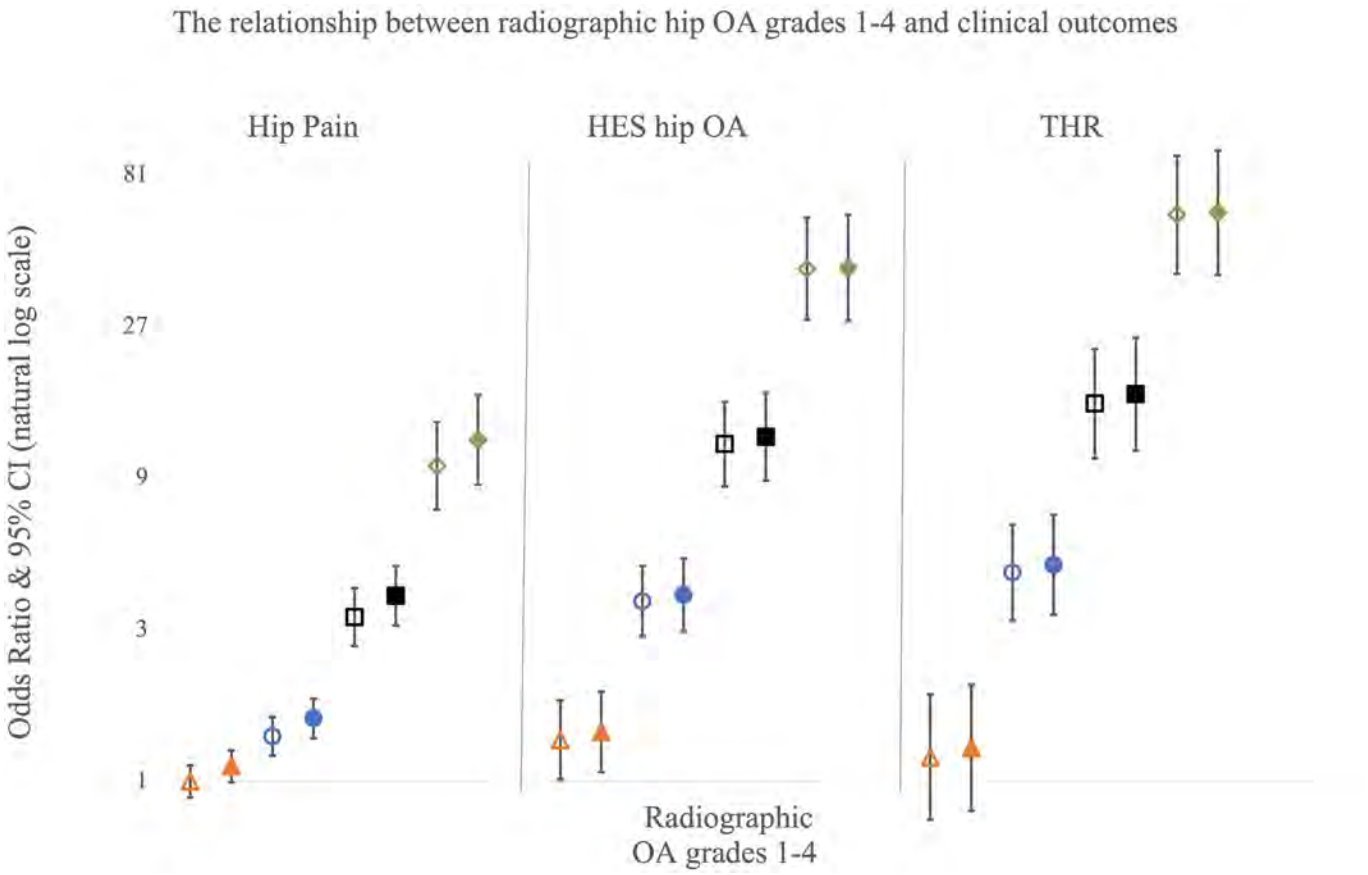

Figure 3. The associations between rHOA grades (1-4) and clinical outcomes. Odds ratios are plotted with 95% confidence intervals either side. Triangles = grade 1, circles = grade 2, squares = grade 3, and diamonds = grade 4. Unadjusted results = hollow shapes, and adjusted results = filled shapes. The Y-axis scale is natural log based.

Signs of Regression to the Mean in Observational Data from a Nation-Wide Exercise and Education Intervention for Osteoarthritis

Martin Englund[1], Dorte Grønne[2], Ewa Roos[2], Søren Skou[2] and Aleksandra Turkiewicz[1], [1]Lund University, Lund, Sweden, [2]University of Southern Denmark, Odense, Denmark

SESSION INFORMATION

Session Date: Saturday, November 6, 2021
Session Title: Abstracts: Osteoarthritis – Clinical (0478–0483)
Session Type: Abstract Session
Session Time: 2:00PM–3:30PM

Background/Purpose: Patients who enroll in interventions are likely to do so when they experience a flare-up in symptoms. This may create issues in interpretation of effectiveness due to regression to the mean (RTM). We evaluated signs of RTM in patients from a first-line intervention for knee osteoarthritis (OA).

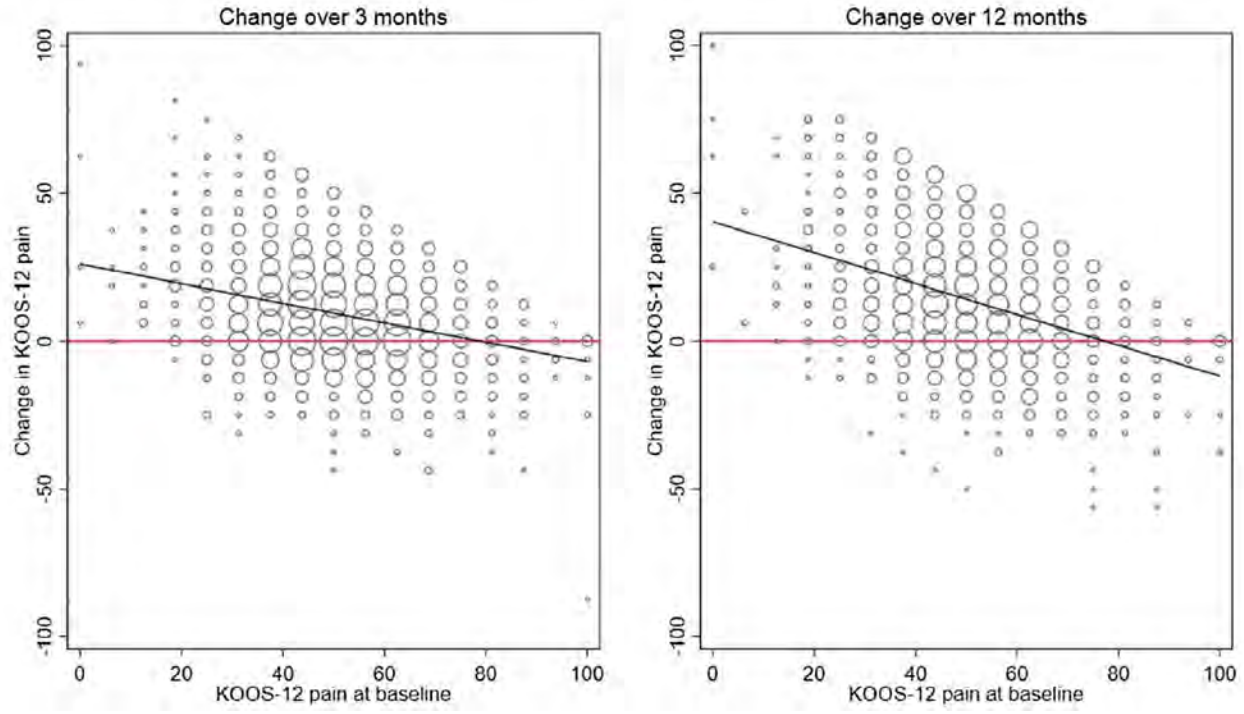
Table 1. Key descriptive statistics for the study cohorts.

		Age, mean yrs (SD)	% women	Body mass index, mean (SD)	KOOS-12 pain, mean (SD)
GLA:D® knee OA participants at baseline	n=4717	66 (9)	69	29 (5)	50 (16)
Persons with knee OA in observational cohorts	OAI, 12 months, n=1085	61 (9)	56	30 (5)	68 (21)
	OAI, 24 months, n=1044	61 (9)	56	30 (5)	69 (21)
	MOA, n=486	73 (7)	65	29 (6)	66 (22)

Methods: We used data from the Good Life with osteoArthritis in Denmark (GLA:D®) program of knee OA patients enrolled from July, 2018 until January, 2019 and included data on knee pain measured with KOOS-12 pain subscale (0-100, worst to best) at baseline, 3 and 12 months. GLA:D® is an 8-week exercise and education program for OA. Radiographic OA is not required, but 86% of the knee OA patients reported that they had knee X-rays taken prior to commencing the program, and more than 90% of those stated that the images showed signs of OA.

To estimate mean levels of pain in a population of persons with knee OA we used cohort data from the Osteoarthritis Initiative (OAI), USA and the Malmö Osteoarthritis study (MOA), Sweden. From OAI we included subjects with radio-

Figure 1. Plot of change in KOOS-12 pain from baseline to 3 months (n=3384) and 12 months (n=2833) vs the baseline pain level; GLA:D® participants with non-missing data. The black line shows linear fit. Size of circles is proportional to the number of persons.



graphic knee OA (KL grade ≥2) at baseline, 12 or 24 months and reporting knee pain, aching or stiffness on most days of at least one month the past 12 months at the baseline visit. We report KOOS-12 values at 12 and 24 months. MOA consisted of two parts – first, persons responded to a postal questionnaire, later they had a clinical visit when knee X-rays were taken. From MOA, we included subjects who had both signs of OA on X-rays and reported knee pain in the postal questionnaire. Thus, taking the fluctuation of OA symptoms into account, we identified the underlying population of persons with knee OA in both OAI and MOA using data collected at one time point (requiring presence of knee pain). We then evaluated their KOOS-12 pain value at *another* time point. This means, that although the persons suffer from OA pain, we do not select them by conditioning on current knee pain.

We evaluated two key signs of potential for RTM: 1) worse pain levels in those enrolled in the first-line intervention than in the underlying population with the disease, and 2) negative correlation between baseline values and change as well as greater/lower average improvement among participants with worse/less pain levels compared to the mean baseline value.

Results: The mean KOOS-12 pain level reported at baseline when enrolling in GLA:D® were worse than in persons with knee OA from OAI and MOA by 16 to 19 points (Table 1). Further, in GLA:D® we found a negative correlation between KOOS-12 pain at baseline and its change of -0.31 (95%CI -0.33, -0.27) at 3 months and -0.39 (95%CI -0.42,-0.35) at the 12 months follow-up (Fig 1). At 12 months, the persons with baseline KOOS pain ≤50 had improved on average by 19 points, while those with baseline pain >50 had improved on average by 6 points. Corresponding data for change from baseline to 3 months were 13 and 4 points, respectively.

Conclusion: Data from a first-line intervention for knee OA display key signs of RTM. As RTM represents no true improvement, but only reflects natural fluctuations of the symptoms, there is a need to determine its magnitude to better understand the true effectiveness of OA interventions in uncontrolled study designs.

The Day-to-day Variability of Pain and the Relationship with Physical Activity in People with Knee Osteoarthritis: A Longitudinal, Observational Feasibility Study

Arani Vivekanantham[1], David Selby[2], Mark Lunt[2], Terence O'Neill[2] and Will Dixon[2], [1]University of Oxford, Oxford, United Kingdom, [2]University of Manchester, Manchester, United Kingdom

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Abstracts: Osteoarthritis – Clinical (0478–0483)
Session Type: Abstract Session
Session Time: 2:00PM–3:30PM

Background/Purpose: Pain is a cardinal symptom in people with knee osteoarthritis (OA). However, pain in knee OA is often infrequently measured both in clinical practice and research studies, meaning little is known about the day-to-day variability of it. Although physical activity is recognised to affect pain, it has been hard to measure both concurrently and study this relationship. In this study we aimed to assess the use of smartwatches to describe the day-to-day variability of pain and assess how this compares to the current standardised assessments of pain at less frequent time points. We also aimed to assess whether the use of a smartwatch can help us to explore the relationship between pain and physical activity levels in people with knee OA.

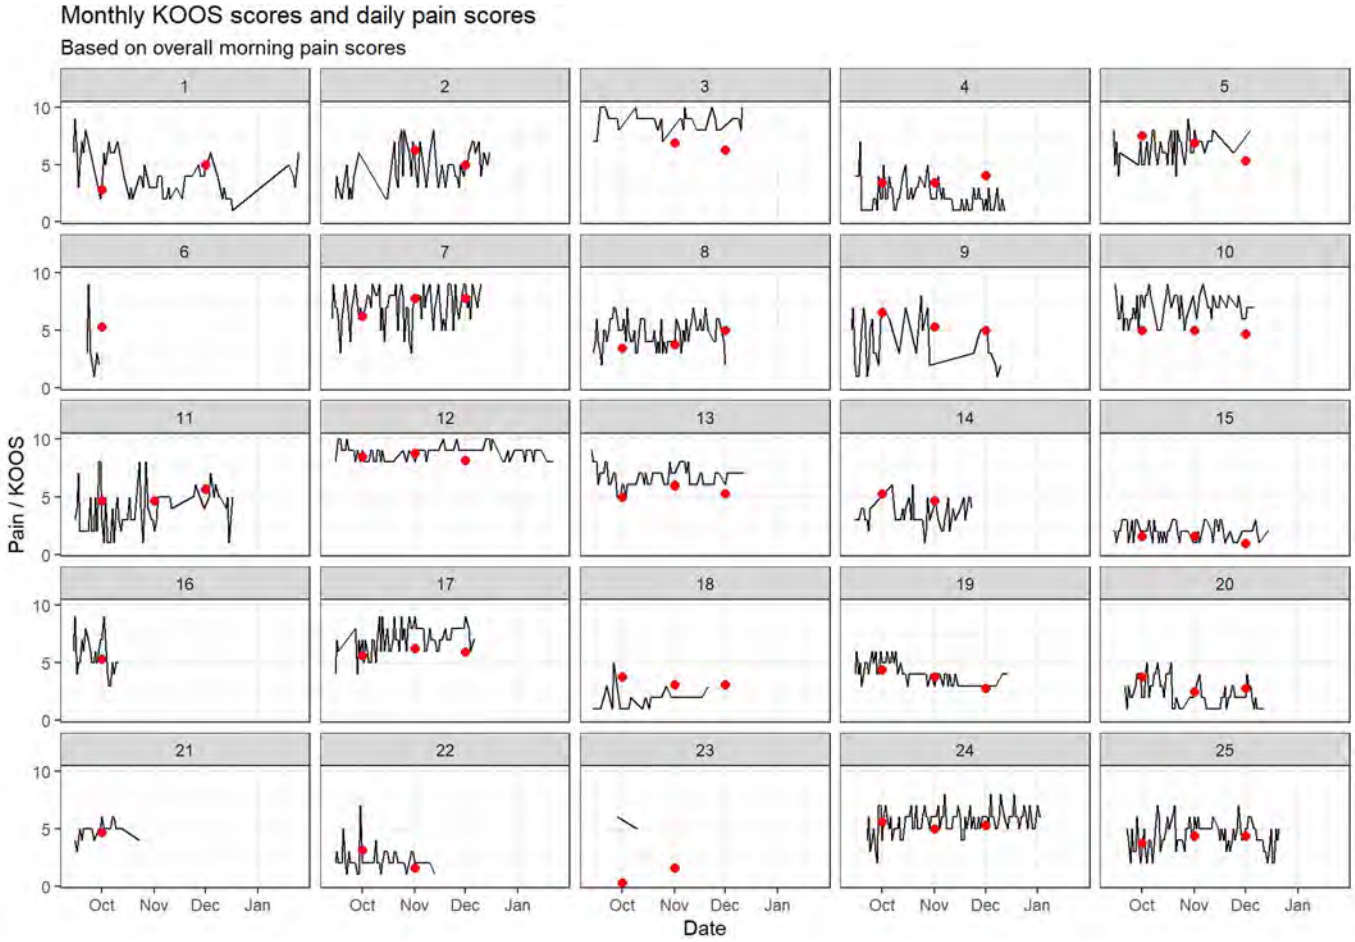

Figure 1. Daily morning pain scores for the 25 participants throughout the three-month study period. The red dots are the respective Knee Injury and Osteoarthritis Outcome Score (KOOS) for each month.

Methods: We performed a longitudinal, observational feasibility smartwatch study in participants with self-diagnosed knee OA over a three-month period. Participants were provided with a consumer cellular smartwatch with a bespoke app that collected patient-reported outcomes via questionnaires. The app triggered questions about daily level of knee pain twice a day and 17 questions from the Knee Injury and Osteoarthritis Outcome Score once a month. Physical activity was measured in the form of daily step counts.

Results: 26 participants were recruited; one left the study early and so was excluded from subsequent analyses. The mean age of participants was 65 years, with a standard deviation of 8 years, 13 were male and the median (IQR) BMI was 27 (25, 35) kg/m^2.

The use of the consumer cellular smartwatch app was successful in assessing and recording data on patient reported outcomes and continuous sensor data simultaneously. We found that pain in knee OA fell into three main categories (sustained high levels of pain, sustained low levels of pain and fluctuating pain) but there was considerable day-to-day variation in pain levels within these categories. Furthermore, as illustrated in Figure 1, we also found that participants with stable monthly KOOS scores had a lot of day-to-day variability in pain levels in between their monthly scores, raising doubt as to whether patients with stable monthly KOOS scores truly represent stable knee OA and whether this is an accurate method for monitoring OA. Interestingly, we also found that those with high/ low levels of pain have a similar step count average but those with fluctuating pain have much lower levels of activity. This may indicate that fluctuating pain (i.e., pain that is unpredictable/ always changing) may be more troublesome to knee OA patients than those with consistently high levels of pain.

Conclusion: This study provides important insights related to the day-to-day variability of pain in knee OA and its links to physical activity. The results from this can help us start to understand pain in people with knee OA. In the

future, larger studies may inform the development of personalized physical activity recommendations for people with knee OA, based on their optimal level of physical activity in relation to their pain.

Abstract Number: 0482

Metformin Use Reduces the Risk of Developing Osteoarthritis: A Propensity Score Matching Study

Khushboo Sheth[1], Di Lu[2], Rong Lu[2], William Robinson[3] and Matthew Baker[4], [1]Stanford University/VA Palo Alto, Atherton, CA, [2]Stanford University, Stanford, [3]Stanford University, Palo Alto, CA, [4]Stanford University, Menlo Park, CA

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Abstracts: Osteoarthritis – Clinical (0478–0483)
Session Type: Abstract Session
Session Time: 2:00PM–3:30PM

Background/Purpose: Preclinical and observational data suggest a protective effect of metformin against developing osteoarthritis (OA).[1,2] In this retrospective cohort study, we evaluated the time to developing osteoarthritis and time to joint replacement in patients with diabetes mellitus (DM) treated with metformin compared to patients with DM who did not receive metformin or any other DM treatment.

Methods: This was a retrospective cohort study using claims data from the Optum Clinformatics™ Data Mart between 2003 and 2019. We identified patients aged 40 years or older with more than two years of continuous enrollment and at least two ICD-9 or ICD-10 codes for DM separated by 14 days or more. Patients were excluded if they had type I DM, if they received any DM medication other than metformin, or if they had a prior diagnosis of OA, inflammatory arthritis, or joint replacement. The exposed group included patients treated with metformin, and the control group included patients with DM who were not treated with any medications for DM. We conducted 1:1 propensity score matching and used Cox proportional hazard models to calculate the adjusted hazard ratio (HR) of 1.) developing OA and 2.) undergoing hip or knee joint replacement. Kaplan-Meier curves were created to report the time to diagnosis of OA.

Results: A total of 384,146 patients met study inclusion and exclusion criteria, of which 104,652 were treated with metformin and 274,494 were not. After propensity score matching, both groups had a mean age of 59.4 years and were 43.2% female (**Table 1**). In a multivariable analysis, after adjusting for age, gender, race/ethnicity, and Charlson comorbidity score, the risk of developing OA was reduced by 21% for patients who had been treated with metformin compared to those who had not (adjusted HR 0.79; 95% confidence interval (CI) 0.77-81; p< 0.001), and the adjusted HR for time to joint replacement was 0.90 (95% CI, 0.83-0.98; p=0.01). After propensity score matching, the adjusted HR for developing OA was 0.77 (95% CI, 0.74-0.81; p< .001) and the adjusted HR for time to joint replacement was 0.86 (95% CI, 0.75-0.99; p=0.038) (**Table 2**). Survival analysis demonstrates separation of the Kaplan-Meier curves by 24 months after treatment initiation (**Figure**).

Conclusion: This study demonstrates a significant reduction in the risk of developing OA and in the need for joint replacement in DM patients treated with metformin compared to DM patients who did not receive metformin. Results from this study further support the preclinical and observational data that metformin may have a protective effect against the development of OA. Future interventional studies with metformin for the treatment or prevention of OA could be considered.

Background/Purpose: Oral NSAIDs are recommended for OA management. However, many patients with OA have contraindications to NSAIDs or have comorbidities that warrant precaution. Because few other oral therapies are available, such patients may still receive NSAIDs or may instead receive opioids, which are not recommended and have numerous concerning adverse effects. They may also receive physical therapy (PT), an effective option, as a safe alternative. We evaluated the patterns of NSAID, opioid, and PT use among persons with newly diagnosed knee or hip OA with and without NSAID contraindications or precautions using population-based Swedish register data.

Methods: We used register data on healthcare use and dispensed drugs, and population register to identify adults aged ≥35 as of Jan 1, 2010 residing in Skåne region in Sweden, between 1998-2009 and without a knee or hip OA diagnosis during this time. Among this cohort, we identified people with incident knee or hip OA using ICD-10 codes between 2010- 2015. We identified contraindications to or precautions for oral NSAIDs based on ICD-10 codes prior to or at the time of OA diagnosis. Contraindications included gastrointestinal bleed/ ulcer, chronic kidney disease (CKD) stage ≥3 (dialysis, transplant), acute renal failure. Precautions included coronary artery disease, heart failure, gastroesophageal reflux disease, inflammatory bowel disease, CKD stage 1 or 2, other kidney diseases. During the first year after a new OA diagnosis among those with vs. without contraindications or precautions, we evaluated the prevalence and relative risk of: 1) regular oral NSAID use (see **Figure 1** for definition); 2) regular opioid use (see **Fig 1**); 3) physical therapy visit descriptively and in confounder-adjusted logistic regression models with standardization to compute risk ratios.

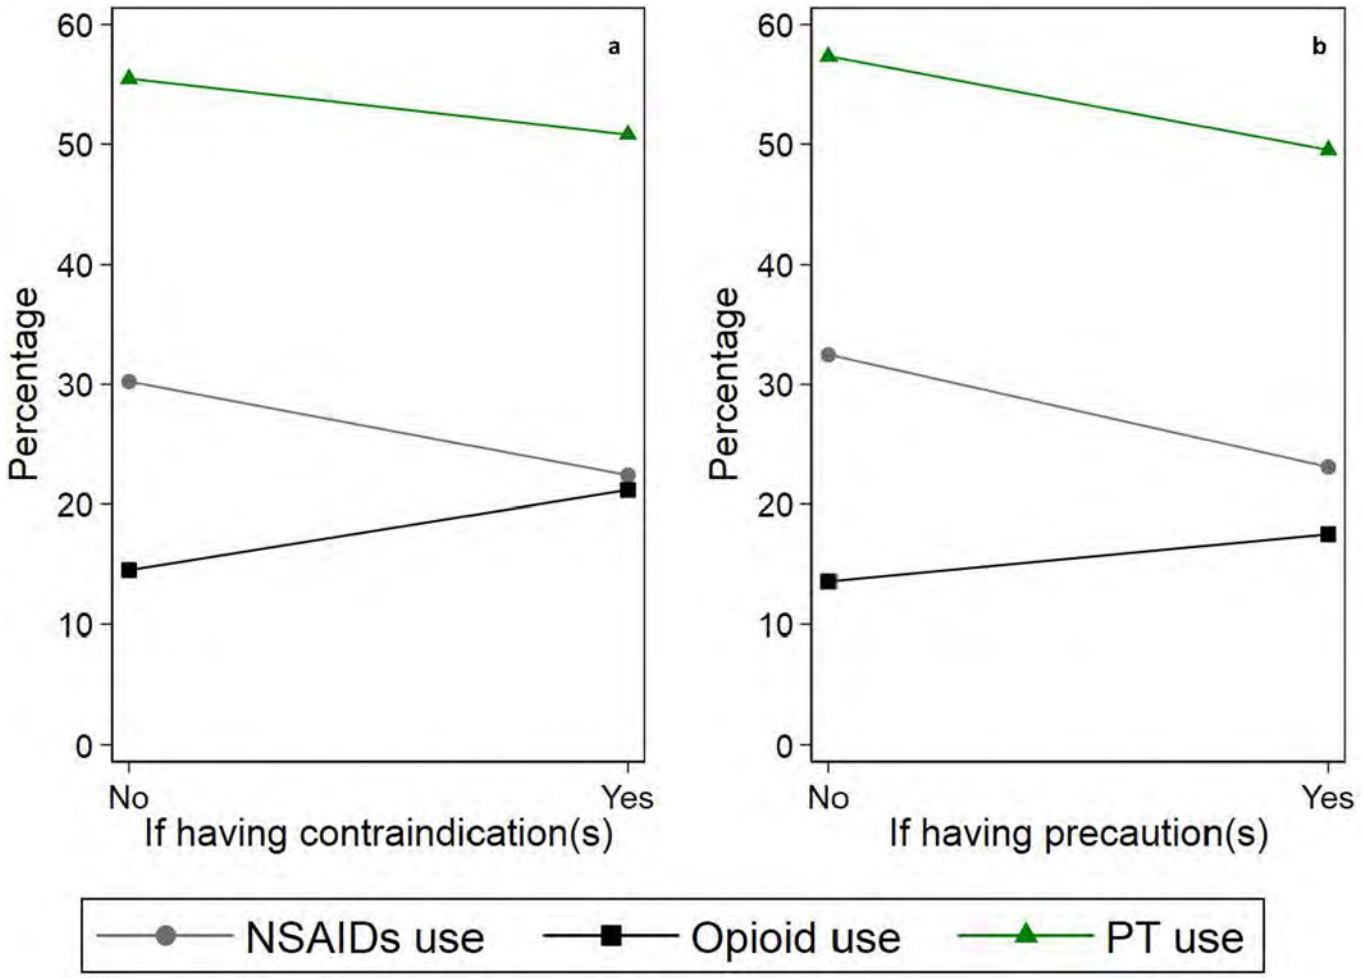

Figure 1. Crude prevalence of NSAIDs, opioid and physical therapy (PT) in persons with newly diagnosed knee or hip OA during the first year after diagnosis, by presence of contraindications or precautions for NSAIDs use. Regular use of NSAIDs or opioids were defined as ≥30 total daily doses prescribed within 90 days from first prescription to ensure regular use for something other than an acute problem.

Results: We included 30,320 persons (21,682 knee OA; 9124 hip OA; 486 were diagnosed with both on the same date; mean age 67, ~41% male, **Table 1**). Overall, 9.1% had contraindications to NSAIDs, and 21.7% had at least one precaution. There was lower prevalence of regular NSAID use among those with vs. without contraindication to NSAIDs (22% vs. 30%), but higher prevalence of regular opioid use (21% vs. 15%) (**Figure 1a**); a similar pattern was seen for those with vs. without precautions for NSAIDs (NSAID use: 23% vs. 32%; (opioid use: 18% vs. 14%) (**Figure 1b**). The lowest prevalence of regular NSAID use was among those with CKD stage ≥3 (10%); they also had highest prevalence of regular opioid use (25%). Prevalence of PT was slightly lower among those with contraindications (51%) or precautions (50%) than those without (55% and 57%, respectively). In adjusted analyses, those with contraindications or precautions were at 1.2 to 1.5 times higher risk of regular opioid prescriptions than those without, while use of PT was not increased for any group (**Figure 2**).

Conclusion: People with knee or hip OA who have contraindications to or precautions for NSAIDs had higher risk of regular opioid use, but not PT, within the first year of their OA diagnosis. These data highlight the negative impact of having a paucity of treatment options for people with OA who are unable to safely use NSAIDs, and lack of sufficient use of PT for these at-risk patients.

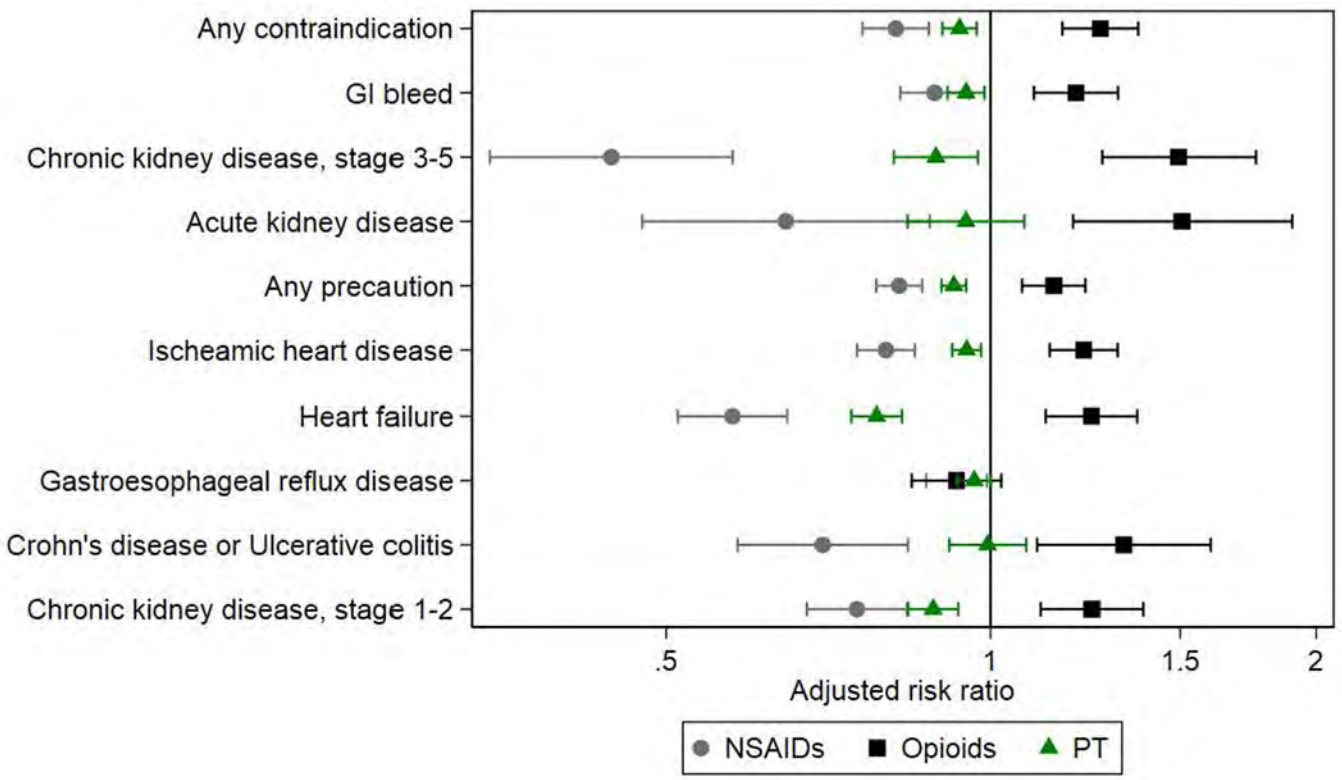

Figure 2. Adjusted risk ratios of NSAIDs, opioid and physical therapy (PT) use in persons with newly diagnosed knee or hip OA during the first year after diagnosis, comparing those with and without contraindications and precautions of NSAIDs use. The logistic regression model was adjusted for age-group, sex, marital status, if born outside Sweden, income group, education level, year of OA diagnosis, healthcare use (operationalized in 5 variables, if inpatient visit, if specialist contact with psychiatry, categorized number of specialist visits in somatic care, primary care and with other healthcare professionals [not physicians]). Risk ratios were derived using method of standardization.

Background/Purpose: RheumMadness is an online collaborative learning experience in which rheumatology concepts compete as teams in a tournament. The Community of Inquiry (CoI) framework describes the cognitive, social, and teaching "presences" in a social constructivist learning activity. This study analyzes participant engagement and the CoI presences in the first year of RheumMadness.

Table 1. Post-survey results: demographics and engagement with RheumMadness

Methods: RheumMadness 2021 included 16 concepts in a single-elimination bracket, scouting reports reviewing each concept created by >40 fellows from 14 fellowship programs, and a podcast (15 episodes). Participants completed brackets predicting the outcome of tournament matchups (decided by 7 judges) and discussed RheumMadness on social media (Facebook/Twitter). Web-based analytics tracked engagement with each element in RheumMadness. A Qualtrics survey was emailed to participants and shared on social media to assess engagement with RheumMadness and perceptions of the CoI presences. CoI questions were adapted from a validated 34-item CoI survey. Respondents were categorized as "full participants" if they listened to at least half the podcast episodes, read at least half the scouting reports and read social media posts at least once per week; the remainder were "partial participants." Survey data were analyzed with Fisher's exact test and Pearson's correlation for linear relationships.

Table Notes

- Rows highlighted in yellow were tested for difference in response frequency between full and partial participants; all showed $p < 0.001$
- 8 out of 1,972 potential responses were left blank. These all occurred in the partial participant group. Blank responses were considered "neutral."

Results: 105 brackets were submitted in the tournament. There were 1,542 scouting report page views (96 per report) and 2,449 podcast downloads (163 per episode). The Facebook group accrued 81 members. On Twitter, there were 486 tweets from 105 users, generating 2,312,386 potential Twitter impressions.

	Overall CoI Score§ r coefficient (p value)¶	Cognitive Presence r coefficient (p value)¶	Social Presence r coefficient (p value)¶	Teaching Presence r coefficient (p value)¶

Podcast Engagement	0.54 ($p < 0.001$)	0.48 ($p < 0.001$)	0.45 ($p < 0.001$)	0.43 ($p < 0.001$)
Scouting Report Engagement	0.49 ($p < 0.001$)	0.49 ($p < 0.001$)	0.31 ($p = 0.016$)	0.46 ($p < 0.001$)
Social Media Engagement†	0.65 ($p < 0.001$)	0.33 ($p = 0.011$)	0.78 ($p < 0.001$)	0.50 ($p < 0.001$)

Table Notes

Correlation strength highlighting key:
green = strong ($r > 0.6$)
yellow = moderate (r of 0.4 - 0.59)
orange = weak (r of 0.2 - 0.39)

*Overall Engagement is the average of podcast, scouting report, and social media engagement ratings

†Social Media Engagement is the average ratings for frequency of social media reading and posting

§ Overall Community of Inquiry Score is the weighted average of the cognitive, social, and teaching presence ratings

¶ p value for significance set at 0.003125 after Bonferroni correction for 16 tests, non-significant values in orange

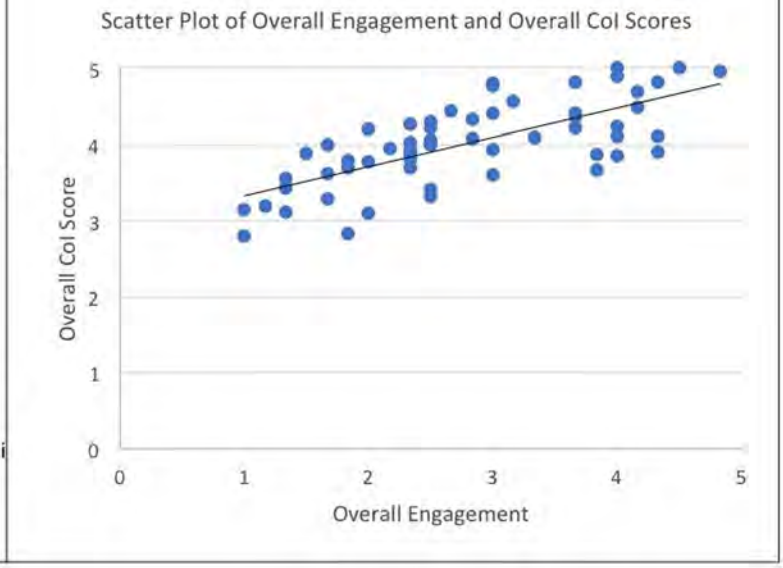

Figure 1. Correlation between Community of Inquiry (CoI) scores and RheumMadness engagement.

The post-survey was sent to 100 participants who submitted a bracket; the remaining 5 brackets were from the study team. Of recipients, 58/100 (58%) responded; 19 (32.8%) were full and 39 (67.2%) partial participants. Demographics and reported engagement are shown in Table 1. CoI results are shown in Table 2. The majority of full and partial participants indicated agreement with prompts relating to the cognitive, social, and teaching presence; agreement was more frequent among full participants in each presence ($p< 0.001$).

Correlation analyses are shown in Figure 1. There was a significant, strongly positive correlation between overall engagement with RheumMadness and overall CoI survey scores ($r=0.72$, $p< 0.001$). The cognitive presence showed a moderate correlation with scouting report and podcast engagement but no significant correlation with social media. The social presence correlated strongly with social media and moderately with podcast engagement but no significant correlation with scouting reports. The teaching presence correlated moderately with all components.

Conclusion: RheumMadness successfully engaged learners in an online learning community. Most participants agreed that RheumMadness fostered meaningful cognitive, social, and teaching presences, especially among full participants. The cognitive presence was fostered primarily by didactic elements – the scouting reports and podcast. The social presence was fostered by social media and, to a lesser extent, the podcast. All elements contributed to the teaching presence.

Session Title: Abstracts: Professional Education (0484–0487)

Session Type: Abstract Session

Session Time: 2:00PM–3:00PM

Background/Purpose: The COVID-19 pandemic has disrupted healthcare delivery and education of physicians, including rheumatology trainees. Our objective was to assess the impact of the COVID-19 pandemic on rheumatology trainee health, well-being, and features of burnout.

Table 1. Characteristics of US respondents

	n (%)
US Geographic Region	
New England	16 (14)
Mid East	36 (31)
Great Lakes	13 (11)
Plains	8 (7)

Pediatric	26 (22)
Combined adult/pediatric	4 (3)

Table 2. Rheumatology trainees reporting health vulnerabilities or having acquired COVID-19

	United States n = 116	Rest of the World (ROW) n = 186	Combined n = 302
Disability, n (%)	1 (0.1)	9 (4)	10 (3)
High risk, n (%)	11 (10)	19 (10)	30 (10)
Pregnant, n (%)	10 (9)	9 (4)	19 (6)
Quarantining, n (%)	44 (38)	38 (20)	82 (27)
Acquired COVID-19, n (%)	8 (7)	33 (18)	41 (14)

Methods: A voluntary, anonymous, web-based survey was administered in English, Spanish, or French from 8/19/20 to 10/5/20. Adult and pediatric rheumatology trainees worldwide who were in training in 2020 were invited to participate via social media and email. Using multiple choice questions and Likert scales, we assessed the impact of COVID-19 on trainee well-being.

Results: The 302 rheumatology trainees who responded were from 33 countries, 116 (38%) from the United States (US); rest of the world (ROW) data includes trainees from Europe (87), Asia (50), South America (21), Canada (12),

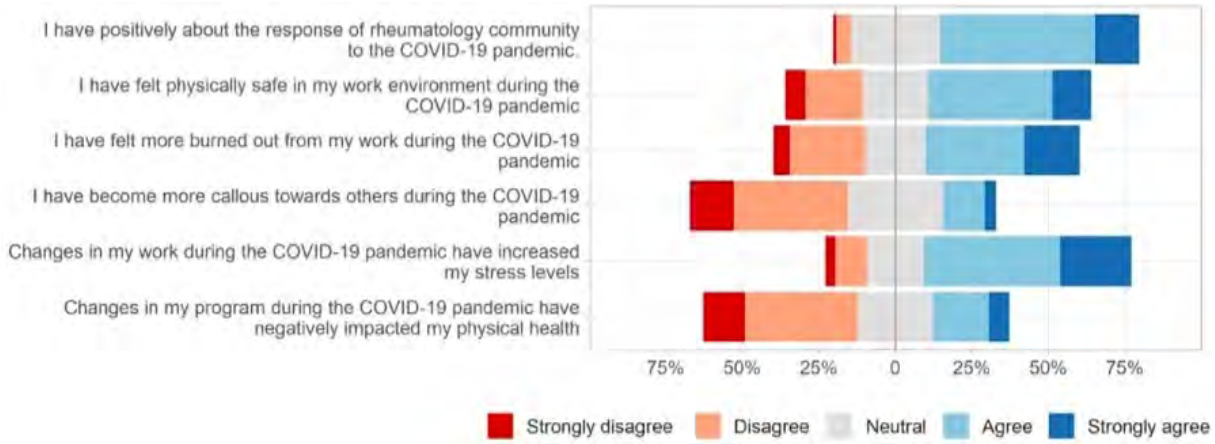

Figure 1. Rheumatology trainee perceptions of pandemic impact.

Australia (8), and Africa (4). The regional distribution of the US trainees is shown in Table 1. The majority of both US and ROW respondents were adult rheumatology trainees (74% and 89%, respectively).

Globally, 30 respondents (10%) reported having health condition(s) putting them at perceived high risk for severe COVID-19; 41 trainees (14%) reported having COVID-19 (Table 2). Seventy-five trainees (25%) reported a negative impact of work changes on their physical health, while 68% (204) reported an increase in stress levels and 50% (151) reported feeling burned out (Figure 1). Less than 20% (52, 17%) reported feeling more callous towards others, a feature of burnout. Compared to US trainees, trainees in ROW more frequently reported that the pandemic negatively impacted their physical health (10% of US vs 34% of ROW trainees, $p < 0.05$). No significant differences were observed between US trainees and ROW in burnout, stress, or feeling more callous towards others.

Trainees globally reported their perceptions of their programs and rheumatology as positive: 66% (198) reported feeling supported by their training program, 72% (212) felt positive about their career choice, and 65% (190) felt positive about the response of the rheumatology community.

Conclusion: We previously reported several negative impacts of the COVID-19 pandemic on rheumatology education and clinical training. The pandemic has also negatively affected rheumatology trainees' physical health, stress levels, and burnout, which should be recognized when supporting trainees post-pandemic. A higher proportion of ROW trainees reported a negative impact of the pandemic on their physical health compared to US trainees, perhaps due to COVID hotspot areas or differences in redeployment requirements. Our survey demonstrates that a large number of trainees feel burned out (52%), compared to 28% of trainees reported feeling burned out in a survey performed before the pandemic[1]. Reassuringly, the majority feel supported by their training program and their perceptions of their choice of career remain positive.

Abstract Number: 0486

A Practical Approach to Competency-based Evaluations and Milestone Mapping for Adult Rheumatology Fellowship Programs

Grant hughes[1], Sarah Chung[1], Elizabeth Wahl[2], Jenna Thomason[1], Bernard Ng[3], Ingeborg Sacksen[4] and Alison Bays[1], [1]University of Washington, Seattle, WA, [2]VA Puget Sound Healthcare System, Seattle, WA, [3]Rheumatology Section, VA Puget Sound HCS, University of Washington, Seattle, WA, [4]University of Washington, Bellingham, WA

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Abstracts: Professional Education (0484–0487)
Session Type: Abstract Session
Session Time: 2:00PM–3:00PM

Background/Purpose: The American College of Rheumatology has developed 14 Entrustable Professional Activities (EPAs) for Adult Rheumatology that define broad clinical competency goals for fellowship. At the same time, the Accreditation Council for Graduate Medical Education (ACGME) requires programs to assess and report fellow progress toward a set of comprehensive training Milestones. While these tools provide a helpful framework for guiding and monitoring fellow progress, they are either too general (EPAs) or too comprehensive (Milestones) to serve as ready-made assessment tools for individual clinical rotations. Here, we describe a strategy for creating practical rotation-specific assessment tools that reflect EPAs and produce useful Milestone data.

Methods: In academic year (AY) 18/19, clinician-educator faculty/senior fellows and site directors from each of 3 training hospitals at a large, urban, university-based adult rheumatology program were asked to craft evaluation objectives for continuity clinic and inpatient consult rotations. Objectives were 1) EPA-representing, 2) task-oriented, 3) readily observable, and 4) frequently or uniquely observed during the rotation. Teams also mapped each objective to Internal Medicine Subspecialty Milestones. A Milestone was mapped to an objective if it met 2 or more of the following: 1) it covered all/most task activities; 2) was critical to task; 3) was unique to task; or 4) was not better represented by another objective (for any rotation). Objectives and mapping were reviewed and approved by the Program Evaluation Committee. Using these objectives, fellows were evaluated every 1 – 2 months using a 5-point competency-based scale. Evaluations (scores + comments) were made available to fellows in real time. For semi-annual reviews, each Milestone level was calculated from the average of scores of all mapped objectives and verified/adjusted by the Clinical Competency Committee (CCC). Fellow perception of evaluation process was assessed via anonymous internal and ACGME surveys of our program.

Results: We developed 9 – 13 objectives for each of six core clinical rotations (Table 1) and mapped them to Milestones. The new evaluation objectives and mapping algorithm were introduced in AY 19/20. Based on internal anonymous surveys, fellow satisfaction with the evaluation process increased from 4.0±0.8 out of 5.0 to 4.8±0.4 out of 5.0. On anonymous ACGME surveys, fellow perception of evaluation processes in general rose from 78.6% compliant in AY 18/19 to 95.8% compliant in AY 20/21. Analysis of Milestone maps and Milestone performance trends over

Table 1. Example of EPA-reflecting, task-oriented evaluation objectives for a continuity clinic rotation (county hospital). For select objectives, evaluator prompts are shown in italics. Dates in parentheses indicate expected time to achieve competence

Accurately diagnose a patient presenting with systemic inflammatory disease. *In this context, consider the fellow's ability to gather and interpret relevant primary medical data; acquire an accurate and appropriately detailed history; perform an appropriately detailed physical exam; demonstrate effective diagnostic reasoning (e.g., framing of problem, assembling an appropriately broad and prioritized differential diagnosis, avoidance of diagnostic pitfalls); and recommend/order appropriate diagnostic tests. (12 months)*
Accurately diagnose a patient presenting with inflammatory arthritis. *(prompt not shown)*
Manage the care of a patient with SLE or other systemic inflammatory disease. *In this context, consider the fellow's ability to gather and interpret relevant primary medical data; effectively acquire an interim history and synthesize information; perform an appropriately detailed physical examination; recognize and address co-morbidities; choose appropriate diagnostic and monitoring tests; formulate an appropriate and evidence-based therapeutic plan; effectively communicate assessment and recommendations to patient; address patient's concerns; effectively educate patient/family; recognize and address barriers to therapeutic relationship; ensure appropriate follow-up; and communicate effectively with primary care provider and relevant specialists. (18 months)*
Manage the care of a patient with rheumatoid arthritis or chronic inflammatory arthritis syndrome. *(prompt not shown)*
Perform a procedure (e.g., arthrocentesis, or injection of tendon, joint, or bursa) and analyze synovial/bursal fluid. *(prompt not shown)*
Prescribe immunosuppressive therapy/chemotherapy for a patient with chronic autoimmune/inflammatory disease. *(prompt not shown)*
Effectively utilize interpreters and cultural liaisons to perform a clinic visit. *(prompt not shown)*
For an individual patient, identify and facilitate solutions for financial, social, cultural, or physical barriers to receiving rheumatology care. *(prompt not shown)*
Perform pre- and post-visit (non-visit) components of an outpatient consultation. *(prompt not shown)*
Accurately diagnose and treat a patient with regional/focal musculoskeletal pain. *(prompt not shown)*
Effectively manage rheumatology care of continuity clinic patients while not in clinic. *In this context, consider the fellow's ability to assume professional responsibility for all assigned patients; arrange for timely and appropriate patient follow-up; develop and utilize a system for obtaining, reviewing, and responding to test results between visits; communicate with patients, staff, and other care providers in a timely and effective fashion when not in clinic; appropriately sign out care of continuity clinic patients when transitioning off-duty (e.g., weekends, leave) (6 months); appropriately document and bill for prolonged services and telephone encounters before/after visits (24 months).*
Practice preventive medicine in a patient with chronic rheumatic disease. *(prompt not shown)*
Improve clinical performance based on feedback, evaluation, and practice data. *(prompt not shown)*

time identified some gaps in overall assessment and areas of curricular strength/weakness (not shown). We are now mapping objectives to the new ACGME Milestones for adult rheumatology (Table 2).

Conclusion: We describe a practical approach for developing rotation-specific, task-oriented evaluation objectives that can generate Milestone data useful for tracking progress of individual trainees as well as curriculum effectiveness. In addition, fellow satisfaction with the evaluation process appeared to improve. We believe our approach is highly adaptable and could be useful to a wide range of training programs.

Table 2. Proposed Rheumatology Milestone mapping of evaluation objectives from Table 1 (continuity clinic, county hospital). Note that some Milestones did not meet mapping criteria with any objective. PC = patient care; MK = medical knowledge; SBP = systems-based practice; PBLI = practice-based learning and improvement; P = professionalism; ICS = interpersonal and communication skills

A Needs Assessment for the Transition into a Rheumatology Program Director Role: Survey of Current and Former Rheumatology Program Directors

Rachel Wolfe[1], **Fotios Koumpouras**[2], Anisha Dua[3], Philip Seo[4], Simon Helfgott[5] and Beth Jonas[6], [1]Wake Forest Baptist Health, Winston-Salem, NC, [2]Yale School of Medicine, New Haven, CT, [3]Northwestern University, Chicago, IL, [4]Johns Hopkins University, Baltimore, MD, [5]Brigham and Women's Hospital, Harvard Medical School, Boston, MA, [6]University of North Carolina at Chapel Hill, Chapel Hill, NC

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Abstracts: Professional Education (0484–0487)

Session Type: Abstract Session

Session Time: 2:00PM–3:00PM

Background/Purpose: Clinical educators taking on the new role as program director (PD) must have the time and resources to learn about all the processes (e.g., accreditation, assessment) that are essential to the effective management of a fellowship training program. Lack of preparation can lead to inadequate performance and dissatisfaction with the role. We conducted a needs assessment of current and former rheumatology PDs to determine the type of

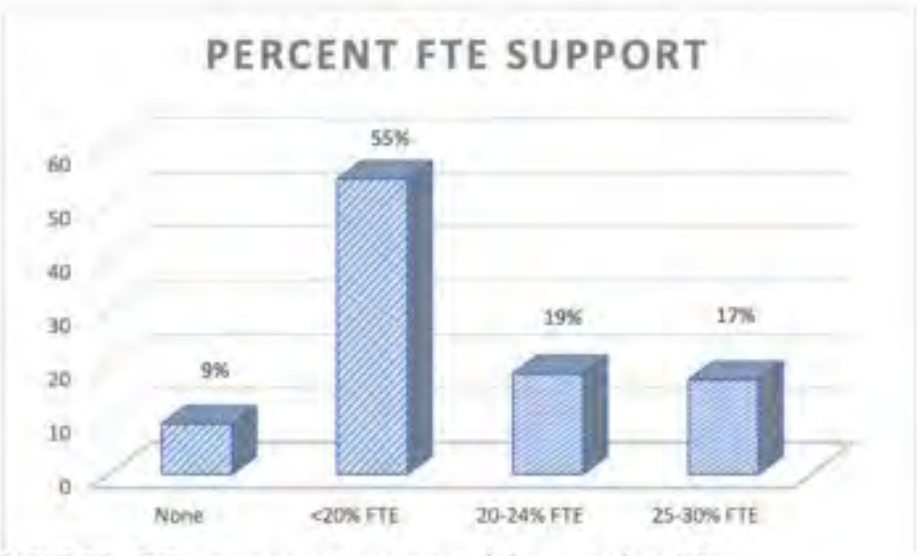

FIGURE 1. FTE support among surveyed rheumatology PDs.

support needed to become an effective rheumatology PD. The survey asked variables that might affect their transition to a leadership role (such as previous experience, fiscal and mentor support), the enthusiasm for rheumatology-specific PD mentorship, overall satisfaction with the transition, and specific resources that would have eased the transition.

Methods: An electronic survey was emailed to 186 current and former rheumatology program directors currently on the American College of Rheumatology's Committee on Training and Workforce listserv. Survey question types included single response, multi-select and free response.

Results: Ninety (48.4%) current or former rheumatology PDs responded to the survey. Of the 90 responses, 86 (46.2%) were completed beyond the demographics questions. Respondents to the survey were evenly split between

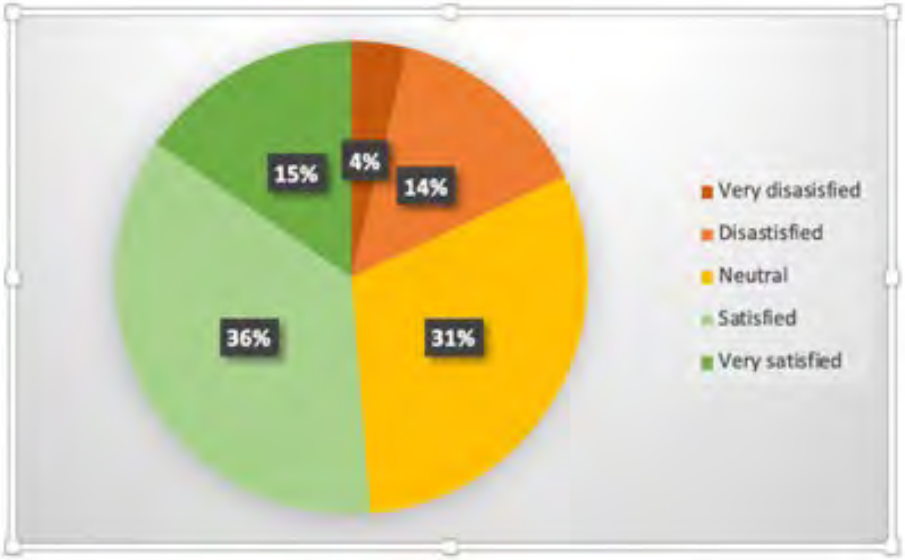

Figure 2.
Satisfaction with process of transitioning to PD role (78 total respondents)

newer and more experienced PDs; 50% of respondents had been a rheumatology PD for 5 years or less in the rheumatology PD role whereas 50% of respondents had been in this role for more than 5 years. Full-time equivalent (FTE) support for PDs varied considerably, with the majority of PDs (64%) receiving less than 20% FTE for their role as program director. Eight (9 %) respondents did not receive any support for their role as PD. Of those who completed a question on their satisfaction with the transition process, only 12 (15.7%) respondents were very satisfied with their transition to becoming a PD whereas 49% (38 out of 78) where neutral, dissatisfied or very dissatisfied with the transition (Fig. 1). There was overwhelming support (88%) for a transition mentorship program for new PDs. Program directors were most interested in a curriculum that included a practical discussion of how to run a program (86.9%), developing core curriculum (46.5%) and assessment of fellows (46.5%).

Conclusion: Based on our survey of PDs, we identified several areas suitable for innovation. A mentor program for new PDs was desired by most, indicating the need for additional support and training during the PD transition period. Furthermore, FTE support was found to be less than that outlined in the Accreditation Council for Graduate Medical Education (ACGME) common program requirements (at least 20%) for the majority of the rheumatology PDs. These results should inform key stakeholders on the need for more support for PDs to include mentorship, educational content and fiscal support.

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Abstracts: Spondyloarthritis Including PsA – Treatment I: Emerging Therapies (0488–0491)

Session Type: Abstract Session

Session Time: 2:00PM–3:00PM

Background/Purpose: Brepocitinib is a small-molecule tyrosine kinase 2/Janus kinase 1 inhibitor that has shown promising results in an oral formulation for plaque psoriasis and alopecia areata and is under investigation for PsA.

Methods: This Phase 2b, randomized placebo (PBO)-controlled trial compared the efficacy and safety of once-daily (QD) oral doses of brepocitinib (10, 30, and 60 mg) vs PBO in patients (pts) with active PsA (NCT03963401). Eligible pts were aged 18–75, met CASPAR (ClASsification criteria for Psoriatic ARthritis), and had active PsA despite treatment or intolerance to NSAIDs/DMARDs; stable doses of conventional synthetic DMARDs were allowed, and up to 30% of pts with prior use of one TNF inhibitor were allowed. Pts were randomized (2:2:1:2) to receive brepocitinib 60

Table 1. ACR20/50/70, MDA, and PASI75/90 response rates at Week 16 and Week 52

	Week 16 (initial dose)				Week 52	
	PBO (N=67)	Brepocitinib 10 mg QD (N=31)	Brepocitinib 30 mg QD (N=60)	Brepocitinib 60 mg QD (N=59)[a]	Brepocitinib 30 mg QD (N=108)	Brepocitinib 60 mg QD (N=110)

PASI90 response, % (n)	12.2 (5)	33.3 (7)*	33.3 (13)*,**	53.9 (21)*,**	53.7 (36)	46.0 (34)

Missing data were treated as non-responses.

[a]One pt was excluded because they missed their Week 16 visit due to COVID-19.

[b]Continuity correction was applied for an observed 0 response rate.

[c]Analysis population of PASI endpoints consisted of a subgroup of pts with baseline BSA ≥3% and PASI >0 (65% of the total population).

*The 1-sided raw p-value for the treatment comparison vs PBO was <0.05.

**The treatment group showed statistically significant treatment effect vs PBO under the pre-specified study testing procedure.

Per pre-specified study testing procedure, the primary endpoint (ACR20 at Week 16) was tested based on the Dunnett's method, with an adjusted one-sided p-value <0.05 defined as a statistically significant treatment effect vs PBO. Other endpoints of interest were tested in the order of PASI75 → ACR50 → PASI90 → PASI100 → HAQ-DI hierarchically under the significance level of 5% (1-sided) only if a dose group was tested significantly for the primary endpoint.

HAQ-DI, HAQ – Disability Index; MDA, minimal disease activity; PASI75/90/100, Psoriasis Area and Severity Index 75/90/100; PBO, placebo; pt, patient; QD, once daily.

mg QD, 30 mg QD, 10 mg QD, or PBO for 16 weeks, advancing to brepocitinib 30 or 60 mg QD from Week 16 to 52. Primary endpoint: pts meeting ACR20 response at Week 16. Selected secondary, exploratory, and safety endpoints are reported.

Results: A total of 218 pts were randomized and treated. Demographics and baseline disease characteristics were generally similar across groups, and the majority of pts (93.1%) completed the Week 16 visit. At Week 16, significantly higher proportions of pts in the brepocitinib 30 and 60 mg QD groups achieved an ACR20 response vs PBO (Table 1). Brepocitinib 30 and 60 mg QD groups achieved significantly higher response rates vs PBO, starting as early as Week 4, and response rates continued to increase to Week 16 for ACR20/50/70, Minimal Disease Activity, and Pso-

Both adjudicated opportunistic infections were herpes zoster

AE, adverse event; PBO, placebo; pt, patient; QD, once daily; SAE, serious adverse event; SOC, system organ class.

riasis Activity and Severity Index 75/90. Responses were maintained to Week 52 (Table 1). Brepocitinib 30 and 60 mg QD were associated with significant improvements in disease activity and quality of life outcomes (e.g. fatigue, functioning) at Week 16 vs PBO (Table 2). Improvements in dactylitis and Spondyloarthritis Research Consortium of Canada enthesitis resolution were observed at Week 16 in the brepocitinib 60 mg group vs PBO; resolution continued to improve or remain steady through Week 52 in the 30 mg and 60 mg groups, respectively. In the 16-week treatment period, there were more pts with adverse events (AEs) in the brepocitinib 30 mg (n=33) and 60 mg (n=40) QD groups vs PBO (n=32). Most AEs were mild in severity (165/250 [66%]) at Week 16. Key safety findings are shown in Table 3. There were 17 serious AEs (SAEs) in 12 pts during this study, including 7 SAEs in 6 pts through Week 16. The overall safety profile over 52 weeks was consistent with approved Janus kinase inhibitors, including cases of serious herpes zoster infections and changes in select lab parameters. There were no major adverse cardiovascular events, venous thromboembolic events, or deaths.

Conclusion: Brepocitinib demonstrated superior efficacy vs PBO across numerous PsA disease domains in pts with active PsA at Week 16, with improvements in more refractory domains continuing over 52 weeks. There were more AEs in the brepocitinib groups vs PBO over 16 weeks. The overall safety of brepocitinib was consistent with other approved Janus kinase inhibitors.

CC-99677: A Novel, Oral, Selective MK2 Inhibitor with Sustainable Multi-Cytokine Inhibition for the Treatment of Ankylosing Spondylitis and Other Inflammatory Diseases

Kofi Mensah[1], Rajula Gaur[1], Jamie Connarn[1], Michael Thomas[1], Liangang Liu[1], Stuart Mair[2], Francisco Ramírez-Valle[1] and Maria Palmisano[1], [1]Bristol Myers Squibb, Princeton, NJ, [2]Quotient Sciences, Nottingham, United Kingdom

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Abstracts: Spondyloarthritis Including PsA – Treatment I: Emerging Therapies (0488–0491)
Session Type: Abstract Session
Session Time: 2:00PM–3:00PM

Background/Purpose: Inhibitors of p38 are associated with tachyphylaxis in patients with RA and other inflammatory diseases, where early reduction in ex vivo production of cytokines, such as TNF-α, or endogenous inflammatory markers, such as CRP, did not persist despite continued treatment. Thus, p38 inhibitors have not advanced in clinical development. Targets downstream of p38 have been identified to avoid these limitations. The mitogen-activated protein kinase-activated protein kinase-2 (MK2) pathway is activated downstream of p38, and activation of MK2 increases the stability and translation of mRNA of proinflammatory factors (e.g., TNF-α, IL-17, IL-6). CC-99677 is a novel, irreversible, covalent MK2 inhibitor. Here, we report data from the first-in-human multiple ascending-dose study to characterize the safety, pharmacokinetics (PK), and pharmacodynamics (PD) in healthy volunteers dosed with CC-99677.

Methods: A phase 1, randomized, double-blind, placebo-controlled study (NCT03554993) was performed involving 37 healthy adult volunteers who were enrolled into 5 dose-level cohorts ranging from 10 to 150 mg of CC-99677 or placebo with 3:1 randomization. Participants were dosed daily for 14 days. The primary outcome of this study was safety and tolerability of multiple daily doses of CC-99677. Secondary and exploratory outcomes included assessment of the plasma CC-99677 PK profile and evaluation of the PD effects of CC-99677 as measured by MK2 target occupancy and ex vivo inhibition of inflammatory cytokines in participant whole blood.

Results: Multiple doses of CC-99677 up to 150 mg for 14 days were safe and well tolerated by the healthy adult subjects in this study. The multiple-dose PK characteristics of CC-99677 showed a linear, dose-proportional increase in exposure from 10 to 150 mg with a once-daily dosing schedule over 14 days. CC-99677 peak concentration (C_{max}), time to reach C_{max} (T_{max}), and area under the curve from time 0 to the time of last measurement (AUC_{0-t}) were similar on day 1 and day 14 (last day of dosing) across the dose range of 10 to 150 mg, suggesting limited or no accumulation of CC-99677 with repeat once-daily dosing. There was a cumulative increase in target engagement with once-daily administration of CC-99677 for 14 days, reaching steady-state levels by day 8. Daily treatment resulted in dose-dependent increases in target engagement between 10 and 120 mg and plateauing at the 120- and 150-mg dose levels. Sustained reduction during the dosing period in TNF-α and other cytokine and chemokine production was observed in ex vivo stimulated blood from subjects who received once-daily doses >10 mg CC-99677 for 14 days.

Conclusion: Administration of CC-99677 was safe and well tolerated, resulted in linear PK, and demonstrated sustained reduction of ex vivo whole blood TNF-α, IL-6, and chemokine synthesis. The lack of tachyphylaxis in human cells exposed to CC-99677, compared with previous disappointing results targeting the p38 axis, is encouraging. Thus, CC-99677 inhibition of MK2 is a promising approach for the treatment of inflammatory diseases. Phase 2 studies of CC-99677 in patients with spondyloarthritis are planned.

Biomarker Changes with Selective Tyrosine Kinase 2 Inhibitor, Deucravacitinib, in PsA: Effects on Disease Markers and Tyrosine Kinase 2− versus Janus Kinase 1/2/3−mediated Pathways

Oliver FitzGerald[1], Dafna Gladman[2], Philip Mease[3], Christopher Ritchlin[4], Josef Smolen[5], Lu Gao[6], Sarah Hu[6], Miroslawa Nowak[6], Subhashis Banerjee[6], Ian Catlett[6] and Xiang Guo[6], [1]Conway Institute for Biomolecular Research, University College Dublin, Dublin, Ireland, [2]Schroeder Arthritis Institute, Krembil Research Institute, Toronto Western Hospital, Toronto, ON, Canada, [3]Swedish Medical Center/Providence St. Joseph Health and University of Washington, Seattle, WA, [4]Division of Allergy, Immunology, and Rheumatology, School of Medicine and Dentistry, University of Rochester Medical Center, Rochester, NY, [5]Medical University of Vienna, Vienna, Austria, [6]Bristol Myers Squibb, Princeton, NJ

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Abstracts: Spondyloarthritis Including PsA – Treatment I: Emerging Therapies (0488–0491)

Session Type: Abstract Session

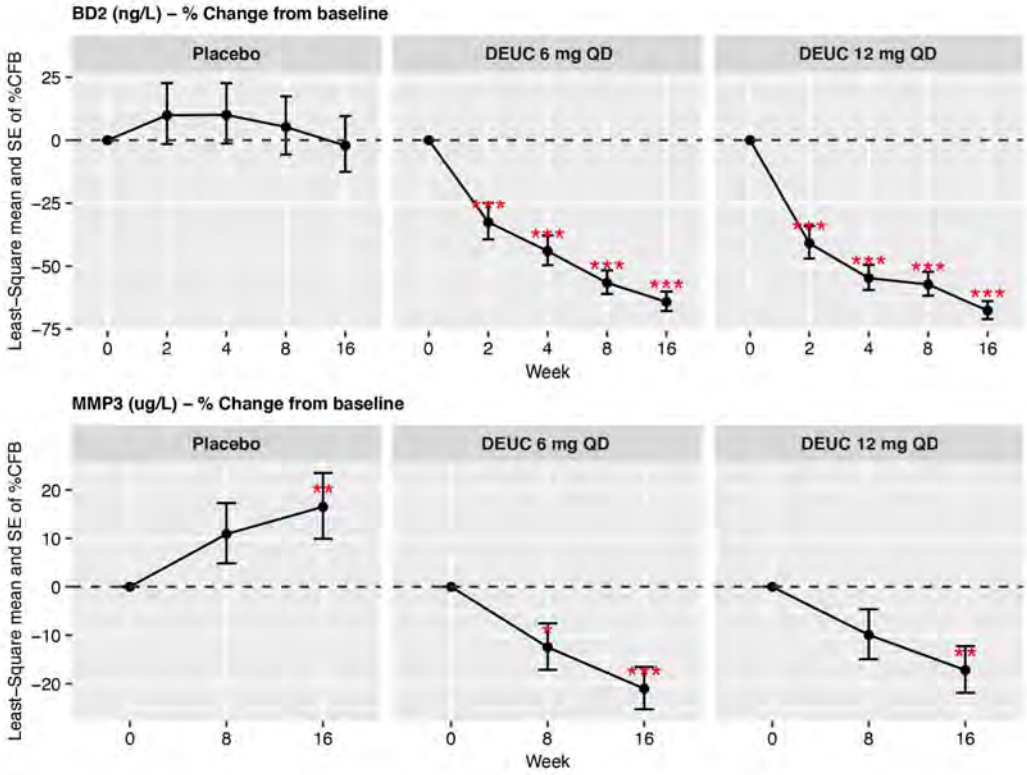
Session Time: 2:00PM–3:00PM

Background/Purpose: Deucravacitinib is a novel, oral, selective tyrosine kinase 2 (TYK2) inhibitor with a unique mechanism of action that has demonstrated efficacy in patients (pts) with psoriasis and PsA. TYK2 selectively mediates cytokine signaling restricted to specific inflammatory pathways (eg, IL-23, IL-12, and Type I interferons), whereas Janus kinase (JAK) 1/2/3 signaling is involved in broader immune responses, as well as in hematopoietic pathways and in lipid metabolism. Use of JAK1/2/3 inhibitors is associated with signature changes in laboratory variables in the blood. The current study assessed the effects of deucravacitinib on biomarkers of TYK2- vs JAK1/2/3–mediated pathways, as well as of joint disease, in patients with PsA.

Methods: A double-blind Phase 2 trial (NCT03881059) enrolled 203 pts with PsA randomized 1:1:1 to deucravacitinib 6 mg once daily (QD), 12 mg QD, or placebo (PBO).[1] Levels of biomarkers of interest and lymphocyte subsets in the blood were measured by immunoassays, flow cytometry, and standard methods from baseline (BL) through Week 16.

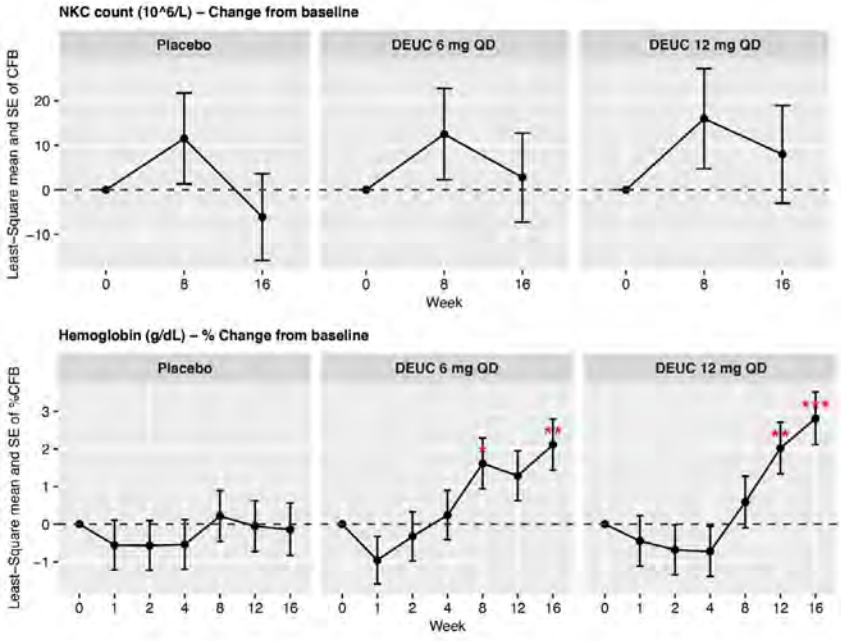
Results: BL serum concentrations of IL-23−driven IL-17A and IL-17−induced β-defensin 2 and IL-19 were elevated and significantly correlated with severity of skin involvement by Psoriasis Area and Severity Index scores ($\rho \geq 0.4$; $P < 0.0001$). Both deucravacitinib doses, but not PBO, reduced IL-17A, β-defensin 2 (Figure 1), and IL-19 over time. Serum levels of IFN-I−driven chemokine ligand 9 (CXCL9) and CXCL10, and Type I/II IFN-inducible proteins, either remained stable or decreased after deucravacitinib treatment vs PBO. TNF-α levels remained stable in deucravacitinib-treated pts but increased in the PBO group. At BL, the neoepitope marker of Type IV collagen degradation mediated by MMPs (C4M) was positively associated with Psoriatic Arthritis Disease Activity Score (PASDAS; $\rho=0.29$; $P < 0.0001$). BL MMP3 concentrations showed modest and positive correlations with swollen joint count ($\rho=0.24$; $P < 0.001$), PASDAS ($\rho=0.21$; $P < 0.01$), and Disease Activity Index in Psoriatic Arthritis ($\rho=0.19$; $P < 0.01$). MMP3 (Figure 1) and C4M were suppressed in deucravacitinib- but not PBO-treated pts. NK cell counts remained stable and small increases in hemoglobin were observed after treatment with deucravacitinib (Figure 2). There were no clinically meaningful changes in mean levels of serum cholesterol, creatinine, neutrophils, and platelets over time with deucravacitinib treatment.

Figure 1. Effects on levels of BD2 and MMP3 by deucravacitinib and placebo



*P<0.05; **P<0.01; ***P<0.001. BD2, β-defensin 2. CFB, change from baseline; DEUC, deucravacitinib.

Figure 2. NK cell counts and hemoglobin profiles in deucravacitinib- and placebo-treated patients



*P<0.05; **P<0.01; ***P<0.001. CFB, change from baseline; DEUC, deucravacitinib.

Conclusion: Deucravacitinib suppressed biomarkers of IL-23/IL-17 and IFN-I pathways concomitant with clinical symptom improvements in deucravacitinib-treated PsA pts. Joint damage is associated with an increase in MMP3, and suppression of C4M and MMP3 by deucravacitinib suggested an improvement in extracellular matrix turnover upon TYK2 pathway inhibition. Differentiation of deucravacitinib from JAK1/2/3 inhibitors was evidenced by the lack of adverse effects of deucravacitinib on hematologic and serum chemistry variables that are known to change with JAK1/2/3 inhibitors.

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Abstracts: Spondyloarthritis Including PsA – Treatment I: Emerging Therapies (0488–0491)

Session Type: Abstract Session

Session Time: 2:00PM–3:00PM

Background/Purpose: Bimekizumab (BKZ), a monoclonal IgG1 antibody that selectively inhibits both interleukin (IL)-17F and IL-17A, has been demonstrated to be efficacious and well tolerated in patients (pts) with ankylosing spondylitis (AS) treated for up to 156 weeks (wks).[1–3] We report 3-year (yr) interim safety and efficacy of BKZ in pts with active AS from a 1-yr phase 2b study (BE AGILE; NCT02963506) and its ongoing 4-yr open-label extension (OLE; NCT03355573).

Table. Safety for exposure to bimekizumab in BE AGILE and the OLE

	BE AGILE Weeks 0–48			OLE Weeks 48–156
n (%) [EAIR/100 PY]	BKZ 160 mg [a] (n=149; 114.2 PY)	BKZ 320 mg [a] (n=150; 119.6 PY)	Total (N=303; 261.3 PY)	Total (N=255; 554.7 PY)

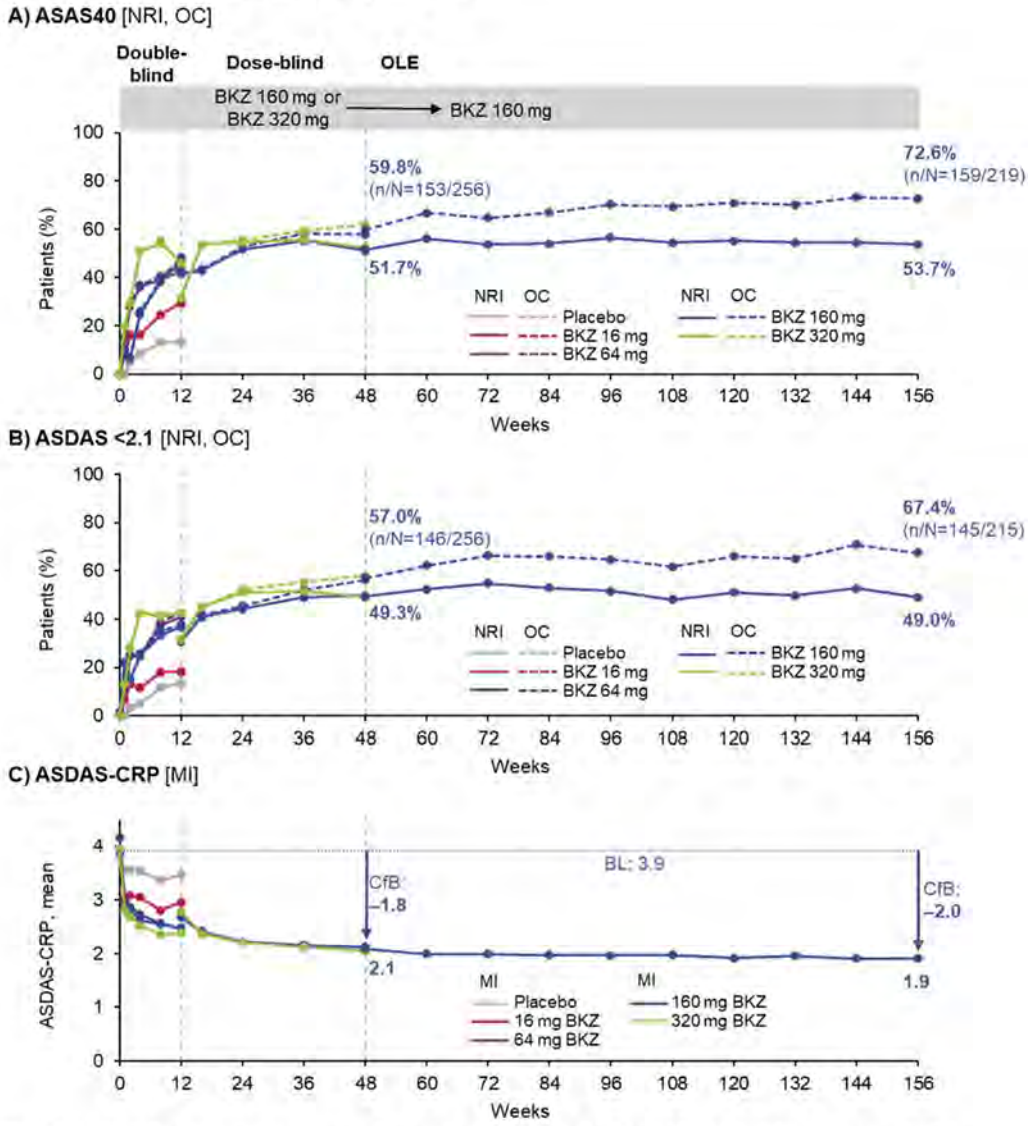
BE AGILE (N=303) and OLE (N=255) safety sets (patients who received ≥1 dose of BKZ during the relevant study period). All patients received BKZ 160 mg Q4W during the OLE (Wks 48–156) after completing BKZ 160 mg or 320 mg Q4W at Wk 48 in BE AGILE. [a] Data are shown for Wks 0–48 by dose-blind treatment group (i.e. patients received the indicated dose during the dose-blind period [Wks 12–48]); [b] All *Candida* infections were mild to moderate, none were systemic; [c] Anterior uveitis was not a TEAE of special monitoring in this study and is included as an extra-musculoskeletal manifestation. There was one death in BE AGILE (cardiac arrest) and one in the OLE (road traffic accident); neither was considered treatment-related. AS: ankylosing spondylitis; BKZ: bimekizumab; EAIR: exposure-adjusted incidence rate; IBD: inflammatory bowel disease; OLE: open-label extension; PY: patient-years; Q4W: every 4 wks; SIB: suicidal ideation and behavior; TEAE: treatment-emergent adverse event; wk: week.

Methods: The BE AGILE study design has been described previously.[1] Following the 12-wk double-blind, placebo-controlled dose-ranging period, pts received BKZ 160 mg or 320 mg every 4 wks (Q4W) in the dose-blind period to Wk 48. Pts completing Wk 48 were eligible to enter the OLE where all pts received BKZ 160 mg Q4W. We report results following a total of 3 yrs of treatment. Treatment-emergent adverse events (TEAEs) are reported separately for BKZ exposure in BE AGILE and the OLE (safety sets). Efficacy outcomes are reported primarily for the dose-blind set.

Figure 1. Efficacy responses to Week 156

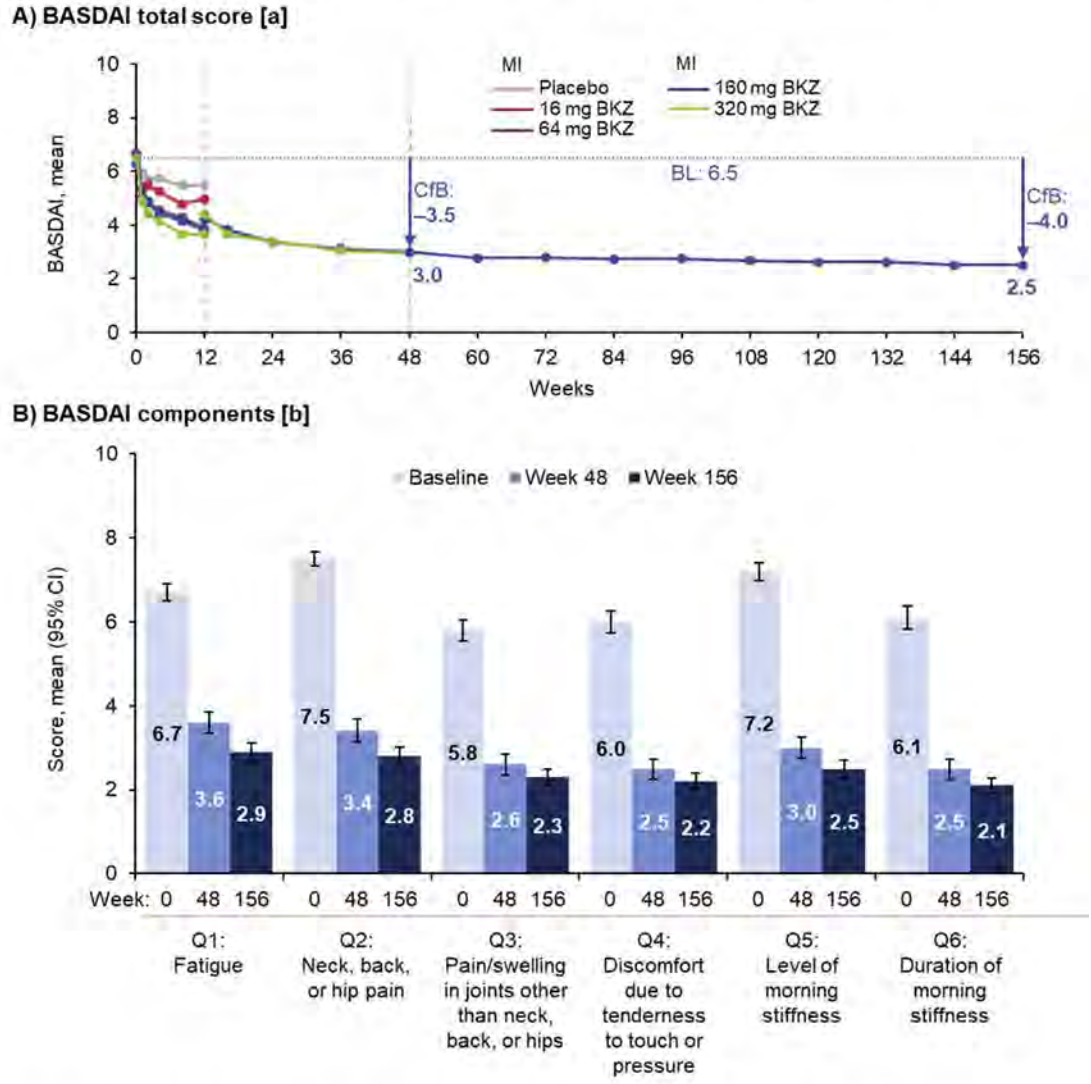


BE AGILE FAS (all randomized patients who received ≥1 dose of BKZ and had a valid measurement of the ASAS components at baseline; N=303) for Wks 0–12; dose-blind set (patients who started the dose-blind period at Wk 12 and received ≥1 dose of BKZ during the dose-blind period, including the dose at Wk 12; N=296) for Wks 12–156. Data (reported as NRI and OC, or MI) are shown for all timepoints from BE AGILE baseline to Wk 156; in the NRI analyses, patients who did not enter the OLE were considered non-responders from Wk 48 onwards. Patients randomized to placebo, BKZ 16 mg or BKZ 64 mg are shown through the dose-blind period following re-randomization at Wk 12 to either BKZ 160 mg or 320 mg. For Wks 48–156, data are shown for all patients entering the OLE; these patients received BKZ 160 mg after completing BKZ 160 mg or 320 mg in Wks 12–48 of BE AGILE. For ASDAS-CRP, baseline mean score (blue dotted line) is shown for the dose-blind set. ASAS: Assessment of SpondyloArthritis international Society; ASAS40: ASAS 40% response; ASDAS: Ankylosing Spondylitis Disease Activity Score; BKZ: bimekizumab; BL: baseline; CfB: change from baseline; CRP: C-reactive protein; MI: multiple imputation; NRI: non-responder imputation; OC: observed case; OLE: open-label extension; wk: week.

Analyses utilized non-responder imputation (NRI) and observed case (OC) methodology, or multiple imputation (MI); for NRI, pts who did not enter the OLE were considered non-responders from Wk 48 onwards.

Results: 296/303 (97.7%) pts randomized at BE AGILE study baseline (BL) entered the dose-blind period at Wk 12; 262/303 (86.5%) pts completed Wk 48 on BKZ. At Wk 48, 256/303 (84.5%) pts entered the OLE, of whom 255 received BKZ 160 mg Q4W; 224/303 (73.9%) pts completed Wk 156. For Wks 0–48 (and the OLE), exposure-adjusted

Figure 2. BASDAI scores from baseline to Week 156 (multiple imputation)



[a] BE AGILE FAS (N=303) for Wks 0–12 and dose-blind set (N=296) for Wks 12–156; [b] Dose-blind set (N=296) for all timepoints; data pooled across all treatment groups. All data reported for MI analyses. 256 patients had a BASDAI efficacy assessment on entering the OLE at Wk 48 and 217 patients had a BASDAI efficacy assessment at Wk 156. For BASDAI total score, patients randomized to placebo, BKZ 16 mg or BKZ 64 mg are shown through the dose-blind period following re-randomization at Wk 12 to either BKZ 160 mg or 320 mg. For Wks 48–156, data are shown for all patients entering the OLE; these patients received BKZ 160 mg after completing BKZ 160 mg or 320 mg in Wks 12–48 of BE AGILE. For BASDAI components, black bars show 95% CI. For BASDAI total score, baseline mean (blue dotted line) is shown for the dose-blind set. It is noted that, as components of the total BASDAI score, the BASDAI component scores are not independent secondary outcomes. BASDAI: Bath Ankylosing Spondylitis Disease Activity Index; BKZ: bimekizumab; BL: baseline; CfB: change from baseline; CI: confidence interval; MI: multiple imputation; OLE: open-label extension; wk: week.

incidence rates (EAIRs) per 100 pt-yrs were 186.2 (OLE: 110.8) for any TEAE, 5.1 (OLE: 5.9) for serious TEAEs, 1.5 (OLE: 1.1) for serious infections, and 7.5 (OLE: 2.8) for Candida infections (Table). Overall, EAIRs of TEAEs in the OLE remained stable or were lower than in Wks 0–48. The majority of Candida infections were oral candidiasis; all Candida infections were mild or moderate. EAIRs of inflammatory bowel disease, anterior uveitis, and injection site reactions were low across BE AGILE and the OLE (Table). In the NRI analyses, the percentage of pts achieving ASAS40 response or ASDAS < 2.1 was sustained from Wk 48 to Wk 156 (Figure 1A–B). Following substantial improvements from BL to Wk 48 in mean ASDAS-CRP (3.9 to 2.1) and BASDAI total score (6.5 to 3.0), responses were sustained

over a further 2 yrs of BKZ treatment to 1.9 and 2.5, respectively, at Wk 156 (Figure 1D & 2A). All BASDAI components demonstrated continued improvements in pt-reported fatigue, spinal pain, joint pain and swelling, discomfort due to tenderness to touch or pressure, and intensity and duration of morning stiffness (Figure 2B).

Conclusion: The long-term safety profile of BKZ in pts with AS was in line with previous observations, with no new safety signals identified after 3-yr BKZ exposure.[1–3] Efficacy was maintained and consistent over 3 yrs of BKZ treatment, highlighting the potential of dual inhibition of IL-17F and IL-17A in the treatment of AS.

Racial Differences in Glucocorticoid Use Among Medicaid Beneficiaries with Incident Systemic Lupus Erythematosus

Mia Chandler[1], Leah Santacroce[2], Karen Costenbader[3], Rishi Desai[4], Seoyoung Kim[2] and Candace Feldman[2], [1]Boston Children's Hospital, Brookline, MA, [2]Brigham and Women's Hospital, Boston, MA, [3]Brigham and Women's Hospital, Belmont, MA, [4]Brigham and Women's Hospital/Harvard Medical School, Boston, MA

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Abstracts: Healthcare Disparities in Rheumatology (0492–0495)
Session Type: Abstract Session
Session Time: 3:30PM–4:30PM

Background/Purpose: Glucocorticoids (GCs) are an integral part of systemic lupus erythematosus (SLE) treatment. Long-term use of GCs is associated with adverse effects. This study evaluated racial differences in GC use among individuals within the first year of SLE diagnosis.

Methods: Using Medicaid claims data (2000-2010) from 27 states, we identified individuals aged 18-65 years with incident SLE (≥3 SLE ICD-9 codes separated by ≥30 days with no SLE codes in the 24 months before the first code [index date]). We required 1 year of continuous enrollment following the index date and ≥1 prescription for oral or intravenous GCs during that year. We calculated the prednisone-equivalent glucocorticoid dose (GD) for each 30-day period for 1

Table 1. Baseline Characteristics of Medicaid Beneficiaries with Incident SLE and Glucocorticoid Use within the First Year Stratified by Trajectory

Characteristics	Overall Cohort at Baseline (N=6,323)	Overall Cohort (0- 6 Months)	Overall Cohort (6- 12 Months)	High Dose Trajectory (N=628)	Low Dose Trajectory (N=3593)	Uptrending Trajectory (N=1060)	Downtrending Trajectory (N=1042)

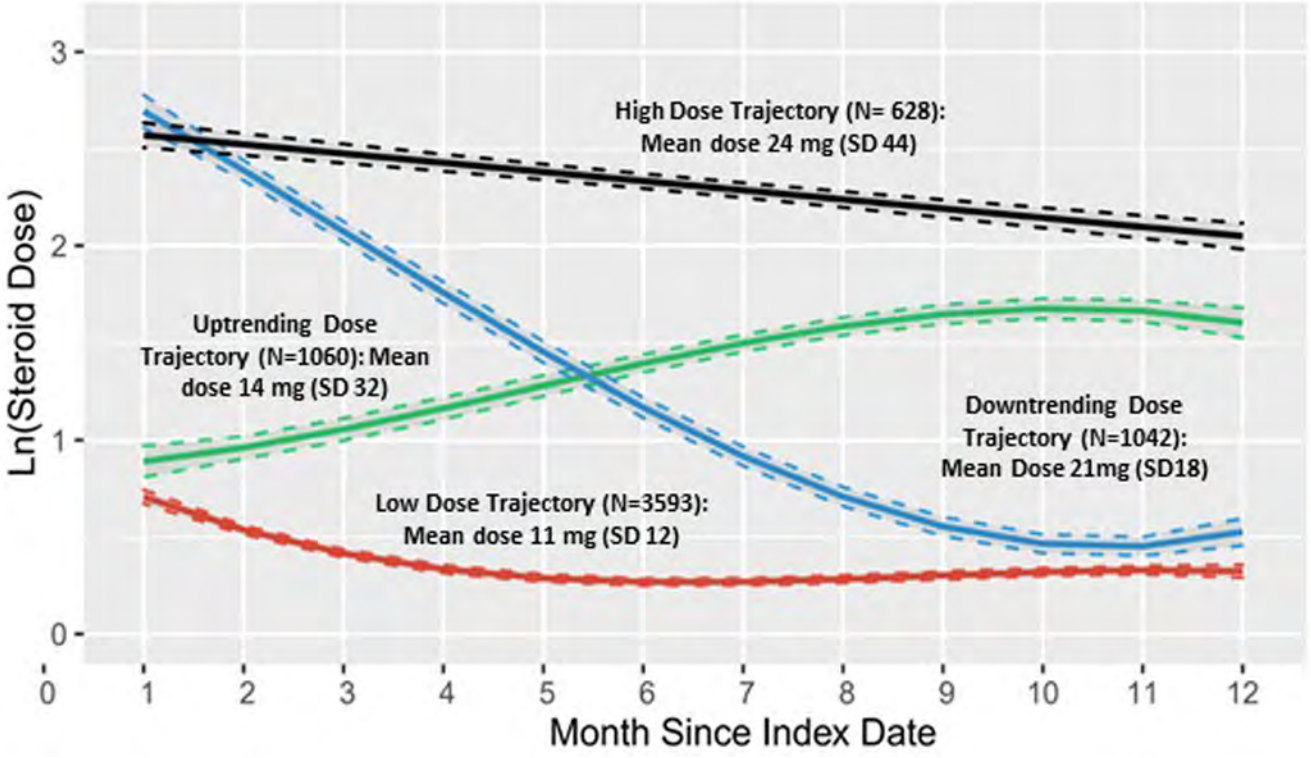

Figure 1. Trajectories of Glucocorticoid Use for Medicaid Beneficiaries with Incident SLE (N=6323).

year following the index date. We constructed group-based trajectory models (GBTMs) to identify dynamic patterns of GC use. We examined baseline demographics, medications, comorbidities, and SLE-related clinical manifestations (SLE risk adjustment index, Ward, MM. J Rheum, 2001), in the 1 year prior to the index date. We used multinomial logistic regression to estimate the odds of being in the highest vs. lowest trajectory (OR, 95% CI). We estimated GBTMs stratified by race/ethnicity and updated covariates at 6 and 12 months to understand differences in GC patterns.

Results: Among 11,280 adults with incident SLE, 6,323 (53%) received ≥1 prescription for GC during the 1-year follow-up period. The mean (SD) age was 37 (12), 5% were male, 30% identified as White, 45% Black, 18% Hispanic, and 4% Asian (**Table 1**). The overall mean (SD) daily prednisone-equivalent GD was 18 mg (33) for Black patients, 17 mg (39) for Hispanic, 17 mg (17) for Asian, and 14 mg (14) for White. A four-group trajectory model for GC use and dose provided the best fit for the data (**Fig 1**). The highest trajectory of persistent moderate-to-high dose GC users included 628 individuals (10%); the mean (SD) GD was 24 mg (44). The lowest trajectory included 3593 individuals (57%); mean (SD) GD 11 mg (12). Multinomial models adjusted for demographics demonstrated greater odds of belonging to the highest vs. lowest steroid trajectory for Black (OR 2.23, 95% CI 1.77-2.80), Hispanic (OR 1.95, 95% CI 1.48-2.56), and Asian (OR 2.56, 95% CI 1.63-4.02) individuals vs. White; after adjusting for comorbidities, medications, healthcare use, and the SLE risk adjustment index, the ORs remained similar. In GBTMs stratified by race/ethnicity, Black, Hispanic and Asian individuals vs. White had more individuals in the highest GD and use trajectories. Comparing the highest GD utilizers by race/ethnicity during 0-6 month and 6-12 month intervals post-index date, there were no differences in immunosuppressive use. Black individuals had fewer outpatient visits and received fewer vaccinations than White individuals.

Conclusion: In this population of Medicaid beneficiaries with incident SLE, >50% received GC, and of those, 26% received at least moderate GC doses during the first year. While Black, Hispanic and Asian individuals had more SLE-related manifestations, this alone may not explain these differences. Access to high-quality outpatient care may be a modifiable factor that could address high dose GC use across racial/ethnic groups.

Abstract Number: 0493

Hospitalization for SLE Flare Has Reduced over Two Decades in the United States: A Longitudinal Population-based Study

Ehizogie Edigin[1], Precious Eseaton[2], Chinenye Osuorji[3], Nneka Chukwu[4], Oluyemisi Amoda[5], Kolade Olabode[6] and Augustine Manadan[7], [1]Internal Medicine, John H Stroger Jr. Hospital of Cook County, Chicago, IL, [2]University of Benin, Benin, Nigeria, [3]Internal Medicine, Burrell College of Osteopathic Medicine, Las Cruces, NM, [4]Nuvance Health Internal Medicine Residency, Poughkeepsie, NY, [5]Internal Medicine, Brookdale University hospital and medical center, New York, NY, [6]College of Public Health, Kent State University, Kent, OH, [7]Rush University Medical Center, Chicago, IL

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Abstracts: Healthcare Disparities in Rheumatology (0492–0495)
Session Type: Abstract Session
Session Time: 3:30PM–4:30PM

Background/Purpose: Longitudinal data are limited on SLE flare hospitalizations. This study aims to study longitudinal trends of SLE flare hospitalizations in the last 2 decades in the United States (U.S) using national population data.

Table 1. Characteristics and longitudinal trends of hospitalizations for Systemic Lupus Erythematosus flare from 1998 to 2018 Abbreviations: SLE, Systemic Lupus Erythematosus; USD, United States Dollars, I: Incidence per 100,000 persons, CCI, Charleston comorbidity index. p<0.005 was statistically significant. * We included hospitalizations for patients aged ≥18 years with a principal diagnosis of SLE * The incidence of SLE flare hospitalizations was calculated by dividing the number of SLE hospitalizations in the NIS by the population estimate of the U.S on July 1 of the corresponding year. The population estimates were obtained from the U.S Census Bureau Website *** All hospital charges were adjusted for inflation by using the medical expenditure panel survey-based factor for hospital care and were presented in 2018 United States dollars (USD)

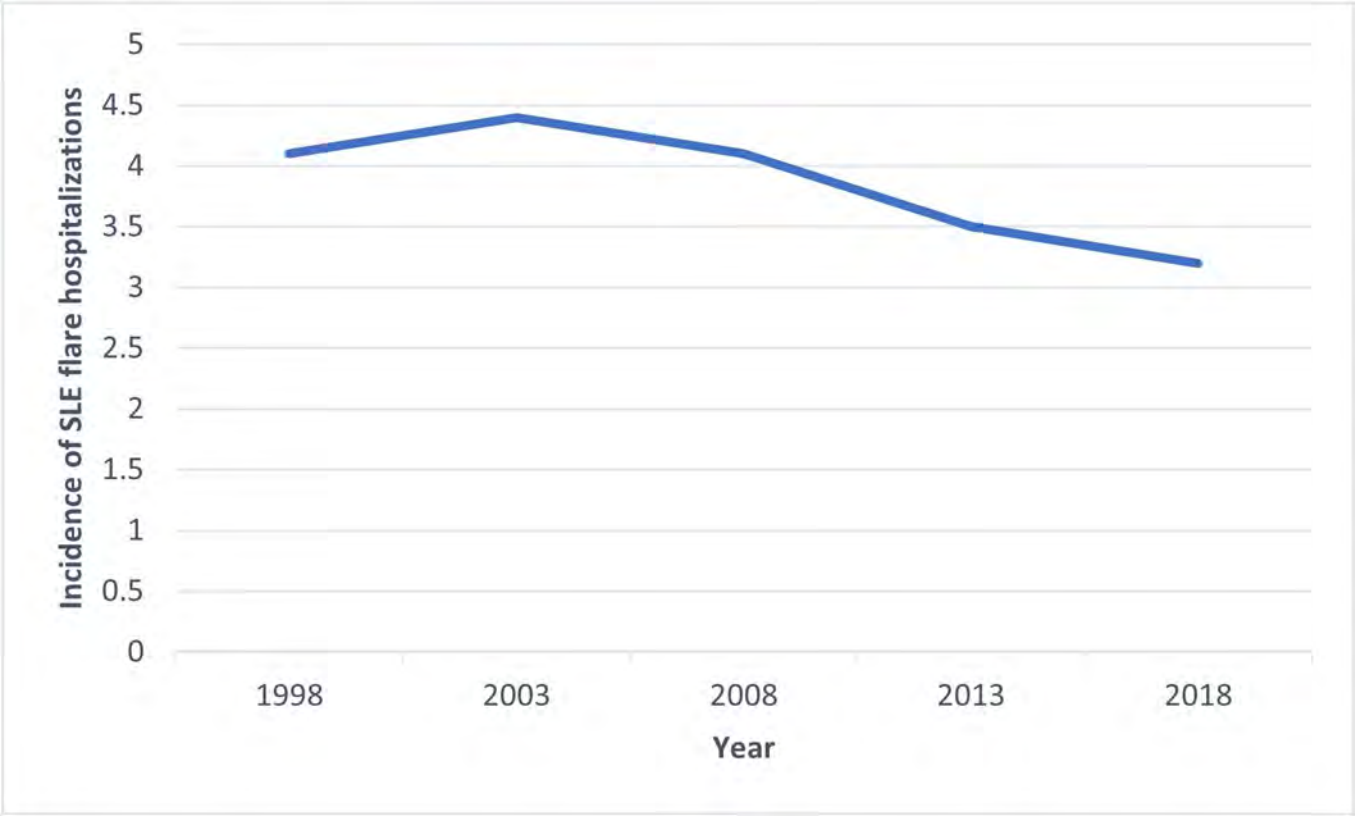

Figure 1. Incidence of Systemic Lupus Erythematosus flare hospitalizations from 1998 to 2018.

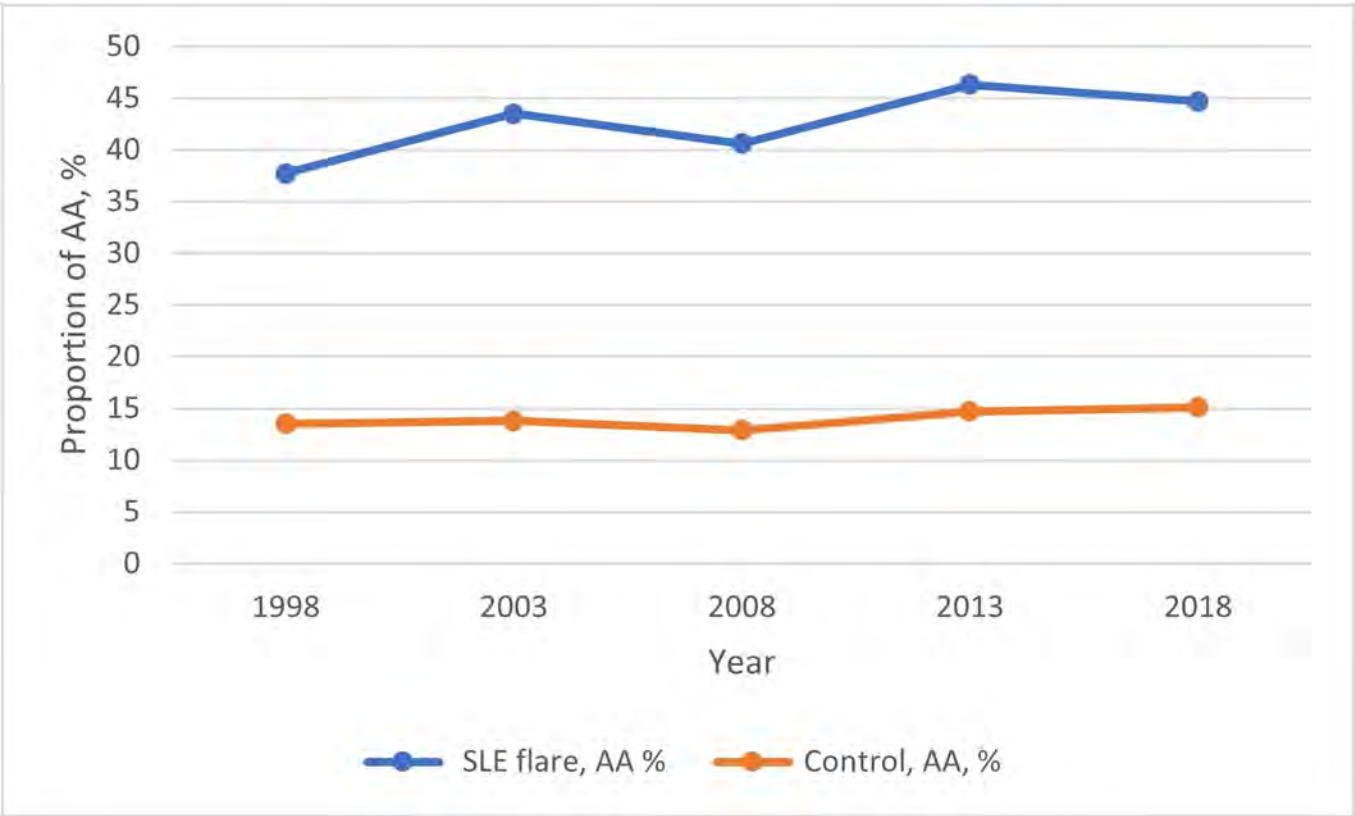

Figure 2. Proportion of African Americans in Systemic Lupus Erythematosus flare hospitalizations and control population from 1998 to 2018. All adult hospitalizations aged ≥ 18 years was used as the control population.

Methods: Data were obtained from the National Inpatient Sample database (NIS), the largest hospitalization database in the U.S. We performed a 21-year longitudinal trend analysis of NIS 1998-2018. Every 5th year of the NIS during this study period was sampled. We obtained data from NIS 1998, 2003, 2008, 2013, and 2018 databases. We searched for hospitalizations for patients aged≥ 18 years with "principal" diagnosis of SLE using ICD 9 code "7100" or ICD 10 code "M32". We defined an SLE flare hospitalization as one with a "principal" diagnosis of SLE. The "principal" diagnosis is the main reason for hospitalization. All hospitalizations for patients aged≥ 18 years were used as the control population. NIS underwent a redesign in 2012, hence revised trend weights were used to make estimates comparable across the years. Multivariable logistic and linear regression was used to calculate adjusted p-trend for categorical and continuous outcomes, respectively. We adjusted for changes in demographics and charlson comorbidity index (CCI) score over time. STATA version 16 was used for analysis.

Results: Incidence of SLE flare hospitalization reduced from 4.1 per 100,000 in 1998 to 3.2 per 100,000 in 2018 (adjusted p-trend < 0.0001). See Figure 1. Proportion of hospitalized African American (AA) SLE flare hospitalizations increased from 37.7% in 1998 to 44.7% in 2018 (adjusted p-trend < 0.0001), while hospitalized AA in the control increased from 13.5% in 1998 to 15.1% in 2018 (adjusted p-trend=0.06). See Figure 2. Racial trends of other ethnic groups were similar between SLE flare and the control population. Hospital length of stay (LOS) reduced and total hospital charges and CCI score increased for both the SLE flare and control groups during our study period (Table 1).

Conclusion: The incidence of hospitalization for SLE flare has reduced in the last two decades in the U.S. This may reflect improving outpatient SLE flare recognition and management. Although AA makes up only 13-15% of the general adult hospitalized population, they constitute the majority of SLE flare hospitalizations (38-46%). The burden of SLE flare hospitalizations among AA has increased over the last 2 decades. This may reflect a lack of access to primary and specialist care among AA. More studies on racial disparities in SLE flare hospitalizations are needed.

Background/Purpose: The overall success of RA therapy is dependent on access to specialty care, insurance coverage and effective management of associated comorbidities. Whether RA disease burden, disease status and care differs amongst patients in various regions of the US, requires further delineation.

Methods: RA patients enrolled in the Rheumatology Informatics System for Effectiveness (RISE) registry with at least two ambulatory visits between 01/2018 and 03/2020 and ≥ 1 prescription for RA medication, were evaluated. Last ambulatory visit was defined as the index date; baseline defined as 18 months prior to index date. Seropositivity was evaluated using all available data, whereas RA disease activity (CDAI, RAPID3), comorbidity burden, sociodemographic status (SES), geographic region (West, Midwest, South, Northeast), health insurance type (Medicare, Medicaid, Private), were baseline. Comorbidity burden was evaluated using treatment risk (Rxrisk-no. of conditions treated out of 46 disease entities). Based on zip codes, we obtained area deprivation index (ADI= national/regional) to define low SES (i.e. ADI > 80 = high deprivation). Median travel distance between patients' and practice sites zip codes, was calculated. A linear regression model was used to analyze associations between RA disease activity (CDAI/RAPID3) and comorbidity (# of RxRisk categories) adjusting for age, sex, geographic region, race and insurance type.

Results: Enrollment data for 184,722 RA patients (mean age 64 years [13.85], 77.2% female) from 182 RISE sites was analyzed (Table 1). Disease activity was higher in blacks, and in patients from South regions and with Medicaid/Medicare coverage. Mean ADI was 45.56 [25.85] with 12% of sites in high deprivation areas (ADI >80), which was particularly relevant to practice sites in the South, and with higher frequencies in rural vs urban areas (Figure 1). Patients with ADI >80 received primarily Medicaid coverage, the majority of whom were seen by a minority of providers; >60% of socially deprived patients were cared for by only 22% of RISE practices. Overall, the median percentage Medicaid participants for sites was 0.16%, with fewer than 20 rheumatology practices caring for 50%

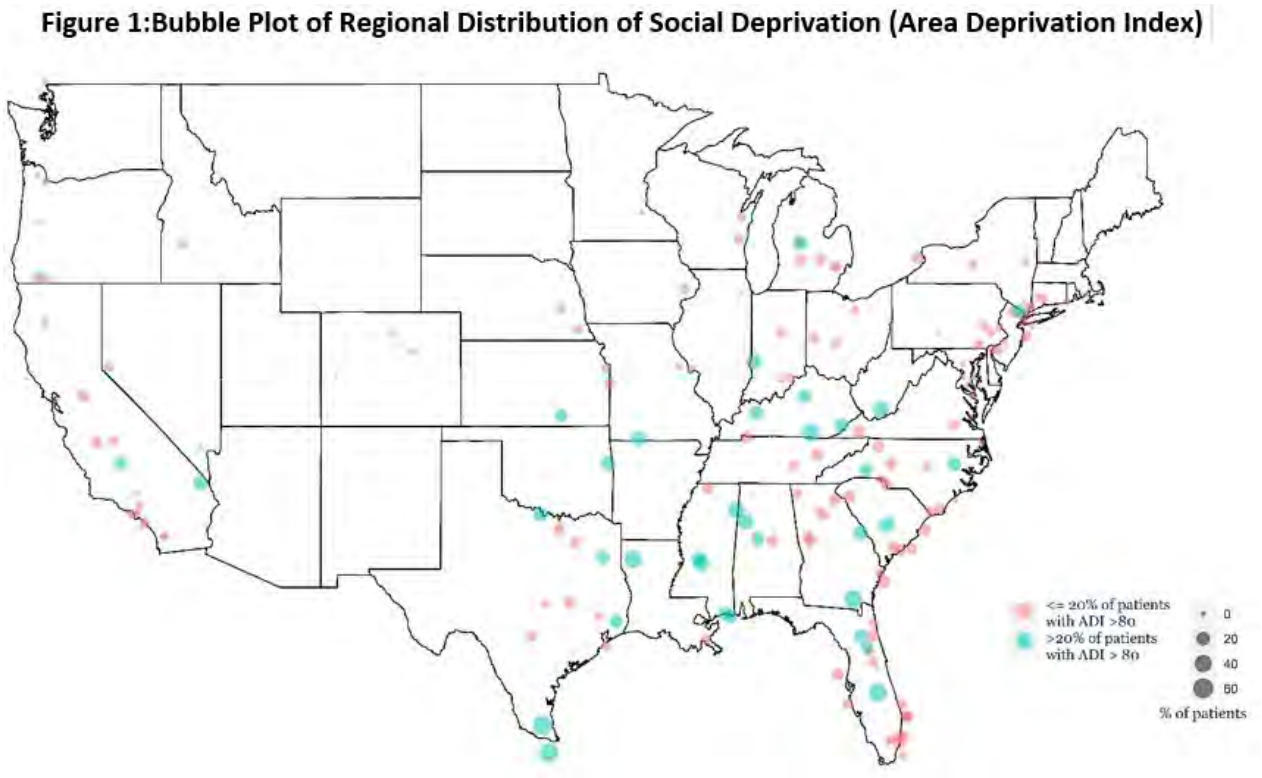

Figure 1 Bubble plot.

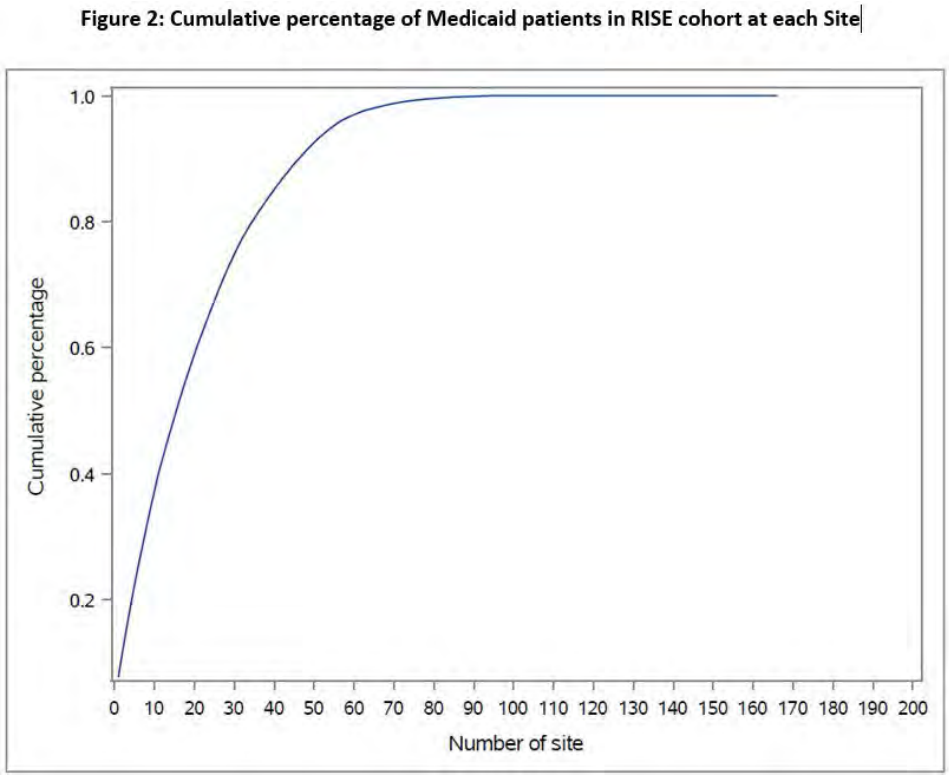

Figure 2 Cumulative percentage.

of all RA patients (Figure 2). Most patients resided within 50 miles of their provider, but 2.9% of patients were >200 miles away from specialist care, mainly in South and West regions. Like disease activity, higher category RxRisk patients had predominant Southern regional distribution and Medicare/Medicaid coverage, but < 200 miles to access care. There was significant correlation between RxRisk and disease activity (Pearson coefficient: RAPID3 0.28, CDAI 0.15).

Conclusion: Type of insurance, not race or distance to specialty care, was associated with overall RA disease activity and burden). A disproportionately large fraction of socially deprived, rural, high comorbidity, and Medicaid-covered RA patients were cared for by a minority of rheumatology practices. Studies are needed in high deprivation areas to determine the impact of interventions targeting more equitable distribution of specialty care, enhanced reimbursement and access to advanced therapies, so as to improve RA patient outcomes in vulnerable patients.

Racial/Ethnic Differences in Multimorbidity Between Patients with Systemic Lupus Erythematosus and Comparators in a Large Nationwide US Study

Ali Duarte-Garcia[1], Herbert Heien[1], Nilay Shah[1] and Cynthia Crowson[2], [1]Mayo Clinic, Rochester, MN, [2]Mayo Clinic, Eyota, MN

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Abstracts: Healthcare Disparities in Rheumatology (0492–0495)
Session Type: Abstract Session
Session Time: 3:30PM–4:30PM

Background/Purpose: Patients with systemic lupus erythematosus (SLE) have an increased burden of multimorbidity. Racial/ethnic disparities have also been associated with an increased burden of multimorbidity. We aimed to compare racial/ethnic difference in multimorbidity between patients with SLE and non-SLE comparators.

Methods: We used the OptumLabs Data Warehouse (OLDW), a longitudinal, real-world data asset with de-identified administrative claims for commercial and Medicare Advantage enrollees, to identify cases of SLE and matched comparators. Cases were defined as patients with ≥3 diagnoses of SLE between January 2006 and September 2015. Controls were persons without SLE matched 1:1 to SLE cases on age, sex, race/ethnicity, and enrollment date. Race was classified as non-Hispanic White (White), non-Hispanic Black (Black), non-Hispanic Asian (Asian), Hispanic, based on derived rule sets. Multimorbidity (2 or more comorbidities) was defined using 172 chronic comorbidities from the chronic condition indicator of the clinical classification software (healthcare cost and utilization project). SLE,

Table. Comparison of multimorbidity prevalence between race/ethnicity among patients without SLE and patients with SLE.		
	Multimorbidity (2+ conditions) Odds ratio*	Multimorbidity (5+ conditions) odds ratio*
Non SLE		
White	Ref.	Ref.
Asian	0.66 (0.55-0.78)	0.67 (0.48-0.93)
Black	1.15 (1.07-1.23)	1.3 (1.17-1.46)
Hispanic	1.0 (0.91-1.09)	1.05 (0.9-1.23)
SLE		
White	Ref.	Ref.
Asian	0.8 (0.7-0.9)	0.72 (0.61-0.87)
Black	1.05 (1.0-1.12)	1.15 (1.07-1.23)
Hispanic	1.08 (1.0-1.16)	1.04 (0.95-1.14)
*Adjusted for age, sex, and region		

cutaneous lupus, and rheumatoid arthritis ICD-9 codes were excluded from the analysis. Two or more ICD-9 codes at least 30 days apart were used to define a comorbidity. A secondary analysis was performed including those with 5 or more comorbidities (substantial multimorbidity). Logistic regression models were used to estimate odds ratios (OR) with 95% confidence intervals (CI) adjusted for age, sex, and region.

Results: The study included 34,869 cases with SLE and 34,869 matched non-SLE comparators. The mean age was 48 (SD 14.2) years, and 90.6% were female for both cohorts. 66.4% of the patients in both cohorts were White, 18.4% Black, 3.4% Asian and 18.4% Hispanic. Patients with SLE had more multimorbidity than non-SLE subjects (58.1% vs 26.3%). Among the non-SLE patients 26.7% of Whites experienced multimorbidity, compared to 16% of Asians, 22.6% of Hispanics, and 29.2% of Blacks. After adjustment for age, sex and geographic region, Blacks had higher multimorbidity (OR 1.15; 95%CI 1.07-1.23), Asians had lower multimorbidity (OR 0.66; 95%CI 0.55-0.78) while Hispanics (OR 1.0; 95%CI 0.91-1.09) had no difference in multimorbidity compared to Whites. Among the SLE patients, 58.6% of Whites experienced multimorbidity, compared to 47.2% of Asians, 56.0% of Hispanics, and 59.5% of Blacks. Adjusted analyses showed less pronounced decrease in multimorbidity for Asians (OR: 0.80; 95%CI: 0.70-0.90) and a less pronounced increase in Blacks (OR: 1.05; 95%CI: 0.99-1.12) and a similar increase in multimorbidity among Hispanics (OR: 1.07; 95%CI: 1.00-1.15) compared to Whites in the SLE cohort. Similar findings were observed in secondary analysis of those with 5 or more comorbidities (Table)

Conclusion: This large nationwide study showed increased occurrence of multimorbidity in SLE versus non-SLE patients across racial/ethnic groups. Racial/ethnic disparities in multimorbidity were more pronounced among patients without SLE compared to SLE patients. These findings suggest that the effects of race/ethnicity and SLE are not cumulative.

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Abstracts: Systemic Sclerosis & Related Disorders – Clinical (0496–0501)

Session Type: Abstract Session

Session Time: 3:30PM–5:00PM

Background/Purpose: Systemic sclerosis (SSc) is a systemic autoimmune disease belonging to collagen diseases, characterized by fibrosis of various organs including the skin and lungs, and vascular damage. SSc is considered to have a high unmet medical need because of its poor prognosis in severe cases and the lack of satisfactory and effective treatments. Previous studies have shown that B cells play a major role in the development of SSc. In fact, several clinical studies have suggested that B cell depletion therapy with rituximab, anti-CD20 antibody, is effective. However, no randomized, placebo-controlled trial has been able to confirm the efficacy of rituximab in SSc, which implies that there has been no high-quality evidence to date.

Methods: In this study, a multicenter, double-blind, placebo-controlled, parallel-group comparison, investigator-initiated clinical trial was conducted to evaluate the safety and efficacy of rituximab for SSc. Patients were randomized 1:1 to rituximab (375 mg/m^2) or placebo and received the study drug intravenously once a week for 4 weeks. The primary endpoint was the change in the modified Rodnan total skin thickness score, a semiquantitative measure of the degree of skin sclerosis, 24 weeks after the start of the intervention. The main secondary endpoint was the change in %forced vital capacity (%FVC) at 24 weeks. This trial had been registered with ClinicalTrials.gov (NCT04274257) and UMIN-CTR (UMIN000030139).

Results: A total of 56 patients participated in the study, 54 of whom received rituximab or placebo. Twenty-four weeks after the start of the intervention, the modified Rodnan total skin thickness score was significantly improved in the rituximab group compared to the placebo group (6.30 decrease in the rituximab group vs. 2.14 increase in the placebo group; difference 8.44 [95% confidence interval -11.00 to -5.88]; $P < 0.0001$). In addition, the %FVC of 48 patients with interstitial lung disease was significantly improved in the rituximab group than in the placebo group at 24 weeks (0.09% improvement in the rituximab group vs. 2.87% deterioration in the placebo group; difference 2.96% [95% confidence interval 0.08 to 5.84]; $P = 0.04$). The incidence of adverse events was comparable between the two groups, and there were no significantly increased adverse events in either group. There were no deaths during the trial.

Conclusion: This study was the first to validate the efficacy and safety of rituximab for skin sclerosis in SSc. Moreover, this clinical trial suggested the efficacy of rituximab for SSc-associated interstitial lung disease. Therefore, it is promising that rituximab becomes a new standard therapy for SSc.

Efficacy in Patient Subgroups in the INCREASE Trial, a Phase III Trial to Evaluate Inhaled Treprostinil in Patients with Pulmonary Hypertension Due to Parenchymal Lung Disease

Victor Tapson[1], Steven Nathan[2], Reda Girgis[3], James Runo[4], Remzi Bag[5], Arunabh Talwar[6], Peter Smith[7], Lisa Edwards[7], Christine Park[7] and Aaron Waxman[8], [1]Cedars-Sinai, Los Angeles, CA, [2]Inova Fairfax, Falls Church, VA, [3]Michigan State University, Lansing, MI, [4]University of Wisconsin, Madison, WI, [5]University of Chicago, Chicago, IL, [6]Hofstra Northwell School of Medicine, Hempstead, NY, [7]United Therapeutics Corporation, Durham, NC, [8]Brigham and Women's Hospital, Boston, MA

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Abstracts: Systemic Sclerosis & Related Disorders – Clinical (0496–0501)
Session Type: Abstract Session
Session Time: 3:30PM–5:00PM

Background/Purpose: INCREASE was a 16-week trial evaluating the safety and efficacy of inhaled treprostinil (iTRE) in patients with pulmonary hypertension associated with interstitial lung disease (PH-ILD). The study met its primary efficacy endpoint of change in 6-minute walking distance (6MWD), demonstrated by a 31m improvement from baseline (260m). Secondary endpoints, including change in N-terminal pro b-type natriuretic peptide (NT-proBNP) and

Figure 1: Treatment Effect of iTRE on Change in 6MWD

mPAP < 35 mmHg	60	64	0.71 (0.52, 0.95)
PCWP ≥ 10 mmHg	72	72	0.54 (0.42, 0.69)
PCWP < 10 mmHg	51	55	0.66 (0.46, 0.96)
PVR ≥ 5 WU	61	52	0.62 (0.50, 0.83)
PVR < 5 WU	62	75	0.51 (0.36, 0.72)

*Denotes statistically significant p value for all values
Least squares mean differences and their 95% confidence intervals are from the mixed model repeated measures
6MWD: six-minute walk distance; FVC: forced vital capacity; CI: confidence interval; DLCO: diffusing capacity for carbon monoxide; LS: least squares; mPAP: mean pulmonary arterial pressure; NT-proBNP: N-terminal pro hormone B-type natriuretic peptide; PCWP: pulmonary capillary wedge pressure; PVR: pulmonary vascular resistance

time to clinical worsening, were also met. Post-hoc analyses were conducted to investigate clinical endpoints within patient subgroups.

Methods: All 326 patients randomized in INCREASE were included in the present analyses, of which 72 patients (iTre 40, placebo 32) had connective tissue disease as the cause of their underlying lung disease. Patient subgroups were delineated by median values of the following baseline characteristics: PVR (< 5 WU, ≥5WU), PCWP (< 10 mmHg, ≥10 mmHg), mPAP (< 35 mmHg, ≥35 mmHg), DLCO (< 27% predicted, ≥27% predicted), FVC (< 60% predicted, ≥60% predicted) and NT-proBNP (< 504 pg/mL, ≥504 pg/mL). Clinical worsening was defined as any of the following: cardiopulmonary hospitalization, decrease in 6MWD >15% from baseline, all-cause death, or lung transplantation.

Results: 6MWD improvements were demonstrated in all subgroups. Statistically significant improvements occurred in patients with above median PVR, PCWP, mPAP; lower than median DLCO; and in both above median and below

Figure 3: Treatment Effect of iTRE on Time to Clinical Worsening

Subgroup	Inhaled Treprostinil	Placebo	HR (95% CI)
NT-proBNP ≥ 504 pg/mL	83	75	0.57 (0.33, 0.98)
NT-proBNP < 504 pg/mL	73	85	0.81 (0.42, 1.56)
FVC ≥ 60% predicted	84	89	0.64 (0.35, 1.16)
FVC < 60% predicted	78	72	0.70 (0.39, 1.27)
DLCO ≥ 27% predicted	87	71	1.01 (0.48, 2.12)
DLCO < 27% predicted	65	82	0.66 (0.38, 1.15)
mPAP ≥ 35 mmHg	89	83	0.57 (0.32, 1.01)
mPAP < 35 mmHg	74	80	0.76 (0.41, 1.42)
PCWP ≥ 10 mmHg	95	91	0.86 (0.50, 1.48)
PCWP < 10 mmHg	68	72	0.46 (0.23, 0.90)
PVR ≥ 5 WU	90	73	0.57 (0.33, 0.98)
PVR < 5 WU	73	90	0.70 (0.36, 1.35)

Treprostinil better
Placebo better
*Denotes statistically significant p value
Hazard ratio and 95% confidence interval were calculated with proportional hazards model
FVC: forced vital capacity; CI: confidence interval; DLCO: diffusing capacity for carbon monoxide; HR: hazard ratio; mPAP: mean pulmonary arterial pressure; NT-proBNP: N-terminal pro hormone B-type natriuretic peptide; PCWP: pulmonary capillary wedge pressure; PVR: pulmonary vascular resistance

median FVC and NT-proBNP cohorts (p≤0.013 for all). Statistically significant reductions in NT-proBNP were demonstrated in all subgroups (p≤0.028 for all). Statistically significant benefit in time to clinical worsening with iTRE was observed in above median PVR, mPAP, and NT-proBNP; and lower PCWP (p≤0.0493 for all). Overall, response separation in clinical endpoints indicated greater improvement for patients with above median NT-proBNP and PVR. A similar trend of benefit was observed in lower DLCO and higher mPAP subgroups.

Conclusion: These analyses demonstrate improvements in clinical endpoints with inhaled treprostinil across patient subgroups. Patients with more advanced pulmonary vascular disease stand to gain the most benefit with inhaled treprostinil therapy.

Background Mycophenolate (MMF) Treatment Is Associated with Improved Outcomes in a Phase 3 Trial of Lenabasum in Diffuse Cutaneous Systemic Sclerosis (dcSSc)

Robert Spiera[1], Dan Furst[2], Tracy Frech[3], Masataka Kuwana[4], Laura Hummers[5], Wendy Stevens[6], Suzanne Kafaja[7], Eun bong Lee[8], Scott Constantine[9], Nancy Dgetluck[9], Barbara White[10] and Christopher Denton[11], [1]Hospital for Special Surgery, New York, NY, [2]University of California Los Angeles, Los Angeles, CA, [3]University of Utah, Salt Lake City, UT, [4]Department of Allergy and Rheumatology, Nippon Medical School Graduate School of Medicine, Tokyo, Japan, [5]Johns Hopkins Univerisity, Baltimore, MD, [6]St Vincent's Hospital, Melbourne, Australia, [7]University of California Los Angeles Division of Rheumatology, Los Angeles, CA, [8]Seoul National University Hospital, Seoul, Republic of Korea, [9]Corbus Pharmaceuticals, Inc., Norwood, MA, [10]Corbus Pharmaceuticals, Norwood, MA, [11]University College London Division of Medicine, Centre for Rheumatology and Connective Tissue Diseases, London, United Kingdom

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Abstracts: Systemic Sclerosis & Related Disorders – Clinical (0496–0501)
Session Type: Abstract Session
Session Time: 3:30PM–5:00PM

Background/Purpose: Treatment of dcSSc is evolving, with limited information on relative efficacies of different immunosuppressive therapies (IST). Our hypothesis was that patients on MMF have better efficacy outcomes than patients on other IST or no IST, in a clinical trial context.

Methods: Data were analyzed from a 1-year Phase 3 double-blind, placebo-controlled study of lenabasum in subjects with dcSSc ≤ 6 years duration. Background IST (bIST) were allowed in doses that were stable for ≥ 8 weeks before Screening. Enrolling sites were mostly academic specialty clinics for patients with SSc. All cohorts were combined for analyses, because the primary efficacy endpoint (ACR CRISS score) was not met. Subjects were categorized by bIST use: None, MMF, Steroids (≤ 10 mg/day oral prednisone or equivalent), Methotrexate (MTX), and All Other IST. Baseline demographics, disease characteristics, and efficacy outcomes were determined and impact of MMF on certain outcomes was determined in mixed model repeated measures analyses (MMRM) with visit, MMF

Table 1. Baseline demographics and baseline immunosuppressive therapies (bIST)

Baseline Demographics or IST	Subjects by Baseline Immunosuppressive Therapies (bIST) n, mean (SD) or % bIST group. N = 325 total subjects					
	All subjects	No bIST	MMF	Steroids	MTX	All Other IST
	325	49 (15%)	171 (53%)	90 (28%)	62 (19%)	77 (24%)
Age, years	50.5 (12.9)	54.6 (11.1)	51.0 (12.9)	47.9 (13.0)	46.4 (13.2)	50.0 (13.2)
Female	244 (75%)	34 (67%)	133 (78%)	71 (79%)	42 (68%)	60 (78%)
Region: US/ Asia/ Other Countries[1]	36%/18%/45%	24%/31%/45%[2]	53%/8%/38%[3]	28%/32%/40%[2]	19%/18%/63%[2]	27%/14%/45%
Race: White/ Asian /Other	68%/21%/10%	53%/31%/16%[4]	75%/13%/11%	52%/37%/11%[3]	73%/18%/10%	75%/17%/8%
Monotherapy bIST	169 (52%)	-	95 (56%)	18 (20%)	32 (52%)	18 (23%)
Combination bIST	107 (33%)	-	76 (44%)	72 (80%)	30 (48%)	59 (77%)
bIST treatment duration						
• ≤ 1 year			94 (55%)	52 (57%)	29 (47%)	31(40%)
• < 1 to ≤ 2 years			20 (12%)	10 (11%)	14 (23%)	15 (19%)
• > 2 years			57 (33%)	28 (31%)	19 (31%)	31 (40%)

[1]Asia indicates Japan and South Korea in this study; Other Countries are Australia, Canada, Germany, Great Britain, Israel, Italy, Netherlands, Poland, Spain, as per randomization. [2]P ≤ 0.05, [3]P ≤ 0.01, [4]P ≤ 0.001 compared to all subjects

use, MMF-by-visit interaction, baseline mRSS score, disease duration, region, lenabasum treatment, and lenabasum treatment-by-visit interaction as fixed effects.

Results: 276/325 (85%) subjects used bIST (Table 1). MMF was used in about twice as many subjects as Steroids (53% vs. 28%), followed in descending order by: MTX (19%); and All Other bIST, comprised of hydroxychloroquine (11%); tocilizumab, immunoglobulins, and azathioprine (4% each); and chloroquine, cyclophosphamide, abatacept, tacrolimus, and cyclosporine (≤ 1% each). Subjects treated with different bIST had similar age and sex. Treatment with MMF was more common in the US and White subjects, whereas treatment with Steroids or No bIST was more common in Asia and Asian subjects. Treatment with MTX was more common in Other Countries (mostly Europe).

Table 2. Baseline disease characteristics and outcomes, by use of baseline immunosuppressive therapies (bIST)

Δ FVC, %	-1.6 (16.66)	-3.9 (6.90)	-0.4 (6.89)	-0.9 (8.54)	-2.5 (7.66)	-1.41 (8.77)

[1] P ≤ 0.05 compared to all subjects

Table 3. Type 3 Tests of Fixed Effects

Effect	ACR CRISS Score Pr > F	FVC, % predicted Pr > F
Visit	< 0.0001	< 0.0001
MMF	0.0002	0.0526
MMF-by-visit interaction	0.0290	0.0530
Baseline FVC	-	< 0.0001
Baseline mRSS	0.4699	-
Region	0.5342	0.2259
Disease duration	0.4074	0.4229
Lenabasum treatment	0.8590	0.9294
Lenabasum treatment-by-visit interaction	0.9980	0.6687

MMF and MTX were used more commonly as monotherapy (56% and 52%), respectively, than Steroids (20%). Treatment duration of bIST (≤ 1 year, >1 – ≤ 2years, > 2 years) did not differ significantly among bIST groups.

Subjects treated with MMF had greater improvement in most efficacy outcomes than subjects treated with MTX or steroids without MMF (Table 2). Visit, use of MMF, and MMF-by-visit interaction had significant effects on ACR CRISS score, whereas baseline mRSS, region, disease duration, lenabasum treatment, and lenabasum treatment-by-visit interaction did not (Table 3). Use of MMF, visit, MMF-by-visit interaction, and baseline FVC % also influenced change in FVC%, whereas the other fixed effects did not.

Conclusion: MMF was the most commonly used bIST in this Phase 3 study of dcSSc subjects. Treatment with MMF during the trial was associated with better outcomes than treatment with MTX or Steroids without MMF. In future dcSSc trials that enroll subjects on bIST, statistical analyses should consider that subjects on placebo added to bIST are, in fact, receiving active concomitant treatment that will confound trial results over time. Differences in proportion of subjects on MMF, other IST, and no IST may also influence results. Efficacy outcomes will need to detect improvement beyond the substantial efficacy already provided by bIST over time.

RP, Raynaud's phenomenon; HAQ-DI, health assessment questionnaire-disability index; VAS, visual analogue scale; DHI, Duruoz Hand Index; CSS, cold sensitivity scale

ASRAP items are grounded in the patient experience of SSc-RP. We report the development and subsequent assessment of internal reliability and preliminary construct validity testing of long and short-form versions of the ASRAP questionnaire.

Methods: The international multicentre ASRAP validation study enrolled English speaking SSc-RP patients from UK and US scleroderma centres during 2 consecutive winters 2019-2021. All participants completed a 39-item ASRAP questionnaire. Item reduction, scale scoring and derivation of a short-form ASRAP were based upon item response theory (IRT) assumptions and calibrated using the graded response model. The final 27-item long-form scores were correlated with a 10-item short form scores using Pearson's correlation. Once scales were devised, preliminary assessment of construct validity was determined by Pearson's correlation between long and short-form ASRAP scores and a range of concurrent disease specific and legacy instruments capturing SSc-RP patient measures of disease activity/impact and relevant domains including cold sensitivity, pain, function and patient global health.

Results: A total of 438 SSc patients were enrolled at UK (n=238) and US (n=200) sites. A data driven approach with expert opinion was used to devise a 27-item long-form and 10-item short-form. Internal reliability between long and short form ASRAP questionnaires was excellent with Pearson correlation coefficient values of 0.976 ($p< 0.0001$). Evidence of construct validity of the long and short form ASRAP was indicated by strong agreement with existing global assessments of RP severity and impact (Scleroderma Health Assessment Questionnaire RP VAS and Patient RP global VAS (Figure 1). The short and long-form ASRAP questionnaire also had statistically significant correlations (in anticipated direction) with legacy instruments for assessing disability, hand function, pain and global health assessment (Figure 1).

Conclusion: Our preliminary analysis from the ASRAP validation study indicates strong internal reliability between long and putative short form ASRAP questionnaires. Cross-sectional psychometric analyses have indicated encouraging agreement with both global assessments of RP impact/severity and legacy instruments for assessing other relevant aspects of health pertinent to SSc. Further work to assess longitudinal reliability and sensitivity of change of the ASRAP questionnaire is planned.

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Abstracts: Systemic Sclerosis & Related Disorders – Clinical (0496–0501)

Session Type: Abstract Session

Session Time: 3:30PM–5:00PM

Background/Purpose: Although two subsets in systemic sclerosis (SSc) have been identified based on degree of skin disease, the current classification system, limited vs. diffuse cutaneous, does not reliably predict which patients will develop progressive skin fibrosis and internal organ involvement. Genome-wide analysis of gene expression in the skin has been used to classify patients with SSc into four intrinsic gene expression subsets: fibroproliferative, inflammatory, limited, and normal-like. The objective of this study was to characterize and define the clinical characteristics and markers of disease severity based upon intrinsic subset.

Methods: Subject-level data were prospectively obtained for SSc patients and healthy controls who underwent skin biopsies. Patients fulfilled the ACR/EULAR 2013 classification criteria and had clinically active disease determined by one treating physician. Paired skin biopsies of the forearm were performed: one for histology and one for DNA microarray analyses to measure gene expression. Intrinsic subsets were assigned using a trained Glmnet machine learning classifier. Clinical information including laboratory, pulmonary function test, chest high-resolution computer tomography (HRCT), echocardiography and patient-reported outcomes (PROs) were collected at baseline and longitudinally. Statistical analysis was performed to compare clinical characteristics and markers of disease severity between intrinsic subset groups (SAS, town and state).

Results: 223 participants (165 SSc and 58 control) were categorized by intrinsic subtypes (Figure 1). Demographic and clinical characteristics of SSc patients by intrinsic subset are shown in Table 1. Normal-like subset had signif-

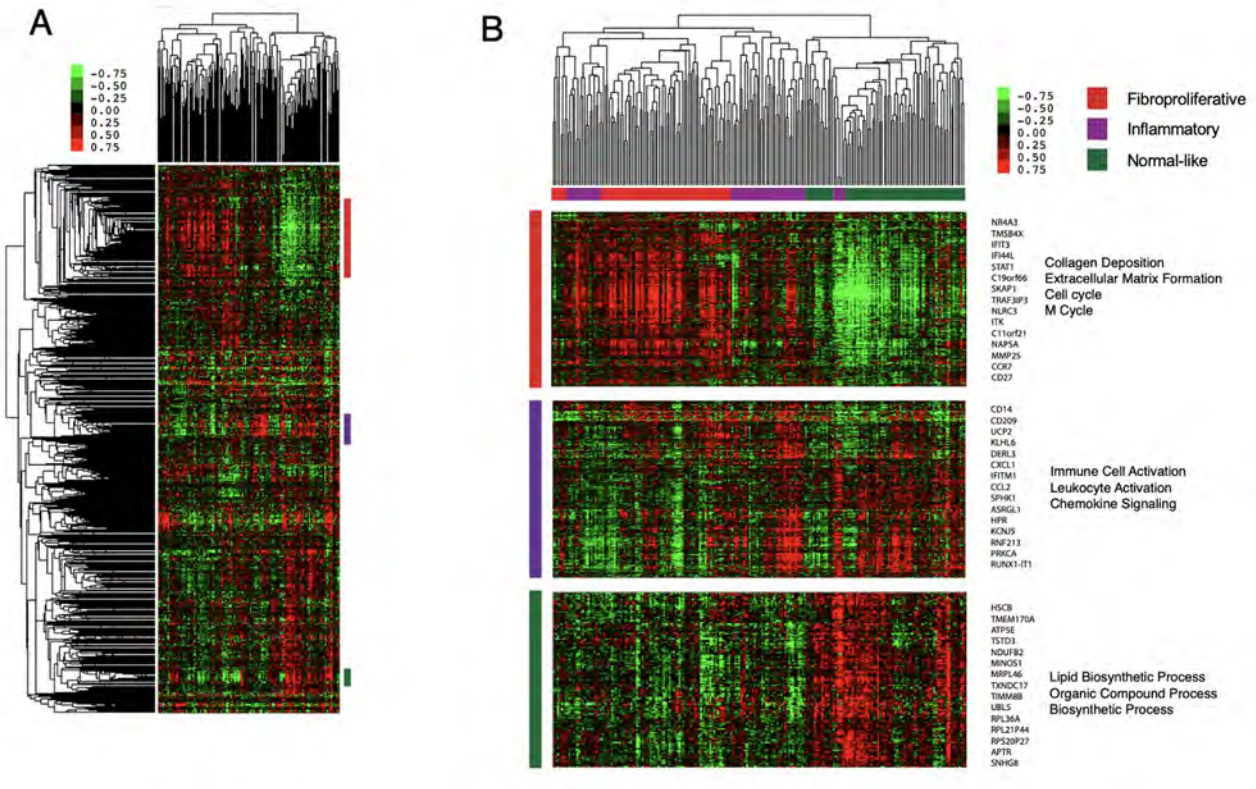

Figure 1. Gene expression signatures and cluster analysis of intrinsic subsets in patients with SSc.

icantly more limited cutaneous patients (p< 0.001) and longer disease duration (p< 0.001). SSc antibodies differed by subsets with ACA, Scl70 and RNA poly III associated with normal-like (p=0.04), fibroproliferative (p=0.04) and inflammatory (p< 0.001) subsets respectively. Pulmonary, cardiac and PROs by intrinsic subset are shown in Table 2. Inflammatory subset had significantly higher modified Rodnan skin scores (p< 0.001). Fibroproliferative subset had a trend toward worse lung fibrosis scores and significantly more ILD present on HRCT (p=0.04). For PROs, inflammatory and fibroproliferative subsets scored worse in fatigue, sleep disturbance, social participation and pain domains (p< 0.04) compared to patients in limited or normal-like subsets.

Conclusion: This study utilized molecular signatures in the skin to classify SSc patients into distinct subsets that had significantly different clinical characteristics. Patients in the normal-like subset were more likely to have limited cutaneous disease and longer disease duration, suggesting milder disease. The inflammatory subset had more severe skin disease and the fibroproliferative subset had more significant fibrotic lung disease. Both inflammatory and fibroproliferative patients endorsed worse PROs than their normal-like counterparts. This study elucidates the clinical relevance of distinct molecular subsets in the skin and contributes to the growing effort to better define and characterize the vast heterogenicity in SSc.

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Abstracts: Systemic Sclerosis & Related Disorders – Clinical (0496–0501)
Session Type: Abstract Session
Session Time: 3:30PM–5:00PM

Background/Purpose: Systemic Sclerosis (SSc) is a rare connective tissue disease with multi-systemic involvement, which at times requires the use of immunosuppressive medication. None of the currently approved vaccines for COVID-19 have been tested for efficacy in Immunocompromised individuals. As no data were available on the potential blunting of the immune response against the vaccine caused by immunosuppressant administration, neither on the potential effects of the vaccines on disease activity or progression, we set out to measure serum markers of disease activity and the immune response of the first dose of Oxford/AstraZeneca and Pfizer vaccine in patients with Systemic Sclerosis with or without immunosuppression.

Methods: Forty patients with SSc from our observational study were invited to participate in this study. At the time of abstract submission full data were available for twenty-two patients. Sera samples were tested before and 4 weeks after (± 7 days) the patients' first Covid vaccine using two Luminex xMAP based assays. The first (LABScreen COVID plus [CE-IVD]) that measures levels of IgG against SARS-CoV-2 spike protein subunits S1 and S2, the spike receptor-binding domain, and nucleocapsid protein [NP]. The second, a custom made multiplex assay to measure the concentration of 6 chemokines (ccl2, ccl8, ccl19, cxcl9, cxcl10, cxcl11) to determine the IFN score, as previously described (Carriero A et al 2019). Patients with known COVID-19 infection were not invited to take part in the study.

Results: Seven patients were found to have evidence of antibodies on the sample prior to vaccination and excluded from seroconversion analysis. None of the patients reported any serious adverse reaction to the vaccine, or any immediate complications, including the ones with previous signs of infection. 88% of patients on immunosuppression (Mycophenalate Mofetil [MMF] or Methotrexate [MTX]) showed no seroconversion, whereas all patients on either Hydroxychloroquine or no immunosuppression seroconverted after the first dose. None of the participants had a positive result for NP in the second sample, testifying no actual infection within the duration of the study. Regardless of immunosuppression, none of the twenty-two patients showed a significant change of serum IFN score at 4 weeks following vaccination.

Conclusion: Within the limitations of our small sample size, our data has shown that there is a clear reduction in the Covid-19 vaccines ability to produce antibodies in patients on standard immunosuppression such as MMF or MTX. On the other hand, the vaccination was safe and did not cause an increase in the serum IFN score of the patients, nor

any immediate complication, regardless of their immunosuppressive treatments. The study is currently analysing the response rate to the second dose. If results are confirmed, a booster third dose preceded by suspension of immunosuppressive therapy should be considered in this patient cohort.

[α]Giant cell arteritis

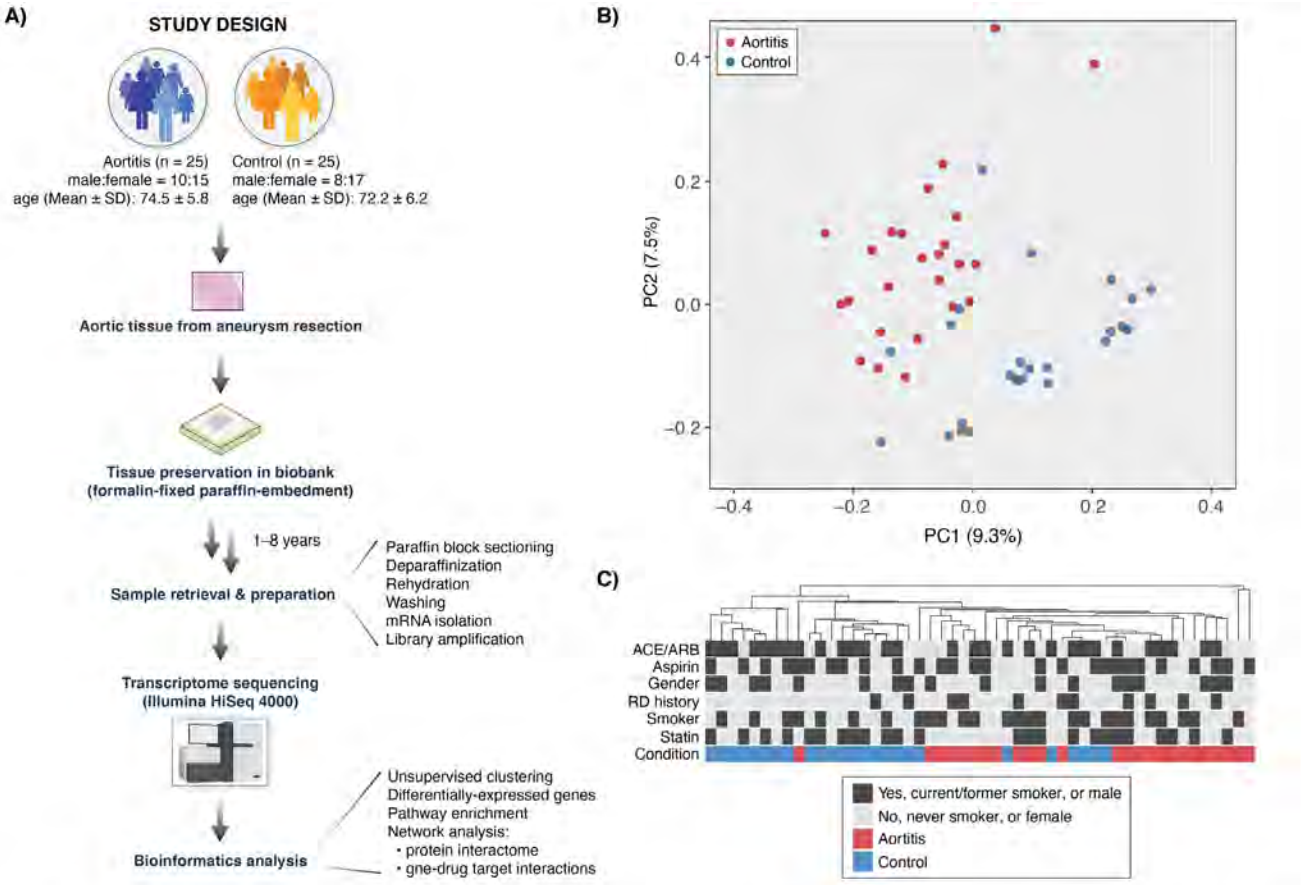

Figure 1. Study design and data analysis pipeline on genome-wide expression (transcriptome) profiles of inflammatory and non-inflammatory aortic aneurysms.
(A) Study design to investigate transcriptomic differences between inflammatory and non-inflammatory aortic aneurysm.
(B) PCA on gene expression profiles (26,475 total genes) from 50 temporal artery tissue samples across two patient groups (Aortitis = 25; Non-inflammatory aneurysm control = 25).
(C) Hierarchical clustering on all 50 gene expression profiles shows that samples group together mostly by disease condition (aortitis/control) rather than by clinical characteristics (i.e., ACE/ARB use, aspirin use, gender, RD history, smoking status, and statin use).
PCA: principal component analysis; ACE/ARB: angiotensin converting enzyme inhibitors/angiotensin receptor blockers; RD history: history of other rheumatic diseases.

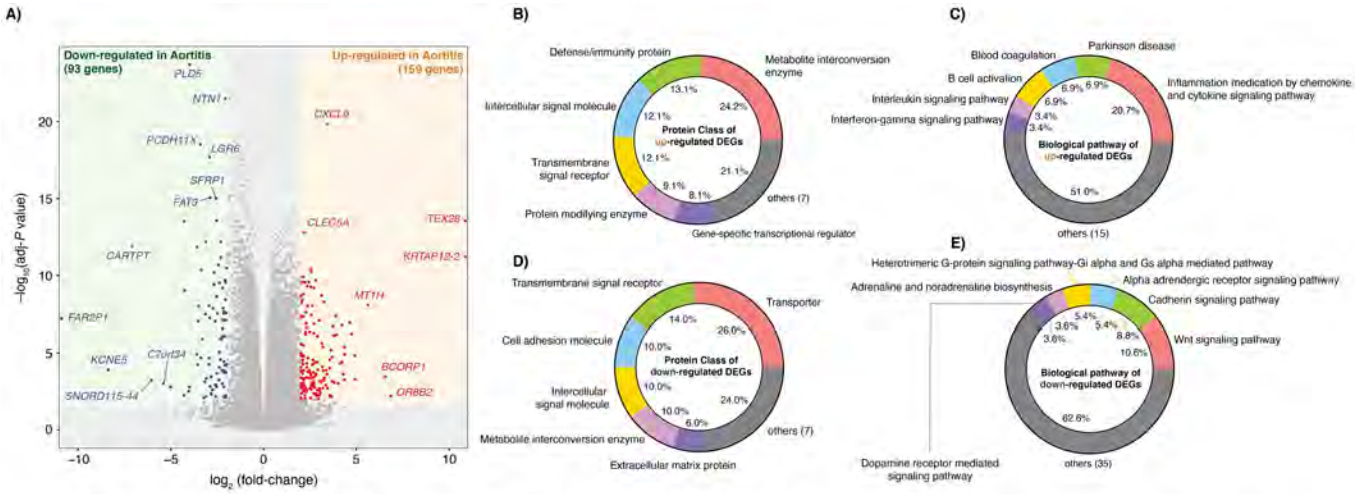

Figure 2. Differentially-expressed genes (DEGs) and their functional categories reveal transcriptomic signatures of aortitis.
(A) A total of 159 and 93 genes were identified to be significantly up-regulated and down-regulated, respectively, in aortitis (Benjamini-Hochberg adjusted P-value < 0.01 and |log2(fold-change in mean expression values)| > 2).
(B) Functional annotations (protein class) of the up-regulated differentially expressed genes (DEGs).
(C) Functional annotations (biological pathway) of the up-regulated DEGs.
(D) Functional annotations (protein class) of the down-regulated DEGs.
(E) Functional annotations (biological pathway) of the down-regulated DEGs.
DEGs and fold-changes were calculated by DEseq2 (v1.30.0) while controlling for clincial covariates (i.e., ACE/ARB, statin, history of RD).
Functional classifications were performed using the PANTHER Database (v16.0).

Background/Purpose: Non-infectious aortitis may be a manifestation of systemic large vessel vasculitis such as giant cell arteritis (GCA) or may be a form of single organ vasculitis termed 'clinically isolated aortitis' (CIA). Aortitis is generally diagnosed after aortic aneurysm surgery and histopathologic examination of resected aortic tissue. At current, there is no specific biomarker that assists physicians in their diagnostic and treatment decisions for aortitis. Moreover, a genome-wide expression analysis to detect differences in transcriptomic signatures between inflammatory and non-inflammatory aortic aneurysms has not been conducted to date. To this end, we used global transcriptome profiling (RNA-seq) to provide novel insights into the biomolecular processes underlying inflammatory aortic aneurysms. We also compared the transcriptomic signature of aortic tissue from patients with CIA and GCA.

Methods: RNA-seq (HiSeq 4000) was performed on formalin-fixed paraffin-embedded (FFPE) resected aortic tissue from 25 aortitis and 25 non-inflammatory aneurysm control patients undergoing surgical aortic repair (Table 1, Fig. 1). Differentially expressed genes (DEGs) between the two groups were identified while controlling for the potentially confounding effects (i.e., use of Statin, use of angiotensin converting enzyme inhibitors or angiotensin receptor blockers, and history of other rheumatic diseases). Protein-protein interactions from STRING and drug-gene pharmacological interaction information from DBIdb were used to construct DEG interactome and pharmacogenomic networks, respectively. In addition, DAVID was used to identify enriched biomolecular functions (Gene Ontology) for the gene sets from the DEGs, the DEG interactome network, and the pharmacogenomic network.

Results: We identified 159 and 93 genes to be significantly up-regulated and down-regulated, respectively, in aortitis (adj-$P < 0.01$, $|\log2(FC)| > 2$) compared to non-inflammatory aortic tissue (Fig. 2). Up-regulated genes were enriched with functions related to immune response and inflammation, defense against bacteria, and interferon response pathways; while the down-regulated genes were enriched with plasma membrane and neuronal processes. Of note, the gene expression profiles of aortic tissue from patients with aortitis related to GCA (n=8) was no different than those of aortic tissue from patients with CIA (n=17). In aortitis, 30 out of 36 genes from the hub of the DEG interactome network were enriched with immune-related functions. Finally, our pharmacogenomic network analysis identified 16 genes that could be targeted with FDA-approved drugs.

Conclusion: Global transcriptome profiling on FFPE aortic specimens from patients with aortitis identified upregulated genes related to immune response and inflammation. Interestingly, we demonstrate for the first time that the transcriptomic signature of CIA is similar to that of GCA, suggesting that CIA may be a limited presentation of GCA. This study also facilitates the characterization of dysregulated molecular pathways in aortitis, and could provide a promising direction for biomarker discovery and treatment.

18F-fluorodeoxyglucose Positron Emission Tomography as a Predictor of Angiographic Progression of Disease in Large-vessel Vasculitis

Kaitlin Quinn[1], Mark A. Ahlman[2], Hugh Alessi[3], Ashkan Malayeri[2], Jamie Marko[2], Elaine Novakovich[2] and Peter Grayson[4], [1]National Institute of Arthritis and Musculoskeletal and Skin Diseases (NIAMS), National Institutes of Health (NIH), Washington, DC, [2]National Institutes of Health, Bethesda, MD, [3]National Institutes of Health, Bethesda, Maryland, [4]National Institutes of Arthritis and Musculoskeletal and Skin Diseases (NIAMS), National Institutes of Health (NIH), Bethesda, MD

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Abstracts: Vasculitis – Non-ANCA-Associated & Related Disorders (0502–0507)
Session Type: Abstract Session
Session Time: 3:30PM–5:00PM

Background/Purpose: There is limited prospective data characterizing arterial lesions over time in giant cell arteritis (GCA) and Takayasu's arteritis (TAK), the two main forms of large-vessel vasculitis (LVV). FDG-PET can detect vascular inflammation. Whether vascular PET findings predict angiographic change is unknown.

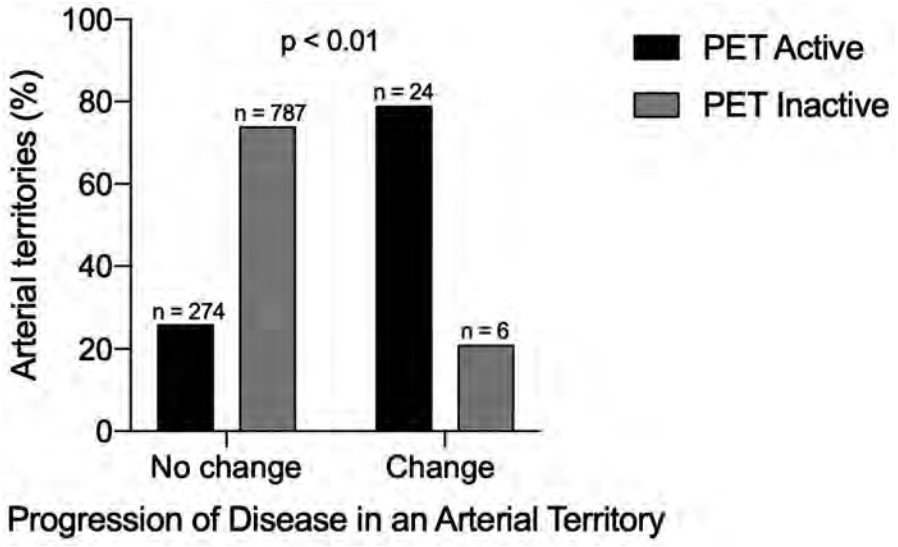
Methods: Patients with GCA or TAK were recruited into a prospective, observational cohort. All patients underwent magnetic resonance (MR) or computed tomography (CT) angiography and a follow-up study ≥6 months after baseline per a standardized imaging protocol. Arterial lesions, defined as stenosis, occlusion, or aneurysm, were evaluated in 4 segments of the aorta and 13 branch arteries by a central reader blinded to clinical status. Development of new lesions in these same territories was recorded, and existing lesions were characterized as improved, worsened, or unchanged over time.

All patients underwent FDG-PET on the same date as angiography. Qualitative assessment of FDG uptake was performed in each corresponding arterial territory evaluated by angiography. Active vasculitis was defined as greater FDG uptake in the arterial wall compared to the liver by visual inspection.

Conditional logistic regression using a within-person matched design selecting for cases of asymmetric angiographic progression in paired arterial territories (e.g. bilateral subclavian arteries) was performed to evaluate whether FDG-PET activity was independently associated with angiographic progression, controlling for all person-level confounders.

Results: 1162 arterial territories were evaluated from 70 patients with LVV (TAK=38; GCA=32). Over 1.6 years of median follow-up, new lesions developed only in 8 arterial territories, exclusively in 5 patients with TAK. Arterial lesions improved in 16 territories (GCA = 7, TAK = 9) and worsened in 6 territories (GCA = 1, TAK = 5). Typically, angiographic change was asymmetric in paired arteries (26/30 territories).

FDG-PET activity was evaluated in 1091/1162 (94%) of corresponding arterial territories. PET activity in an arterial territory at baseline was significantly associated with change in that arterial territory on follow-up angiography



($p < 0.01$), with a sensitivity of 80% and specificity of 74% **(FIGURE)**. Most arterial territories without PET activity at baseline remained unchanged over time by angiography, yielding a negative predictive value of 99%. Most territories with PET activity also did not show change over time, but of the territories with angiographic change, the majority had PET activity (24/30 territories). Using conditional logistic regression, an arterial territory with baseline PET activity had a 3-fold increased risk for angiographic progression of disease compared to the paired arterial territory without PET activity ($p < 0.01$).

Conclusion: Development of angiographic change was infrequent in this cohort of patients with LVV. Lack of PET activity was strongly associated with stable angiographic disease. Most cases of angiographic change were asymmetric in paired arterial territories with PET activity present only in the affected side at baseline. These data may inform recommendations for imaging monitoring in LVV.

Longitudinal Patterns of Vascular Inflammation in Large-vessel Vasculitis

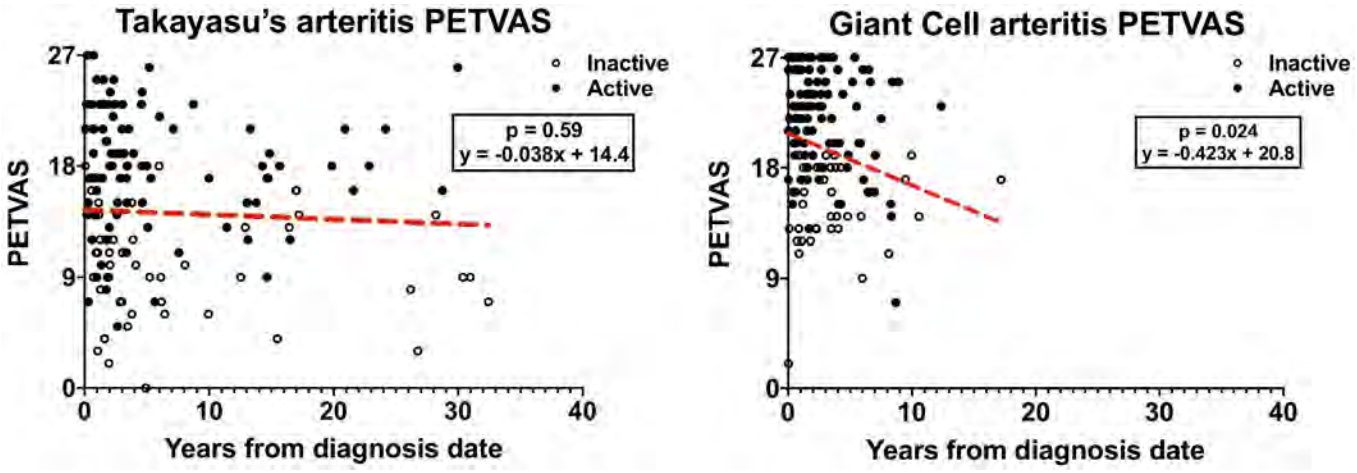
Hugh Alessi[1], Kaitlin Quinn[2], Mark A. Ahlman[3], Yiming Luo[3], Elaine Novakovich[3] and Peter Grayson[4], [1]National Institutes of Health, Bethesda, Maryland, [2]National Institute of Arthritis and Musculoskeletal and Skin Diseases (NIAMS), National Institutes of Health (NIH), Washington, DC, [3]National Institutes of Health, Bethesda, MD, [4]National Institutes of Arthritis and Musculoskeletal and Skin Diseases (NIAMS), National Institutes of Health (NIH), Bethesda, MD

SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Abstracts: Vasculitis – Non-ANCA-Associated & Related Disorders (0502–0507)
Session Type: Abstract Session
Session Time: 3:30PM–5:00PM

Background/Purpose: The two main forms of large vessel vasculitis (LVV), giant cell arteritis (GCA) and Takayasu's arteritis (TAK), are clinically heterogenous diseases with variable disease courses. Although ^{18}F-fluorodeoxyglucose positron emission tomography (FDG-PET) can be used to detect vascular inflammation, there is little data detailing PET activity over time in LVV.

Methods: Patients with TAK or GCA who fulfilled existing classification criteria were recruited into a single-center prospective, observational cohort. Patients could be enrolled at any point in the disease course. All patients underwent FDG-PET at recruitment per a standardized imaging protocol with follow up imaging at ≥6-month intervals whenever possible. Qualitative assessment of FDG uptake was performed via visual assessment of 9 arterial territories each scored on a scale from 0-3, yielding a summary score ranging from 0-27, PETVAS (PET Vascular Activity Score). Higher scores indicate greater global burden of vascular inflammation. Each study was subjectively interpreted by a central reader, blinded to clinical status, as active or inactive vasculitis. Fisher exact and Mann-Whitney *U* tests were used to compare variables. Linear regression was used to study trends in PETVAS over time.

Results: A total of 322 FDG-PET scans were examined in 121 LVV patients (TAK = 66; GCA = 55). There were 160 FDG-PET scans from TAK patients and 162 scans from GCA patients.



In the first year after diagnosis, 48 patients (TAK = 21; GCA = 27) had at least one PET at a mean disease duration of 175 days (TAK = 146 days; GCA = 197 days). Of these, 37 patients (77%, TAK = 17; GCA = 20) had an active FDG-PET scan. Median PETVAS in the first year after diagnosis was significantly greater in GCA than TAK (22 vs. 17, $p < 0.01$), but median daily steroid dose at time of imaging was not significantly different between GCA and TAK (10 vs. 7.5mg/day, $p = 0.32$). One to five years after diagnosis, 68 patients (TAK = 34; GCA = 34) contributed 152 scans (TAK = 68, GCA = 84), and 105 (69%, TAK = 44; GCA = 61) showed active disease. Beyond 5 years, 38 patients (TAK = 27; GCA = 11) contributed 77 scans (TAK = 49, GCA = 28), and 45 (58%, TAK = 27; GCA = 18) showed active disease.

PETVAS scores significantly decreased at a rate of -0.42 PETVAS/year over a mean disease duration of 2.9 years for GCA patients. PETVAS scores did not significantly decrease for TAK patients over a mean disease duration of 6.3 years (FIGURE).

Of 36 patients with ≥3 FDG-PET scans performed >1 year after diagnosis, scans from 13 patients (TAK = 6; GCA = 7) always showed active disease, scans from 3 patients never showed active disease (TAK = 3; GCA = 0), and scans from 20 patients (TAK = 8; GCA = 12) showed active or inactive disease on serial imaging.

Conclusion: Longitudinal patterns of vascular PET activity are different between TAK and GCA. Patients with GCA have a higher burden of vascular inflammation on FDG-PET during the first year of disease compared to TAK. On average, vascular PET activity significantly decreases over time only in GCA. Most patients with LVV continue to have active vasculitis on PET years after diagnosis despite treatment. Changes in PET activity are dynamic, even in later phases of disease, suggesting LVV is a chronic, inflammatory and relapsing disease.

Risk of Venous and Arterial Thromboembolism in Patients with Giant Cell Arteritis And/or Polymyalgia Rheumatica: A Veterans Health Administration Population-Based Study in the United States

Despina Michailidou[1], Tianyu Zhang[2], Pavlos Stamatis[3] and Bernard Ng[4], [1]Division of Rheumatology, University of Washington, Seattle, WA, [2]Department of Biostatistics, University of Washington, Seattle, WA, [3]Lund University, Lund, Sweden, [4]Rheumatology Section, VA Puget Sound HCS, University of Washington, Seattle, WA

SESSION INFORMATION

Session Date: Saturday, November 6, 2021

Session Title: Abstracts: Vasculitis – Non-ANCA-Associated & Related Disorders (0502–0507)

Session Type: Abstract Session

Session Time: 3:30PM–5:00PM

Background/Purpose: Giant cell arteritis (GCA) and polymyalgia rheumatica (PMR) are two chronic systemic inflammatory diseases that primarily affect elderly women. Both diseases can be complicated by inflammatory induced thrombosis, however the risk of thromboembolism among male patients with GCA and/or PMR is yet unknown. Due to the tight relationship between inflammation and thrombosis contributing to increased morbidity and mortality, we sought to determine the incidence rate of venous and arterial thrombotic events in patients with GCA and/or PMR among Veterans of the US. The objective of this study was to evaluate the risk of thromboembolism and retinal vascular events in GCA, PMR, and/or overlap of GCA with PMR compared to osteoarthritis (OA) in a Veteran's based population.

Methods: 1,581 patients with GCA, 10,940 with PMR, and 1,230 with GCA and PMR as well as 120,708 age- and sex-matched patients with OA, were identified in this retrospective study. Incidence rate ratios (IRR) of pulmonary embolism (PE), deep venous thrombosis (DVT), arterial thromboembolism of extremities (ATE), central retinal artery and vein occlusion (CRAO and CRVO) were calculated. We also calculated hazard ratios (HRs) of thromboembolic events in study groups, adjusting for independent risk factors of thromboembolism.

Results: Patients with GCA, PMR and GCA with PMR had higher IRs of all thromboembolic events as compared to patients with OA (Table 1). Patients with overlap of GCA and PMR had a lower risk of deep venous thrombosis (HR: 2.13, 95%CI:1.53-2.97, p< 0.001) and retinal vascular events (HR: 4.46, 95%CI:2.49-7.96, p< 0.001) as compared to patients with GCA (HR: 4.17, 95%CI:3.38-5.15, p< 0.001, and HR: 10.60, 95%CI: 7.56-14.86, p< 0.001, respectively), but a higher risk of retinal vascular events as compared to patients with PMR (HR: 2.33, 95%CI:1.75-3.11, p< 0.001) (Table 2).

Table 1. Risk of Incident PE, DVT, ATE, and combined CRAO/ CRVO among patients with GCA, PMR, GCA&PMR and OA

Incidence Rate Ratio (95% CI)	9.84 (6.32-14.59)	2.94(2.17 -3.91)	7.82 (4.26 -13.06)	1

Table 2. Hazard Ratios (HRs) of PE, DVT, ATE, and combined CRAO/CRVO associated with GCA, PMR, and GCA&PMR compared to OA

	GCA	PMR	GCA&PMR
PE (HR, 95%CI, p-value)	4.29 (3.15-5.85), <0.001	3.03 (2.57-3.57), <0.001	3.42 (2.29-5.10), <0.001
DVT (HR, 95%CI, p-value)	4.17 (3.38-5.14), <0.001	2.25 (1. 99-2.54), <0.001	2.13 (1.53-2.97), <0.001
ATE (HR, 95%CI, p-value)	3.25 (1.82-5.82), <0.001	1.80 (1.27-2.55), <0.001	3.10 (1.53-6.29), <0.001
CRAO /CRVO (HR, 95%CI, p-value)	10.60 (7.56-14.86), <0.001	2.33 (1.75-3.11), <0.001	4.46 (2.49-7.96), <0.001

Conclusion: The risk of thromboembolic events was higher in patients with GCA, PMR, and GCA with PMR compared to referenced population, and differed based on disease diagnosis. These findings may alert providers to be mindful of the importance for close monitoring of these patients for thromboembolic risk factors and may emphasize the need for a risk stratification strategy that would allow identification of high-risk patients.

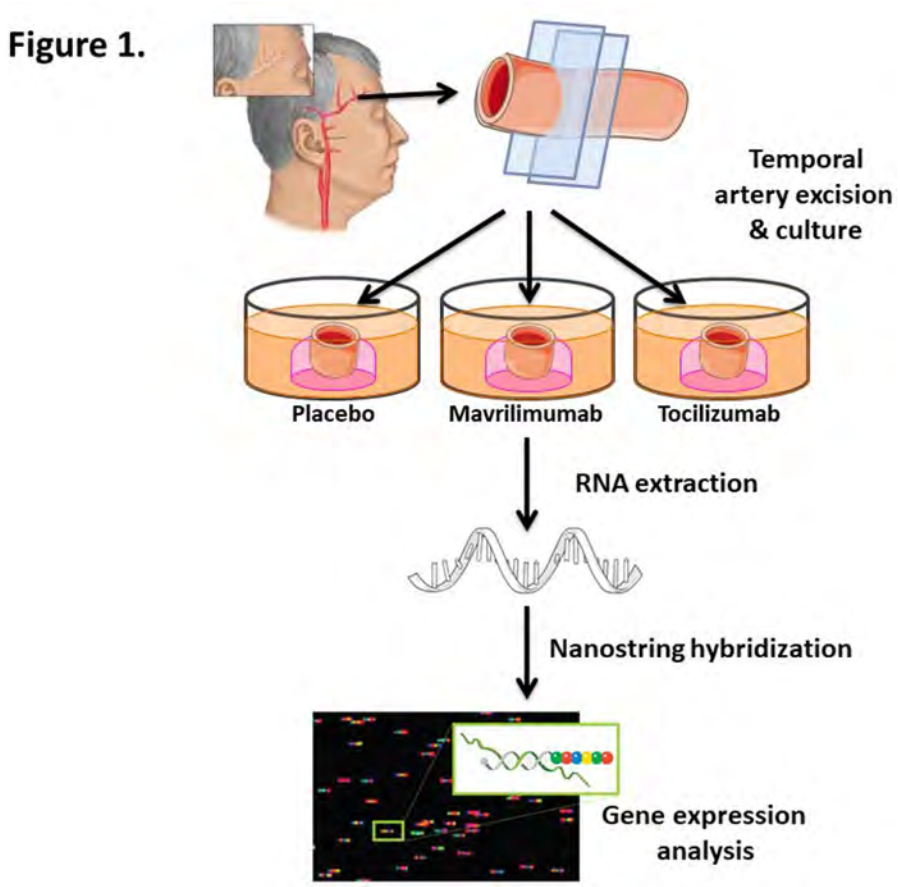
SESSION INFORMATION
Session Date: Saturday, November 6, 2021
Session Title: Abstracts: Vasculitis – Non-ANCA-Associated & Related Disorders (0502–0507)
Session Type: Abstract Session
Session Time: 3:30PM–5:00PM

Background/Purpose: Giant cell arteritis (GCA) is a chronic disease, and affected patients suffer from relapses and glucocorticoid (GC)-related toxicity. Targeted therapies are emerging with the aim of achieving better disease control and reducing GC exposure. Blocking IL-6 receptor with tocilizumab has been a major advance in the treatment of GCA. However, approximately 40% of patients treated with tocilizumab in combination with GCs experience a flare or tocilizumab-related adverse event. Blocking GM-CSF receptor a with mavrilimumab significantly reduced risk of relapse and improved sustained remission at week 26 vs placebo in a Phase 2 trial. Not all patients satisfactorily respond to any therapy, indicating heterogeneity in leading pathogenic pathways among patients. For these reasons, it is crucial to understand the specific impact of targeted therapies on vascular lesions.

In this study we investigated transcriptomic changes induced by tocilizumab or mavrilimumab in *ex-vivo* cultured arteries from patients with GCA.

Methods: Temporal artery sections obtained for diagnostic purposes from 11 patients with histopathologically-confirmed GCA and 3 controls were cultured *ex-vivo* and exposed to placebo, mavrilimumab, or tocilizumab (both at 20 µg/mL) for 5 days (Fig 1). Of 11 GCA donors, 2 had received no treatment prior to biopsy, 2 had received a single prednisone (60 mg) dose, 1 had received 2 daily doses, and the remaining 6 had extended treatment; in prednisone-



treated patients, mean (SEM) treatment duration was 17.9 ±8.7 days. Samples were homogenized, and total RNA was extracted with TRIzol reagent. 100 ng of RNA per sample were processed with Nanostring Inflammation gene expression assay (256 transcripts) and hybridized using nCounter Prep Station. Barcode counts from nCounter Digital Analyzer were processed with nSolver 4.0 Software. Normalised data were analyzed using R Studio 4.0.5 and IBM SPSS 22.0, and paired Wilcoxon tests were applied individually to each treatment comparison group for each analysed gene.

Results: 67 out of 250 transcripts were differentially expressed between arteries from GCA patients and arteries from control patients (all placebo-treated). Of those, only 9 transcripts remained significant after correction for multiple comparisons, with a false discovery rate ≤0.05. 81 transcripts were differentially expressed in at least one comparison across groups (Fig 2). 15 transcripts were lower, and 6 were higher in the mavrilimumab group vs placebo; 3 transcripts were lower, and 2 were higher in the tocilizumab group vs placebo (Fig 3A-3B). Most changes elicited between treatments were unique, but CXCL-1 was common (Fig 3C). None remained significant after correction for multiple comparisons.

Conclusion: Mavrilimumab and tocilizumab have a different transcriptomic impact on cultured arteries from patients with GCA, with some overlapping effects, although differential effects may have been attenuated by prior GC use. A better understanding of the impact of targeted therapies on vascular inflammation is needed to improve treatment options for patients with GCA.

Session Date: Saturday, November 6, 2021
Session Title: Abstracts: Vasculitis – Non-ANCA-Associated & Related Disorders (0502–0507)
Session Type: Abstract Session
Session Time: 3:30PM–5:00PM

Background/Purpose: PMR is the second most common inflammatory rheumatic disease of people aged 50 years or older. Glucocorticoid therapy is highly effective, but many patients require treatment for several years with significant risk of adverse events. Therefore, effective glucocorticoid sparing agents are needed. Here we investigate the efficacy and safety of tocilizumab versus placebo on background treatment with glucocorticoids in patients with new onset PMR.

Methods: In this double-blind, multi-center phase 2/3 clinical trial, we randomly assigned patients from three centers with new onset PMR in a 1:1 ratio to receive subcutaneous tocilizumab at 162mg weekly or matching placebo for 16 weeks, with 8 weeks of follow-up. All patients received oral prednisone at a starting dose of 20mg, but were rapidly tapered to nil over eleven weeks. The primary endpoint was the proportion of patients in glucocorticoid-free remission at week 16; key secondary endpoints, including time to first relapse and cumulative glucocorticoid dose at weeks 16 and 24, were evaluated. This study is registered with clinicaltrials.gov (NCT03263715).

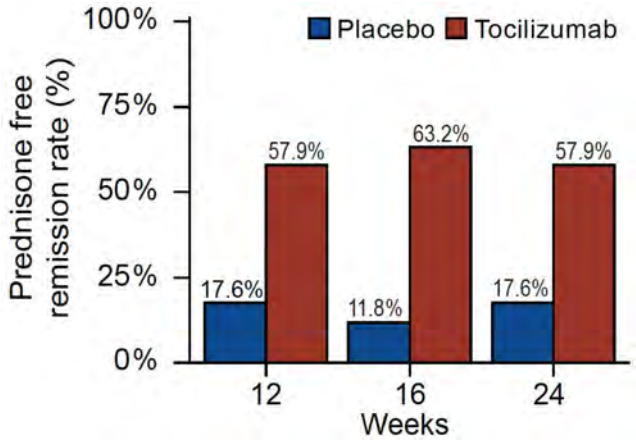

Figure 1. GC-free remission in PMR patients treated with TCZ vs Placebo.

Results: In accordance with the power calculation informed by previous open studies, 36 patients were randomly assigned to tocilizumab (n=19) or placebo (n=17). Glucocorticoid-free remission at week 16 was achieved in 12/19 patients treated with tocilizumab (63.2%) vs 2/17 patients treated with placebo (11.8%), corresponding to an odds ratio of 12.9 (95 % confidence interval: 2.2 to 73.6) in favor of tocilizumab (p=0.002 by Fisher's exact test). Mean (±SD) time to first relapse was 130±13 and 82±11 days (p=0.007), and the median (interquartile range) cumulative glucocorticoid dose was 727 (721;842) and 935 (861;1244) mg (p=0.003), respectively (Figure 1).

In hierarchical analyses, statistical significance was reached for many secondary outcomes including cumulative prednisone dose at week 24 **(Table 1)**.

Serious adverse events were observed in five patients receiving placebo and in one patient receiving tocilizumab.

Conclusion: In this first randomized controlled trial of tocilizumab in PMR, patients with new onset PMR undergoing rapid glucocorticoid tapering, tocilizumab was superior to placebo regarding sustained glucocorticoid-free remission, time to relapse, and cumulative glucocorticoid dose.

Table 1. Secondary endpoints in the intention to treat population

Testing hierarchy	Secondary endpoints*	Tocilizumab	Placebo	p-value
1	Proportion of patients in glucocorticoid-free remission at week 12	57.9%	17.6%	0.02
2	Proportion of patients in glucocorticoid-free remission at week 24	57.9%	17.6%	0.02
3	Time to first relapse (days; mean±SE)	130 (±13)	82 (±11)	0.007
4	Cumulative prednisone dose at week 16 (mg)	727 (721-842)	935 (861 - 1244)	0.003
5	Cumulative prednisone dose at week 24 (mg)	781 (721-972)	1290 (1106 - 1809)	0.001
6	Proportion of subjects with increased ESR (>20mm/h) at week 24 **or** Proportion of subjects with increased CRP (> 5mg/L) at week 24	21.1% 42.1%	47.1% 52.9%	n.r. n.r.
7	Pain by visual analogue scale (mm) at week 16	12.0 (4.0-29.0)	15.0 (1.5 - 45.5)	n.d.
8	Patient global assessment of disease activity by visual analogue scale (mm) at week 16	8.0 (3.0-25.0)	16.0 (3.0 - 50.0)	n.d.
9	Evaluator global assessment by visual analogue scale (mm) at week 16	2.0 (0-6.0)	5.0 (1.0 - 30.0)	n.d.
10	Short Form-36 (Physical Component Score) at week 16	56.3 (48.8-61.0)	46.9 (42.2 - 49.8)	n.d.
11	Health Assessment Questionnaire (0-3) at week 16	0.0 (0.0-0.5)	0.88 (0.13 - 1.13)	n.d.

* Data shown are medians and interquartile ranges, unless stated otherwise n.d., not done (given the hierarchical testing rule); n.r., not reported (first non-significant value in the hierarchical testing)

The Impact of Macrophages Stimulated with Malondialdehyde-Acetaldehyde And/or Citrulline Modified Proteins on Fibroblasts Activation

Nozima Aripova, Michael Duryee, Evan Ryan, Peter Maloley, Bryant England, James O'Dell, Ted Mikuls and Geoffrey Thiele, University of Nebraska Medical Center, Omaha, NE

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Cytokines & Cell Trafficking Poster (0508–0516)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: In rheumatoid arthritis (RA), chronic synovial inflammation is accompanied by fibrotic responses that together lead to pannus formation and progressive joint damage. Exposure to malondialdehyde-acetaldehyde adducts (MAA) and/or citrullinated (CIT) proteins in isolation or in combination significantly influence in vitro inflammatory and fibrotic responses in macrophage and fibroblast cell lines in isolation. However, the potential interaction between these two cell types in the context of exposure to different post-translationally (co-)modified proteins has not been well delineated. The purpose of this study was to evaluate whether soluble factors secreted by macrophages (U937 cells) in response to MAA and/or CIT modified proteins affect the inflammatory and/or fibrotic responses by human fibroblast-like synoviocytes derived from RA synovium (HFLS-RA).

Methods: PMA-treated U937 cells were stimulated with MAA, CIT, or MAA-CIT modified human serum albumin (HSA) or fibrinogen (FIB) for 24 hours. Cell supernatants were collected and analyzed for the following cytokines: MIP-1α, IL-1β, and IL-18 using Meso Scale Discovery (MSD) platform. In a separate experiment, HFLS-RA cells were co-incubated with previously collected U937 supernatants (following antigen stimulation as above) and mRNA was isolated to evaluate fibrotic markers with PCR: type II collagen (COL2A1), MMP9, and vimentin (VIM). To account for the fact that increased mRNA expression could derive from modified antigens in the supernatant, we set a control following direct stimulation of HFLS-RA cells with MAA and/or CIT modified antigen in the absence of supernatants. One-way ANOVA was used to compare cytokine and mRNA levels across groups.

Results: Stimulation of U937 cells with MAA, CIT, or MAA-CIT modified HSA demonstrated a significant increase in MIP-1α and IL-1β release (**Fig.1A, C**). In contrast, MIP-1α and IL-1β release were the greatest with FIB-CIT stimulation, followed by FIB-MAA-CIT (**Fig.1B, D**). IL-18 concentrations were increased significantly with HSA-MAA, HSA-MAA-CIT, and FIB-MAA-CIT stimulation (**Fig.1E, F**). When HFLS-RA cells were stimulated with HSA-MAA treated U937 supernatants, mRNA levels of COL2A1 and MMP9 increased 3 and 4-fold, respectively, compared to HSA-MAA stimulation without U937 supernatants (**Fig.2A**). Dually modified (MAA-CIT) HSA and FIB treated U937 supernatants increased HFLS-RA mRNA levels for VIM (**Fig.2A, B**). FIB-CIT and FIB-MAA-CIT treated U937 supernatants

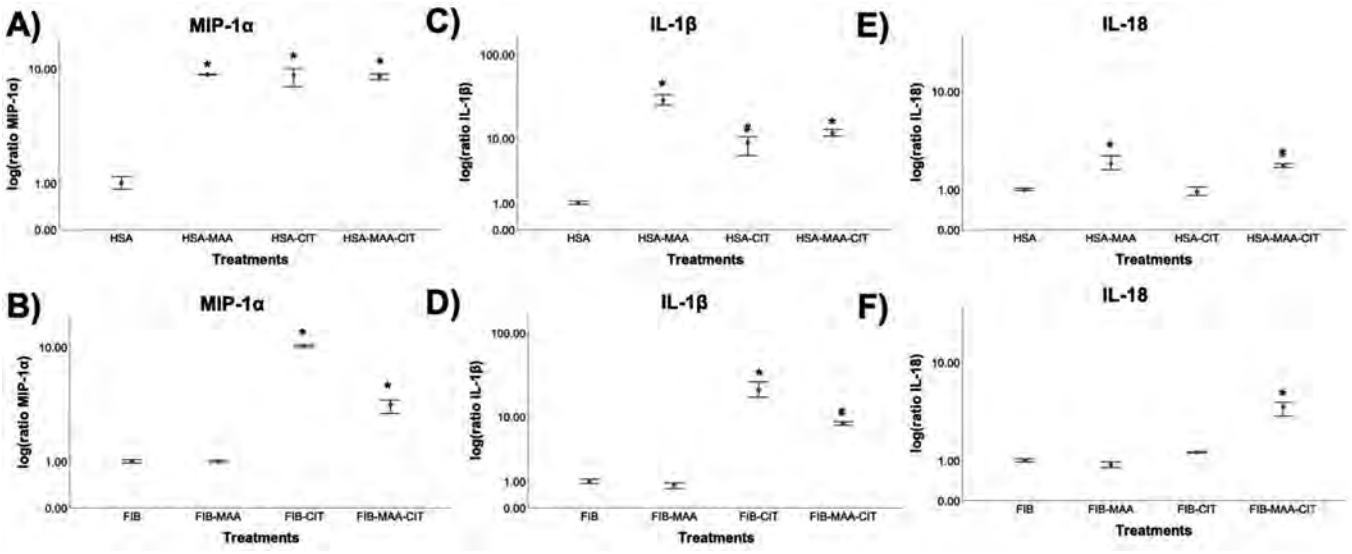

Figure 1. Cytokine release from stimulated U937 cells. U937 cells were incubated with HSA (A,C, and E) and FIB (B,D and F) modified antigens. Afterwards, the supernatants were collected for analysis of; MIP-1**α** (A,B), IL-1**β** (C,D), and IL-18 (E,F) release using Mesoscale Discovery assay kit. The concentration of all cytokines were measured in pg/mL and normalized to native protein. Log based 10 ratio of modified protein to native protein is represented on y-axis (HSA and FIB respectively). #p<0.05, *p<0.001, n=3.

increased HFLS-RA mRNA levels for both COL2A1 and MMP9 as compared to direct stimulation of HFLS-RA with FIB-CIT and FIB-MAA-CIT antigens without U937 supernatants (**Fig.2B**).

Conclusion: These results suggest a disease model whereby MAA and/or CIT modified proteins stimulate macrophages to release a unique combination of soluble mediators (such as MIP-1α, IL-1β or IL-18) that activate HFLSs and upregulate protein expression driving tissue fibrosis, in an antigen-specific manner (**Fig. 3**). Together with prior studies demonstrating MAA and CIT co-localization in RA synovium, these results indicate that MAA and/or CIT modified antigens may play a direct role in the development of fibrosis that has been observed in RA joint pathogenesis.

Selective Inhibition of Tyrosine Kinase 2 with Deucravacitinib Compared with Janus Kinase 1/2/3 Inhibitors

Anjaneya Chimalakonda[1], James Burke[1], Lihong Cheng[1], Ian Catlett[1], Michael Tagen[1], Qihong Zhao[1], Aditya Patel[1], Jun Shen[1], Ihab Girgis[1], Subhashis Banerjee[1] and John Throup[2], [1]Bristol Myers Squibb, Princeton, NJ, [2]Bristol Myers Squibb, Princeton

SESSION INFORMATION

Session Date: Sunday, November 7, 2021
Session Title: Cytokines & Cell Trafficking Poster (0508–0516)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Deucravacitinib is a novel, oral, allosteric agent that selectively inhibits intracellular signaling by binding to the tyrosine kinase 2 (TYK2) pseudokinase domain rather than to the conserved active site in the kinase domain. The high functional selectivity for TYK2 versus other signaling tyrosine kinases has been confirmed in cell- and whole blood–based assays.[1] Kinase selectivity should provide a differentiated risk/benefit profile due to potent TYK2 inhibition and minimal activity against other kinases. In a 1-year, double-blind, Phase 2 trial (NCT03881059), deucravacitinib was efficacious and well tolerated versus placebo in patients with active PsA.[2] The objective of this analysis was to understand the selectivity profile of deucravacitinib for TYK2 versus Janus kinase (JAK) 1/2/3, compared with the approved JAK inhibitors tofacitinib (Tofa), upadacitinib (Upa), and baricitinib (Bari), at clinically relevant doses and plasma concentrations.

Methods: In vitro whole-blood assays were established to measure the activity of common intracellular pairings of signaling tyrosine kinases (JAK1/3, JAK2/2, and TYK2/JAK2). Deucravacitinib, Tofa, Upa, and Bari concentrations providing half-maximal inhibition (IC_{50}) of relevant signaling readouts were determined. Whole-blood IC_{50} values were plotted against known pharmacokinetic profiles of these agents at doses evaluated in Phase 3 trials, including approved doses. Time durations when concentrations were greater than IC_{50} and projected average daily inhibition were evaluated.

Results: At clinically relevant doses and exposures, deucravacitinib steady-state plasma concentrations were higher than the TYK2 whole-blood IC_{50} for a considerable part (9–18 hours) of the day. The maximal plasma concentration (C_{max}) of deucravacitinib was 8- to 17-fold lower than the JAK1/3 whole-blood IC_{50} and >48- to >102-fold lower than the JAK2/2 whole-blood IC_{50}, indicating lack of meaningful inhibition of JAK1/2/3 by deucravacitinib at clinically relevant doses. Average daily inhibition of TYK2 by deucravacitinib ranged from 50% to 69%. Tofa, Upa, and Bari exhibited varying degrees of daily average inhibition at steady-state against JAK1/3 (70%–94%) and JAK2/2 (23%–67%). Projected C_{max} values of Tofa, Upa, and Bari were 17- to 33-fold lower than TYK2 IC_{50}, indicating minimal or no meaningful inhibition of TYK2.

Conclusion: Deucravacitinib has high functional selectivity for TYK2 at clinically relevant doses and plasma concentrations. In contrast, Tofa, Upa, and Bari inhibit JAK1/2/3 to varying degrees but do not inhibit TYK2 at clinically relevant concentrations. These results indicate that deucravacitinib is a distinct class of signaling kinase inhibitor compared with JAK1/2/3 inhibitors. Studies in multiple immune-mediated inflammatory diseases including plaque psoriasis, psoriatic arthritis, lupus, and inflammatory bowel disease will further assess the safety and efficacy of deucravacitinib.

Fibrinogen Modified with Malondialdehyde-Acetaldehyde Adduct (MAA) And/or Citrulline (CIT) Induces Unique Cellular Responses in Human RA Synoviocytes

Brittany Wordekemper, Nozima Aripova, Michael Duryee, Eric Daubach, Bryant England, James O'Dell, Ted Mikuls and Geoffrey Thiele, University of Nebraska Medical Center, Omaha, NE

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Cytokines & Cell Trafficking Poster (0508–0516)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

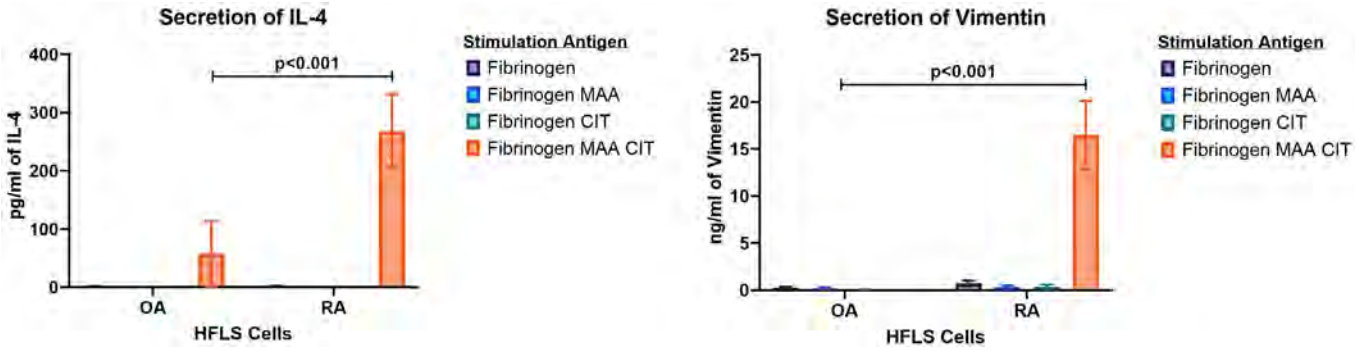

Figure 1. Pro-fibrotic factors release from stimulated HFLS-RA cells. HFLS-RA cells were incubated with Fibrinogen modified antigens. Afterwards, the supernatants were collected for analysis of: IL-4 (A) and vimentin (B) release using Mesoscale Discovery assay kit. The concentration of all cytokines was measured in ng/mL. p<0.001 significantly different from all OA cell antigen treatments. n=4.

Background/Purpose: Malondialdehyde (MDA) is produced in response to oxidative stress and is associated with inflammation and disease pathogenesis. MDA can break down and form acetaldehyde (AA). Together MDA and AA can non-enzymatically combine to create a stable protein adduct termed malondialdehyde-acetaldehyde adduct (MAA), which is strongly immunogenic, even in the absence adjuvant. Our group showed that MAA modified proteins are present in Rheumatoid Arthritis (RA) synovium and co-localize with citrullinated (CIT) antigens known to be strongly associated with the pathogenesis of RA. RA synovium is characterized by a combination of pro-inflammatory and pro-fibrotic signals secreted by immune cells and resident human fibroblast-like synoviocytes (HFLS). The purpose of this study is to evaluate pro-inflammatory and pro-fibrotic signals released by HFLS from patients with RA (HFLS-RA) vs. HFLS from patients with osteoarthritis (HFLS-OA) when stimulated with an extracellular matrix protein fibrinogen (Fib) modified with MAA, CIT, or the combination of MAA-CIT.

Methods: The HFLS-RA and HFLS-OA cell lines were cultured for 24 hours in the presence of 25 µg/mL of; unmodified Fib or Fib modified with MAA, CIT, or MAA-CIT. Supernatants were collected and analyzed by ELISA using the Meso Scale Diagnostics (MSD) platform for the release of pro-inflammatory and pro-fibrotic markers.

Results: Compared to HFLS-OA cells, HFLS-RA cells stimulated with Fib-MAA-CIT (Figures 1 and 2) significantly increased the secretion of vimentin and IL-4 (pro-fibrotic markers), and IL-6, IL-8, and MCP-1 (pro-inflammatory markers). HFLS-RA cells stimulated with Fib-CIT showed significantly increased levels of only the pro-inflammatory markers; IL-6 and MCP-1 (**Figure 2**) as compared to HFLS-OA cells. Additionally, HFLS-RA cells stimulated with Fib-MAA showed significantly increased secretions of the pro-inflammatory marker IL-8 (Figure 2B) compared to HFLS-OA cells.

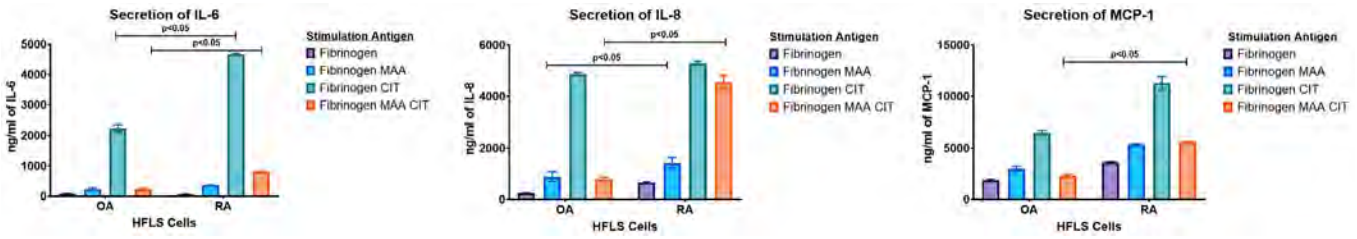

Figure 2. Pro-inflammatory cytokines release from stimulated HFLS-RA cells. HFLS-RA cells were incubated with Fibrinogen modified antigens. Afterwards, the supernatants were collected for analysis of: IL-6 (A), IL-8 (B), and MCP-1 (C) release using Mesoscale Discovery assay kit. The concentration of all cytokines was measured in ng/mL. p<0.05 significantly different from OA cells treated with Fib-Cit. p<0.05 significantly different from OA cells treated with Fib-MAA-CIT. n=4.

Conclusion: These studies demonstrate that HFLS-RA cells secreted significantly increased pro-inflammatory and/or pro-fibrotic markers when compared to HFLS-OA cells depending on whether fibrinogen was modified with MAA, CIT or MAA-CIT. Additionally, these data also suggest that the HFLS-RA cells developed unique cellular responses compared to OA cells, making them useful in understanding how these modified proteins affect HFLS cells. Thus, further studies will evaluate the effects of other extracellular proteins that have been implicated in the pathogenesis of RA, and modified with MAA, CIT or MAA-CIT on the expression of pro-inflammatory and pro-fibrotic markers.

Tumor Necrosis Factor-α Modulates Endothelial-to-mesenchymal Transition and Increases Protein Tyrosine Phosphatase 1B

Jorge Romo-Tena[1], Jose Esparza-Lopez[2], Carmelo Carmona-Rivera[3], Luz P blanco[3], Mariana Kaplan[4] and María de Jesús Ibarra-Sánchez[2], [1]INNSZ / NIAMS, Mexico City, Mexico, [2]INNSZ, Mexico City, Mexico, [3]NIAMS, Bethesda, MD, [4]National Institutes of Health, Bethesda, MD

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Cytokines & Cell Trafficking Poster (0508–0516)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Endothelial dysfunction is a hallmark in the pathogenesis of many inflammatory diseases. The endothelial-to-mesenchymal transition (EndoMT) is a process where endothelial cells lose their endothelial features and acquire fibroblast-like phenotype. EndoMT has been associated with vasculopathy, atherogenesis, and it is promoted by several proinflammatory cytokines, such as tumor necrosis factor α (TNF-α). Protein tyrosine phosphatase 1B (PTP1B) modulates many signaling pathways associated with inflammatory mediators and has been associated with endothelial dysfunction and cardiovascular disturbances. However, it remains unclear the role of PTP1B in TNFα-induced EndoMT.

Objective. To characterize EndoMT promoted by TNF-α in human endothelial cells (ECs) and the putative role of PTP1B in this process.

Methods: Human aortic endothelial cells (HAECs) were used as model for *in vitro* induction of EndoMT. These ECs were incubated with human recombinant TNF-α (25 ng/mL) for 2 and 4 days. Expression of endothelial markers (eNOS, CD31, VE-cadherin) and mesenchymal marker (N-cadherin), and the transcription factors SNAI1, TWIST1 and ZEB1 along with PTP1B during EndoMT were evaluated by Western blot (WB). Canonical NF-κB pathway activation in EndoMT was assessed by phosphorylation of p65-Ser536, degradation of IkB-α and nuclear translocation of p65 by WB and immunofluorescence (IF). Inhibition of NF-kB pathway was assessed by using the IKK-β specific inhibitor BMS-345531 (5 μM).

Results: HAECs underwent EndoMT after 2- and 4-days TNF-α treatment. Expression of eNOS, CD31 and VE-cadherin were downregulated, and N-cadherin was upregulated as well as the transcription factors SNAI1, TWIST1

and ZEB1. Concomitant with this process, PTP1B increased its expression levels. TNF-α induced phosphorylation of NF-κB (p65-Ser 536) and degradation of IκB-α. Nuclear translocation of p65 was more evident 15 min after treatment. ECs pre-treated with BMS-345531 before TNF-α addition decreased TNF-α-induced phosphorylation of NF-κB (p65-Ser 536) and nuclear translocation of p65, and prevented degradation of IκB-α. Furthermore, decreased expression of N-cadherin, SNAI1 and TWIST1 was observed after 2 days of treatment with BMS-345531 + TNF-α.

Conclusion: TNF-α promotes EndoMT in human ECs by activating canonical NF-κB pathway. During this process PTP1B increases its expression levels. Pharmacological inhibition of IKK-β attenuated TNF-α-induced NF-kB activation with concomitant inhibition of EndoMT. These findings unveil an important pathway in endothelial dysfunction and vasculopathy associated with inflammatory conditions and suggest novel avenues for intervention.

Abstract Number: 0512

Peficitinib and Filgotinib Inhibit Angiogenesis via Suppression of VEGF Production in Rheumatoid Arthritis Fibroblast-like Synoviocytes

Yuzo Ikari, Takeo Isozaki, Kuninobu Wakabayashi and Tsuyoshi Kasama, Division of Rheumatology, Department of Medicine, Showa University School of Medicine, Tokyo, Japan

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Cytokines & Cell Trafficking Poster (0508–0516)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Peficitinib and filgotinib are novel Janus kinase (JAK) inhibitors developed for the treatment of rheumatoid arthritis (RA). Peficitinib inhibits all JAKs, especially JAK3. Filgotinib, on the other hand, is a JAK1 selective inhibitor. In this study, to clarify the effect of different JAK inhibition selectivity on angiogenesis in RA fibroblasts, we examined the role of peficitinib and filgotinib in RA angiogenesis.

Methods: In order to confirm if the effect of peficitinib and filgotinib on IL-6 and IL-6R responses in RA fibroblast-like synoviocytes (FLS) and human umbilical vein endothelial cells (HUVECs), western blot analysis was performed. RA FLS and HUVECs were stimulated with IL-6 (100 ng/ml) and IL-6R (100 ng/ml) after treated peficitinib (0.1, 1, 5μM) or filgotinib (0.1, 1, 5μM) for 24 h. Next, to evaluate the effects of peficitinib and filgotinib on RA angiogenesis, we performed in vitro Matrigel tube formation assays using HUVECs. In addition, HUVECs were co-cultured in peficitinib (5 μM) or filgotinib (5 μM) treated RA FLS supernatant, and added on Matrigel. Furthermore, to confirm the direct effects of peficitinib and filgotinib on HUVECs, peficitinib or filgotinib was added to HUVECs supernatant. Finally, to measure the cytokines and chemokines in RA FLS supernatant, RA FLS supernatant was obtained from RA FLS-conditioned medium stimulated with IL-6 (100 ng/ml) and IL-6R (100 ng/ml) with or without adding peficitinib (5 μM) or filgotinib (5 μM). The amount of VEGF, RANTES/CCL5, MCP-1/CCL2, MMP-3, fractalkine/CX3CL1, ENA78/CXCL5 and IL-8 in RA FLS conditioned medium was determined using ELISA.

Results: We found phosphorylation of STAT1, STAT3 and STAT5 in RA FLS was suppressed by peficitinib and filgotinib. However, phosphorylation of STAT3 in HUVEC was not suppressed by filgotinib. Next, peficitinib or filgotinib treated RA FLS conditioned medium reduced HUVEC tube formation compared to nontreated RA FLS conditioned

medium (number of endothelial cell tubes formed ± SEM; Control 13.8 ± 1.23, peficitinib 8.5 ± 1.12, filgotinib 8.33 ± 0.73). Filgotinib directry reduced HUVEC tube formation compared to nontreated HUVECs supernatant (Control 7.41 ± 1.04, peficitinib 7.5 ± 0.95, filgotinib 4.58 ± 0.73). Furthermore, we found peficitinib and filgotinib suppress the secretion of VEGF in RA FLS (mean ± SEM; Control: 72.2 ± 1.17, Peficitinib: 42.6 ± 0.26, Filgotinib: 57.35 ± 0.41 pg/ml). Peficitinib significantly suppressed the secretion of VEGF in RA FLS than filgotinib.

Conclusion: Peficitinib and filgotinib suppressed the secretion of VEGF in RA FLS and RA angiogenesis through inhibition of VEGF. Differences in JAK inhibition selectivity of peficitinib and filgotinib affect the suppression of RA angiogenesis.

Spirulina Activates IFNγ via TLR4 in Dermatomyositis Skin and Peripheral Blood

DeAnna Diaz[1], Thomas Vazquez[2], Christina Bax[3], Jay Patel[4], Madison Grinnell[5], Emily Keyes[6], Yubin Li[5] and Victoria Werth[7], [1]Philadelphia College of Medicine, Philadelphia, PA, [2]FIU Wertheim College of Medicine, Virginia Beach, VA, [3]Corporal Michael J. Crescenz VAMC/ Department of Dermatology, U Penn, Philadelphia, PA, [4]Corporal Michael J. Crescenz VAMC, Department of Dermatology, U Penn, Philadelphia, NJ, [5]Corporal Michael J. Crescenz VAMC, Department of Dermatology, U Penn, Philadelphia, PA, [6]Department of Dermatology, Perelman School of Medicine at the University of Pennsylvania and Philadelphia VAMC, Philadelphia, PA, [7]University of Pennsylvania, Philadelphia, PA

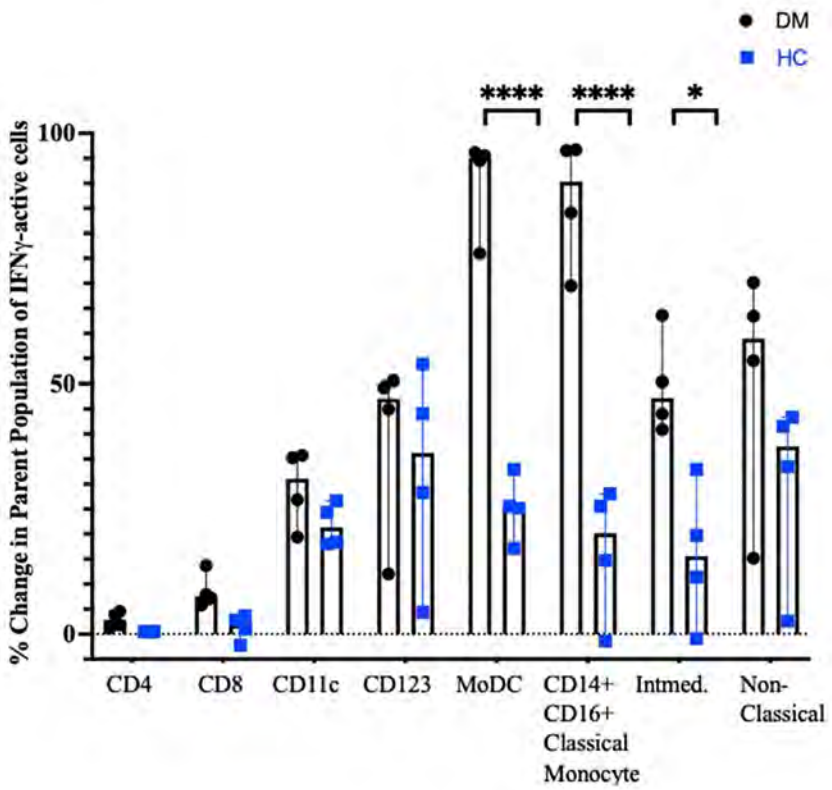
SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Cytokines & Cell Trafficking Poster (0508–0516)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Our group has previously shown that Spirulina, a popular herbal supplement with purported immune boosting effects, is temporally associated with dermatomyositis (DM) onset and flare. We have previously shown *in vitro* that Spirulina induces IFNγ.

Methods: Here, we sought to identify which cells and inflammatory pathways are activated as a result of Spirulina stimulation in DM patients. Given the important differences between the blood and end organ immune compartments, we sought to interrogate the effects of Spirulina in both blood and skin. We utilized multiplexed flow cytometry on DM patient PBMCs stimulated with 0.3mg/mL of Spirulina. Using GraphPad prism V8.4.3, comparisons between healthy controls and DM were made with Students t-test and comparison of multiple groups were made by one way ANOVA with a post hoc Tukey test. Correlations were analyzed with Pearson's r. With flow cytometry, we investigated Spirulina's immunostimulatory effects at the cellular level. Eight cell lineages were evaluated in PBMCs using FACS Symphony A3 Lite and analyzed with FlowJo V10.7.1.

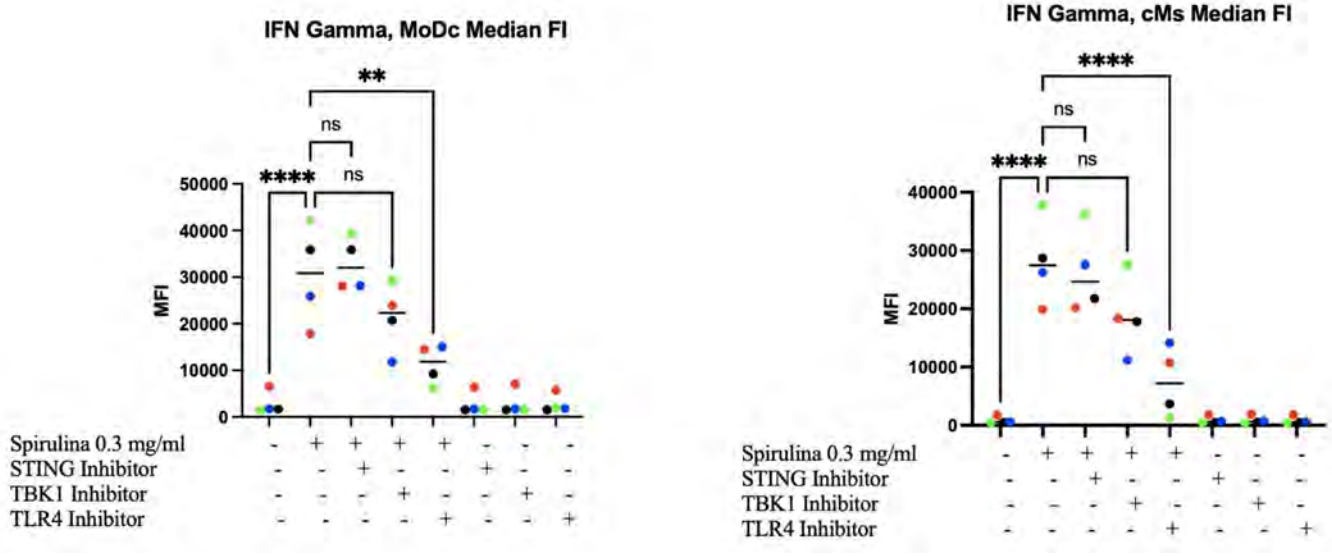
Results: When evaluating % change in activation with 0.3 mg/ml of Spirulina in DM and HC for IFNγ, monocyte-derived DCs (moDCs) and classical monocytes (CMs) had a significantly greater % increase in CMs and moDCs in DM compared to HC (Figure 1). With stimulation at 0.3 mg/mL of Spirulina, the IFNγ+ moDCs MFI increased by 11.7 fold relative to no stimulation ($p < 0.0001$). The MFI of CMs secreting IFNγ increased 32.0 fold with 0.3 mg/mL when compared to no added Spirulina ($p < 0.0001$) (Figure 2a and 2b). Pre-treatment with TLR4 inhibitor prior to Spirulina 0.3mg/ml of stimulation suppressed the MFI of IFNγ activation by 63.07% in moDCs, and by 73.4% in CMs ($p < 0.05$

Figure 1

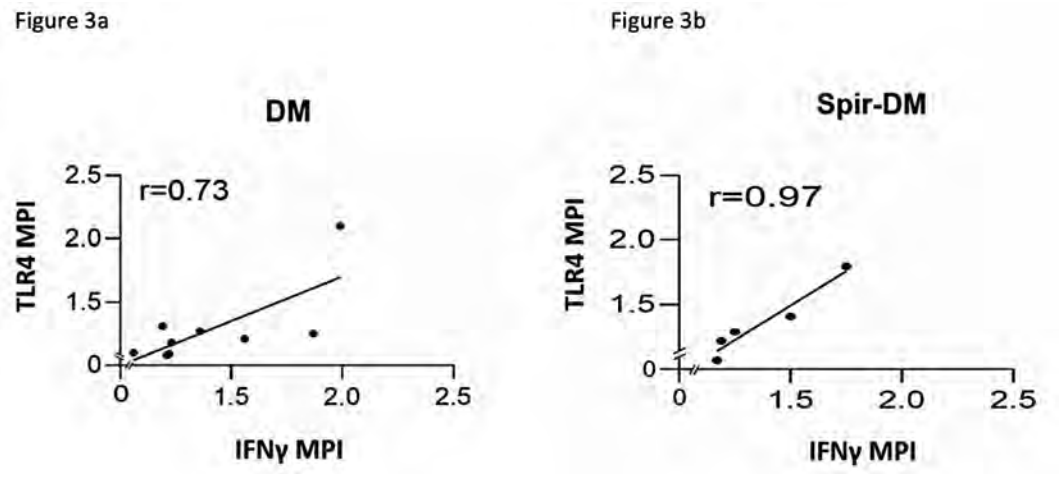


Cell specific production of IFNγ as a percent change of parent population with 0.3 mg/ml of Spirulina in dermatomyositis and healthy control patients measured by multiplexed flow cytometry.

and p< 0.001, respectively). We then performed imaging mass cytometry on lesional DM skin from patients with new-onset DM and a clear history of novel Spirulina consumption in the immediately preceding period (Spir-DM). Unsupervised clustering of dermal cells using the Phenograph algorithm yielded 14 unique cell types. MoDCs were



IFNγ production is stimulated by 0.3mg/mL of Spirulina in moDCs and CMs and is suppressed by inhibition of TLR4.



TLR4 expression is positively correlated with IFNγ production in DM (r=0.73) and Spir-DM (r=0.97) skin.

manually gated on CD14 and CD11c. CMs, were the predominant cell type (16.1%), followed by CD4 T cells (14.6%), CD163+ macrophages (9.6%), and moDCs (9.3%). There was overlap of CD14, CD11c, and IFNγ in Spir-DM skin, supporting an important role for moDCs and CM in the production of IFNγ. We then compared IFNγ and TLR4 expression in DM (Figure 3a) and Spir-DM (Figure 3b), finding a stronger positive correlation in Spir-DM (r=0.97) than in DM alone (r=0.73).

Conclusion: These results further implicate Spirulina as a likely culprit in the development of DM in some patients. Our data suggest that Spirulina may promote autoimmunity via production of IFNγ in CMs and moDCs in both the blood and skin, thereby implicating Spirulina in the development of DM in some susceptible patients.

Extracellular Sulfatase-2 Mediates TNF-α Inflammatory Signaling in Human Rheumatoid Arthritis Synovial Fibroblasts

Ruby Siegel[1], Anil singh[1], Judy Vinh[1], H. Mark Kenney[2], Edward Schwarz[3], David Fox[4], Sadik Khuder[5] and Salah-uddin Ahmed[1], [1]Washington State University, Spokane, WA, [2]University of Rochester Medical Center, Rochester, NY, [3]University of Rochester, Rochester, NY, [4]Division of Rheumatology, University of Michigan Medical School, Ann Arbor, MI, [5]Department of Medicine and Public Health, University of Toledo,, Toledo, OH

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Cytokines & Cell Trafficking Poster (0508–0516)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: TNF-α drives RA synovial fibroblast (RASF)-mediated hyperplasia and joint tissue destruction. Extracellular sulfatase-2 (Sulf-2) influences receptor/ligand binding and subsequent signaling of chemokines, cytokines, and growth factors, however, the potential role of Sulf-2 in TNF-α signaling has remained unexplored. Our

study compared Sulf-2 expression in synovial tissues and serum from hTNFtg mice and human RA patients vs. non-diseased controls and determined effects of Sulf-2 on TNF-α signaling and inflammation in human RASFs.

Methods: Sulf-2 expression was measured in human non-diseased vs. RA synovial tissues (NLSTs vs. RASTs) by qRT-PCR and Western blotting. Sulf-2 expression in wild-type C57BL/6 vs. hTNFtg mouse ankle sections was compared by fluorescence IHC. Soluble Sulf-2 in mouse and human serum was measured by ELISA. Global effects of Sulf-2 gene knockdown by siRNA on TNF-α-induced gene expression were studied using an RNA sequencing (RNA-seq) array. Differentially expressed genes (DEGs) were analyzed using edgeR package of R software. Selected gene targets were validated by qRT-PCR and Western blotting/ELISA. TNF-α signaling pathways affected by Sulf-2 knockdown were analyzed.

Results: Sulf-2 mRNA was 3-fold higher (n=6 each; $p< 0.001$) and protein 5-fold higher (n=5 each; $p< 0.01$) in RAST vs. NLST. Soluble Sulf-2 in human serum was ~2-fold higher in RA (n=48) over non-diseased (NL, n=50; $p< 0.001$). Sulf-2 expression was elevated in the inflamed synovium of hTNFtg mice over wild-type (n=3 each). Soluble Sulf-2 was elevated ~20% in hTNFtg male mice (n=3, n.s.) and 2-fold in females (n=3, $p< 0.05$) over wild-type. In the RNA-seq array of TNF-α-activated RASFs, Sulf-2 siRNA modulated ~2,500 DEG vs. NC siRNA (FDR< 0.05). Gene ontology showed Sulf-2 significantly altered expression of genes in the canonical pathway *role of macrophages, fibroblasts and endothelial cells in RA*. qRT-PCR confirmed that Sulf-2 knockdown reduced TNF-α-induced ICAM1 (-58%), VCAM1 (-50%), CAD11 (-45%), PDPN (-34%), CCL5 (-55%), CX3CL1 (-59%), CXCL10 (-65%), CXCL11 (-63%) compared to NC siRNA (n=4-6, $p< 0.01$). Signaling studies identified PKC-δ as a key intermediate in TNF-α induced adhesion proteins. Sulf-2 knockdown suppressed TNF-α-induced p-PKC-δ (Thr^{505})(-52%) and p-JNK(Thr^{183}/Tyr^{185}) (-36%)(n=6; $p< 0.05$) and nuclear translocation of inflammatory transcription factors including NFkB p65 and c-Rel.

Conclusion: Our results provide novel evidence of the role of Sulf-2 in TNF-α activated signaling pathways in human RASFs. Further studies may decipher the therapeutic value of targeting Sulf-2 in the treatment of RA.

Abstract Number: 0515

The Extracellular Sulfatase-2 Inhibitor OKN-007 Abrogates TNF-α-induced Inflammatory Mediators in Human Rheumatoid Arthritis Synovial Fibroblasts

Ruby Siegel, Sang Han and Salah-uddin Ahmed, Washington State University, Spokane, WA

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Cytokines & Cell Trafficking Poster (0508–0516)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Recent unpublished findings from our lab show that the extracellular enzyme sulfatase-2 (Sulf-2) facilitates pro-inflammatory TNF-α signaling which activates rheumatoid arthritis synovial fibroblasts (RASFs). The small molecule drug OKN-007 has been reported to inhibit Sulf-2 activity. OKN-007 demonstrated safety in hu-

man clinical trials at sustained plasma concentrations averaging 300 micromolar. In this study, we tested the efficacy of OKN-007 in reducing TNF-α-induced adhesion molecule and chemokine production by RASFs.

Methods: Experiments utilized primary human RASFs (n=5; age 30-61) from de-identified synovial tissues obtained under an IRB-approved protocol, from patients who met the ACR criteria for RA and were not treated with biologics. MTT viability assay was used to measure potential toxicity of OKN-007 [0-1000 μM] alone or with TNF-α for 24 h. To test effect of Sulf-2 inhibition on TNF-α induced proteins, RASFs were pre-treated with OKN-007 (0-1000 μM) for 12 h followed by TNF-α (20 ng/mL) stimulation for 24 h. RASFs not stimulated with TNF-α served as a negative control. Concentration of CCL2, CXCL5, CCL5, CXCL10, CXCL11 in cell supernatants were measured by ELISA. Expression of MAPK/NF-κB signaling and adhesion molecules (ICAM-1 and VCAM-1) were measured by densitometry on Western blots. The Sulf-2-inhibitory effects of OKN-007 were further validated by Sulf-2 small-interfering RNA (siRNA) method. Statistical value $p< 0.05$ was considered significant.

Results: OKN-007 alone at a dose range of 0-1000 μM did not significantly affect RASF viability (n=4). When combined with TNF-α, OKN-007 [500, 1000 μM] reduced the RASF viability by 22% and 29%, respectively (n=4; $p< 0.05$), suggesting sensitization of RASFs to TNF-α-induced apoptosis. Adhesion molecule expression was normalized to β-actin, accounting for any cell loss. OKN-007 [500, 1000 μM] decreased TNF-α-induced ICAM-1 by 20% and 36% and VCAM-1 by 23% and 35%, respectively (n=4; $p< 0.05$). OKN-007 (500-1000 μM) inhibited TNF-α-induced CCL2 (23-28%), CXCL5 (66-75%), CCL5 (~65%), CXCL10 (80-95%), and CXCL11 (43-65%) (n=4; $p< 0.05$). Further validation of the pharmacologic inhibition using Sulf-2-directed siRNA showed similar inhibition of TNF-α-induced chemokine production and adhesion molecule expression by human RASFs (n=4; $p< 0.05$). Evaluation of the signaling molecules suggest that OKN-007 suppressed TNF-α-induced signaling pathways to elicit its anti-inflammatory activity.

Conclusion: Our study in human RASFs suggests that pharmacologic inhibition of Sulf-2 with a safe, non-immunosuppressive compound may provide an adjunct therapeutic value with anti-TNF therapy for the treatment of RA.

Dual Fibroblast Transdifferentiation Mediated by Type I Interferon: Application to Anti-Ro Mediated Congenital Heart Block

Christina Firl[1], Miao Chang[2], Jill Buyon[3] and Robert Clancy[1], [1]NYU Grossman School of Medicine, New York, NY, [2]NYU Langone Health, New York, NY, [3]NYU School of Medicine, New York, NY

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Cytokines & Cell Trafficking Poster (0508–0516)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Linking inflammation to fibrosis, a common end stage feature of many autoantibody mediated rheumatic diseases, remains a challenge. Indeed the signature hallmark of anti-Ro associated congenital heart block (CHB) is rapid replacement of the AV node by fibrosis during the late 2nd trimester. Previously reported in vitro coculture experiments and transcriptomic analysis position type I Interferons in the pathogenesis of conduction disease, but it remains to be identified how IFNa contributes to a pathological cardiac fibroblast. By focusing solely

on smooth muscle actin (SMAc), heterogeneity in myofibroblasts has been underappreciated. The current study was initiated to evaluate Fibroblast-Specific Protein 1 (FSP1), a fibroblast marker with demonstrated responsiveness to the Wnt/β-catenin pathway, and its contribution, in concert with interferon alpha (IFNa), to cardiac injury propagated by maternal anti-Ro.

Methods: An in vitro model of anti-Ro mediated CHB employed co-culture of supernatants by hY3 (a noncoding ssRNA, anti-Ro proxy)-treated human macrophages (THP1 cells) with human cardiac fetal fibroblasts. In addition, fibroblasts were treated with IFNa or recombinant Wnt3A with and without their respective inhibitors (neutralizing IFNa antibody (NIFNa), ICG-001). Using standard techniques, assessments included transcriptomics (qPCR, IFNa stimulated genes (ISG)), immunofluorescence (IF) and flow cytometry (FC).

Results: Use of derivative of hY3-transfected THP1 cells (hY3 supernatants) markedly upregulated the fibroblast expression of ISGs, IFIT-1 and SIGLEC-1 supporting the secretion of IFNa by the THP-1 cells. After exposure to IFNa, SMAc and FSP1 expression in fibroblasts were significantly increased compared to untreated cells (SMAc: 23,347±2077 vs. 89.5±21, p< 0.01; FSP1: 2282.7±293 vs. 70.1±3, N=3, p< 0.01). As predicted, fibroblasts treated with hY3 supernatants also significantly promoted SMAc and FSP1 myofibroblast subtypes compared to untreated fibroblasts using IF (**Figure 1**) and FC (SMAc: 6463.7±593 vs. 89.5±21, N=3, p< 0.01; FSP: 1339.0±154 vs. 70.1±3, N=3, p< 0.02) but to a lesser degree than observed with IFNa . There was a gap in SMAc and FSP1 expression between IFNa and hY3 treatments, however, it was mitigated when fibroblasts were co-treated with hY3 supernatants and Wnt3a. hY3 supernatants/Wnt3a co-treatment showed remarkable synergy, unexplained by either treatment alone (hY3 supernatant + Wnt3a vs IFNa-induced expression (SMAc: 20,526.3±2617 vs. 23,346.7±2077, N=3, n.s., FSP1: 2118.7±193 vs. 2282.7±293, N=3, n.s.)., a phenotype that was attenuated by cotreatment with NIFNa, a result implicating IFNa as an autacoid factor of dual fibroblast transdifferentiation (IF, **Figure 1,** lower right panel). In parallel, the contribution of Wnt3a to IFNa a-induced FSP1 and SMAc expression was supported by their reduced expression when IFNa -treated fibroblasts were exposed to ICG-001.

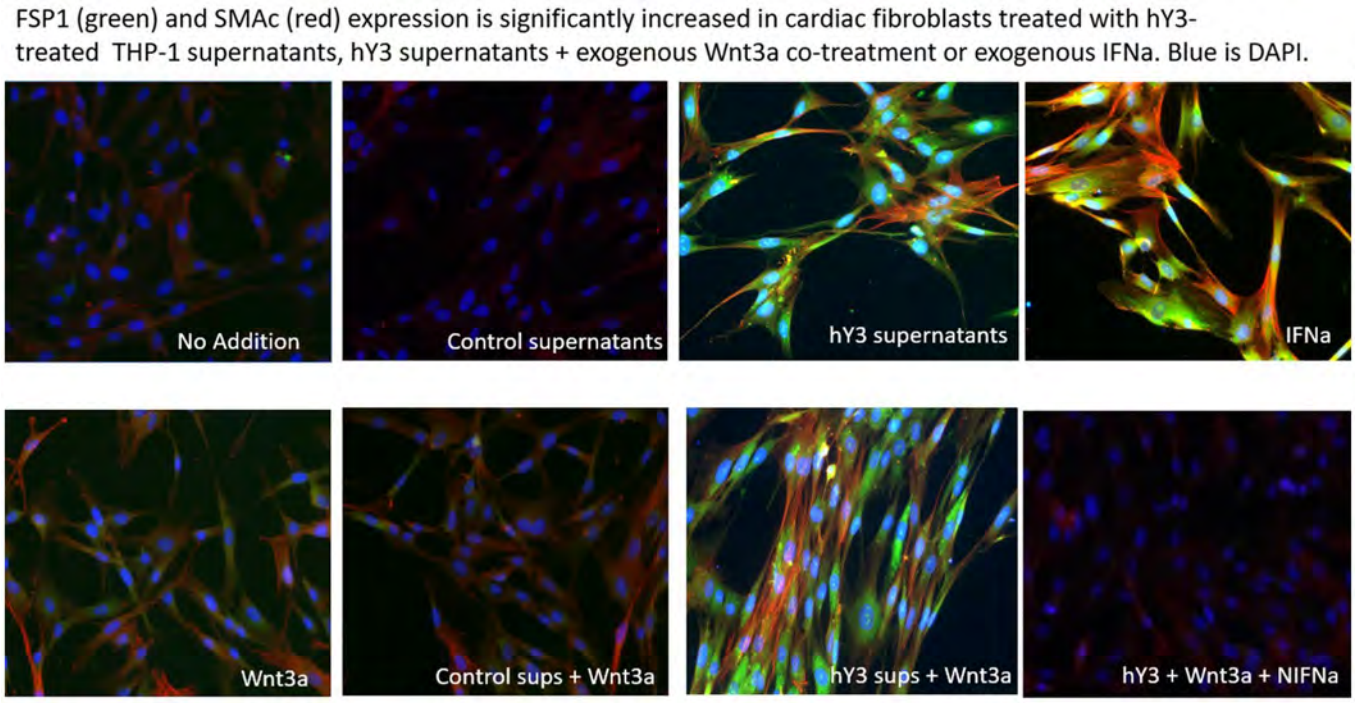

Figure 1. Condition hY3 sups/Wnt3a co-treatment of human fetal cardiac fibroblast result in the extreme phenotype extending to every fibroblast within the culture. Lower right panel shows attenuation of phenotype by neutralizing antibody to IFNa (NIFNa), a result implicating IFNa as an autacoid factor of dual fibroblast transdifferentiation.

Conclusion: These data support that an important component of anti-Ro mediated injury involves pathological activated fibroblast phenotypes reflecting dual transdifferentiation mediated by type I Interferon and disorders of the Wnt/β-catenin pathway.

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Genetics, Genomics & Proteomics Poster (0517–0533)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Azathioprine is frequently used for the treatment of several inflammatory conditions. However, treatment is often limited by adverse events, in particular myelotoxicity. Both thiopurine-S-methyltransferase (TPMT) and nudix hydrolase-15 (NUDT15) are enzymes involved in the metabolism of azathioprine; variants in the genes encoding these enzymes contribute to an increased risk for azathioprine myelotoxicity. Recently, the Clinical Pharmacogenetics Implementation Consortium (CPIC) provided information on how to interpret *TPMT* and *NUDT15* genotype data to guide azathioprine use and to decrease the risk of azathioprine-related myelotoxicity. However, despite these recommendations, little is known about the role of this genetic information in routine clinical care of patients with inflammatory conditions treated with azathioprine. We hypothesized that *TPMT* and *NUDT15* genotype information predicts azathioprine discontinuation due to myelotoxicity.

Methods: We performed a retrospective cohort study in new azathioprine users. All patients were prescribed azathioprine to treat rheumatological and inflammatory conditions (e.g, vasculitis, systemic lupus erythematosus, rheu-

Table. Baseline Characteristics by TPMT or NUDT15 phenotype

	NUDT15 or TPMT poor or intermediate metabolizers n=123	NUDT15 or TPMT normal or indeterminate metabolizers n=1425	p-value
Age in years, mean±SD	42.1±17.0	43.4±17.6	0.72
Female sex, n (%)	80 (65.0%)	963 (67.6%)	0.62
White, n (%)	99 (81.8%)	1234 (87.4%)	0.21
Indications, n (%)			0.24
Systemic lupus erythematosus	17 (13.8%)	162 (11.4%)	
Inflammatory bowel disease	33 (26.8%)	484 (34.0%)	
Autoimmune disease other than lupus	73 (59.4%)	779 (54.7%)	
Azathioprine initial dose (mg/day), mean±SD	67.8±38.3	79.1±47.9	0.02

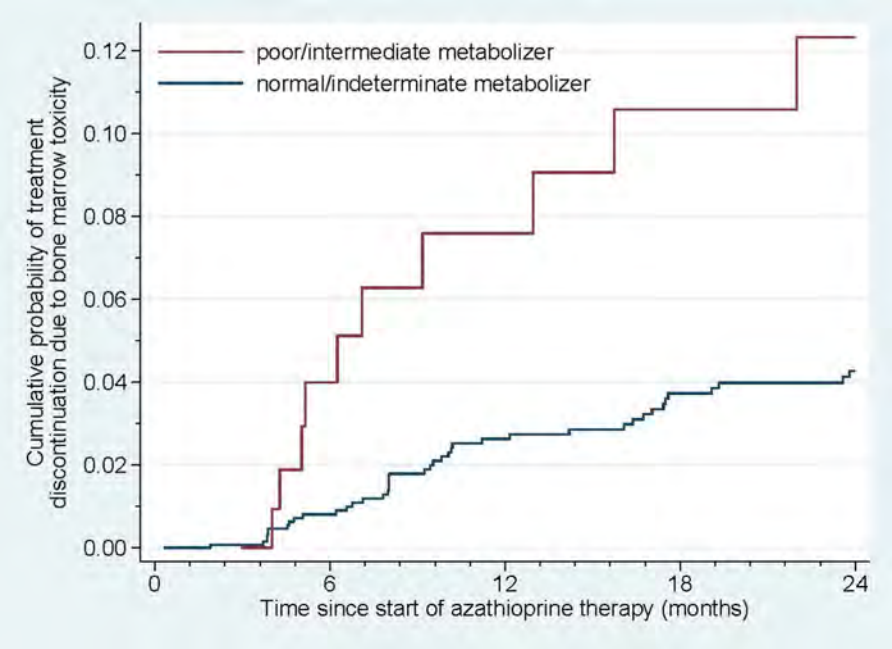

Figure. Probability of azathioprine discontinuation through 24 months by TPMT or NUDT15 phenotype.

matoid arthritis, autoimmune hepatitis and inflammatory bowel disease). Using BioVU, a clinical practice-based biobank at a tertiary medical center, we first identified new users for the conditions listed above and then reviewed de-identified clinical records, collected variables (age, sex, clinical indication for azathioprine use, and azathioprine daily dose); for those who discontinued azathioprine, we adjudicated the attributed reason blinded to genotypes. Genotyping was performed on the MEGAchip. Following quality control and imputation, we used CPIC guidelines to determine TPMT and NUDT15 metabolizer status; patients were classified based on the poorer of the two as either: (1) poor/intermediate (PM/IM); or (2) normal/indeterminate metabolizers (NM/ID).

Results: We studied 1548 new users of azathioprine followed over a median of 1.9 years. Their median age was 43.4±17.5 years, 67% were female, and 87% were white. A total of 123 patients were classified as PM/IM, and 1425 patients as NM/ID; 75 patients stopped azathioprine treatment due to myelotoxicity (13 among PM/IM and 62 among NM/ID)(Table). PM/IM metabolizer status was associated with a 2.56 times higher risk of stopping azathioprine due to myelotoxicity compared to NM/ID (HR=2.56, 95% CI:1.41-4.67, p=0.002)(Figure). This association remained significant after adjustment for race, age at baseline, sex, primary indication, and initial dose of azathioprine (aHR=2.48, 95% CI: 1.35-4.56, p=0.003) as well as when restricted to whites (aHR2=2.16, p=0.04). A sensitivity analysis, excluding patients who were classified as indeterminate metabolizers (n=8), showed similar results (HR=2.60, p=0.002 and aHR=2.50, p=0.003). The cumulative hazard for discontinuation due to myelotoxicity at two years was 12.3% (95% CI: 6.6-23.2%) in PM/IM, compared to 4.3% (95% CI: 3.1-5.8%) in NM/ID.

Conclusion: TPMT and NUDT15 phenotype metabolizer status predicts an increased risk for myelotoxicity in patients who received azathioprine for inflammatory conditions.

SESSION INFORMATION

Session Date: Sunday, November 7, 2021

Session Title: Genetics, Genomics & Proteomics Poster (0517–0533)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Background/Purpose: Azathioprine is a thiopurine used to treat inflammatory conditions; however, it is often discontinued due to dose-dependent bone marrow toxicity. The Pharmacogenomics Knowledgebase (PharmGKB) lists 25 genes in the metabolic pathway, therefore, small effect changes caused by variants in these genes may combine to large effect. Only two of these genes (*TPMT* and *NUDT15*) are in clinical guidelines for thiopurine use and only explain less than 25% of azathioprine-induced bone marrow toxicity. We hypothesize that a risk score that combines the expression of other genes in the thiopurine metabolic pathway would be associated with azathioprine discontinuation due to bone marrow toxicity among TPMT and NUDT15 normal metabolizers.

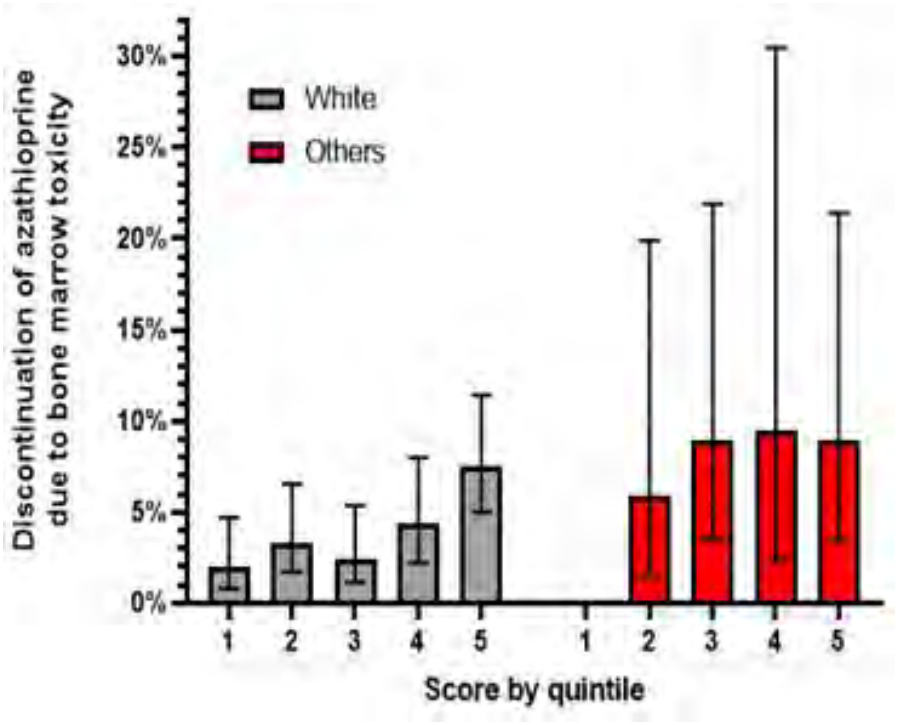

Figure: Association between discontinuing azathioprine and risk score by quintile. Vertical axis is percent discontinued azathioprine due to possible bone marrow toxicity with 95% confidence interval. The horizontal axis separates each quantile by White and non-White.

Methods: In a retrospective cohort of patients with vasculitis, SLE, RA, or other inflammatory conditions (e.g., autoimmune hepatitis, IBD) we identified new users of azathioprine who were TPMT and NUDT15 normal metabolizers and collected information from their clinical records. The outcome was possible bone marrow toxicity—defined as discontinuing azathioprine due to any cytopenia. Genotyping was performed using the MEGAchip and, following imputation and quality control, we used PrediXcan (GTEx version 8 MASHR-based eQTL models) to estimate the genetically regulated expression of 13 genes involved in azathioprine metabolism (*ADK*, *AOX1*, *GDA*, *GMPS, GSTA1, GSTM1, IMPDH1, ITPA, NME1, NME2, NT5C2, PPAT, RMM2*), and 4 involved in azathioprine transport (*ABCC4, SLC29A1, SLC29A1*, and *SCL29A2*). As most drug metabolism occurs in the liver, we selected liver-specific estimations. We used Lasso regression that included all 17 predicted gene expressions and 5 principal components for model selection (i.e. relaxed Lasso). We built a score based upon the resulting coefficients of selected variables. Based on score quintiles, we used cox hazard models to test whether scores were associated with azathioprine discontinuation due to cytopenia among Whites and whether the same score showed similar trends in those who reported other races or race unknown.

Results: We studied 1417 patients followed over a median of 1.9 years. Mean age was 43.6±17.6 years, 959 (67.7%) were female, initial daily dose 78.9± 47.8, and 1230 (87%) were White; 61 discontinued azathioprine due to cytopenia. The risk score included the predicted expression of the two genes (*AOX1* and *NME1*) that had non-zero coefficients from the lasso regression. White patients with the highest score quintile had a significantly higher risk of discontinuing azathioprine due to cytopenia compared to those in the lowest quintile [HR=3.65 (95% C.I. 1.37-9.73, p=0.010]. Results remained significant after adjustment for age, sex, azathioprine indication, and azathioprine initial daily dose [HR=3.77 (95% C.I. 1.41-10.06), p=0.008]. A similar association was observed among 187 patients who either reported other races or race unknown ($p< 0.001$).

Conclusion: Among patients who were TPMT and NUDT15 normal metabolizers, a score combining AOX1 and NME1 expression was associated with discontinuation of azathioprine due to bone marrow toxicity. Further studies are needed to replicate these findings in different cohorts.

The Relationship of Genetics and Clinically Suspect Arthralgia in RA Development Assessed Using HC, CSA and RA Patients

Marc Maurits, Fenne Wouters, Ellis Niemantsverdriet, Tom WJ Huizinga, Annette H.M van der Helm-van Mil and Rachel Knevel, Leiden University Medical Center, Leiden, Netherlands

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Genetics, Genomics & Proteomics Poster (0517–0533)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

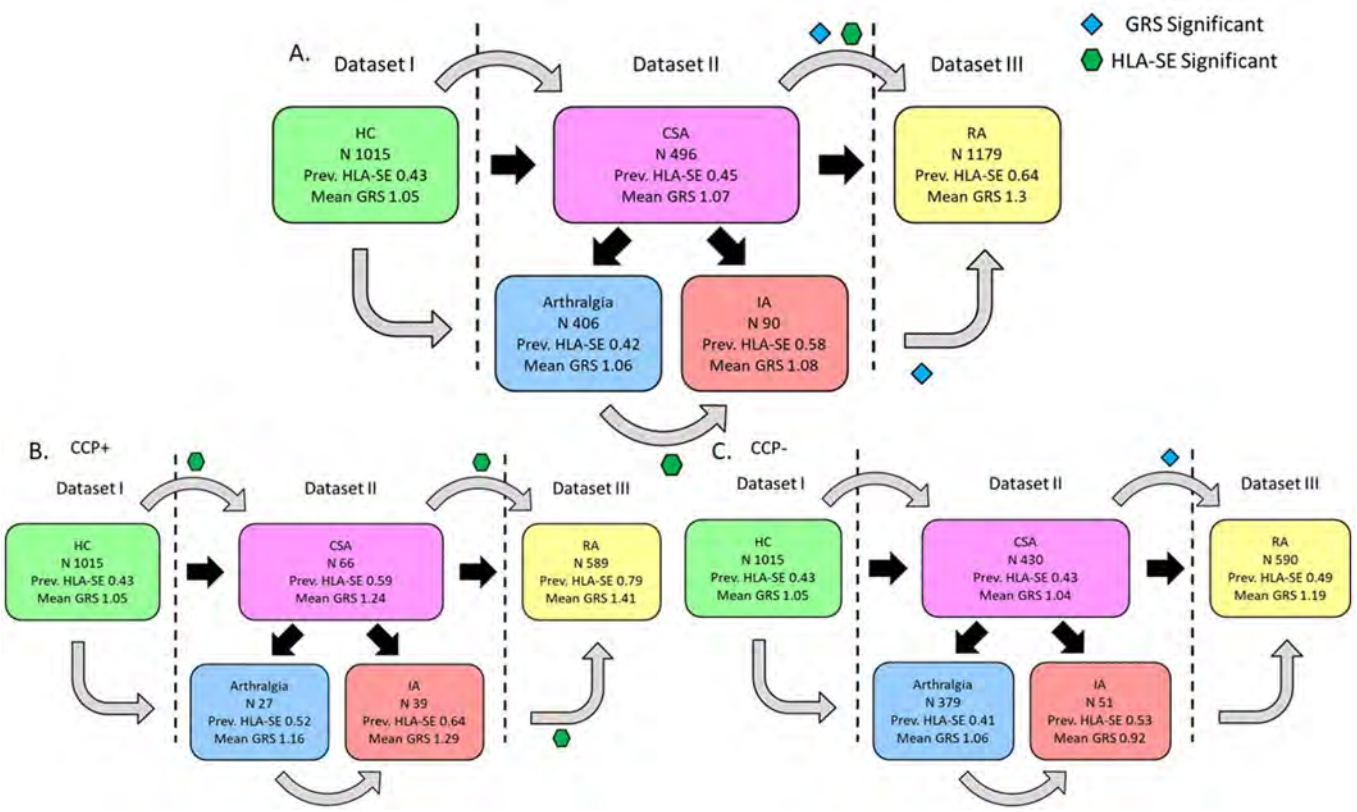

Figure 1. Distribution of HLA-SE and RA Genetic Risk Score (GRS) across Healthy Controls (HC), CSA (converters to Inflammatory Arthritis (IA) and non converters (Arthralgia)) and established RA. Blue diamonds (GRS) and green hexagons (SE) indicate logistic regression significance. Both full datasets (A) and CCP+ (B) and CCP- (C) strata of CSA and RA are shown.

Background/Purpose: The identification of a pre-RA stage of patients with clinically suspect arthralgia (CSA) has proven to be beneficial in the early detection of Rheumatoid disease. Similarly, genetic susceptibility studies have identified important genetic risk factors for the development of (CCP positive) RA.[1] The question that arises is whether these findings represent independent etiological pathways and could therefore be complimentary in the early diagnosis of RA. We therefore aimed to corroborate the knowledge of genetic differences between HC and RA patients and extend it to include the CSA stage of disease.

Methods: We used three datasets sampled from the same region: 1,085 healthy controls (HC), 530 CSA and 1,277 RA patients. CSA patients were monitored for a median of 2 years for conversion into clinically apparent inflammatory arthritis (CSAc) or not (CSAnc).[2] Genotype data of all individuals was identically processed, including separate imputation of the HLA region using SNP2HLA with the T1DGC panel. A Genetic Risk Score (GRS) consisting of 85 RA risk SNP's derived from literature was calculated for all samples.[3] HLA-SE positivity was defined as the presence of at least 1 of the HLA-DRB1 alleles.

We assessed the association of the GRS and HLA-SE with disease stage using logistic regression in the full data and in the CCP+ and CCP- strata of the CSA and RA populations.

Results: The GRS increased with disease stage, from 1.05 in HC to 1.3 in established RA cases. This was significant between CSA and RA (OR: 1.36, 95%CI: 1.21 – 1.53, P-value: < .001), and CSAc and RA (OR: 1.29, 95%CI: 1.02 – 1.64, P-value: .037). HLA-SE prevalence also differed significantly between CSA and RA (OR: 2.59, 95%CI: 2.07 – 3.24, P-value: < .001), which could be attributed to the difference between CSAnc and CSAc (OR: 1.88, 95%CI: 1.18 – 2.99, P-value: .007). (Fig. 1A) In CCP+ patients only the differences in SE between HC and CSA (OR: 1.89, 95%CI:

1.14 – 3.13, P-value: .014), CSA and RA (OR: 2.6, 95%CI: 1.53 – 4.41, P-value: < .001) and CSAc and RA (OR: 2.1, 95%CI: 1.06 – 4.16, P-value: .033) were significant. (Fig. 1B) The increase in GRS from CSA to RA, observed in the full datasets, remained significant in the CCP- strata (OR: 1.21, 95%CI: 1.04 – 1.42, P-value: .013). (Fig. 1C).

Conclusion: The current results seem to indicate a role for HLA-SE in the development of arthritis, whereas the GRS more specifically associates with the development of RA. This latter association was also observed in the CCP- CSA and established RA populations. We can conclude that known RA genetics distinguish progressed disease from earlier stages independently of CCP, even when taking the at-risk stage of CSA into consideration.

Abstract Number: 0520

Leukocyte Immunoglobulin-like Receptor A3 Facilitates Neutrophil Extracellular Trap Formation in TLR7-induced Lupus Mice

Hongjiang Liu[1], Yundi Tang[1], Chen Chen[2] and Jianping Guo[2], [1]Peking University People's Hospital, Beijing, China (People's Republic), [2]Peking University People's Hospital, Beijing, China (People's Republic)

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Genetics, Genomics & Proteomics Poster (0517–0533)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Leukocyte immunoglobulin-like receptor A3 (LILRA3) is a secreted protein belongs to LILR family. Our research group previously reported that the functional *LILRA3* is a novel genetic risk for multiple autoimmune diseases including systemic lupus erythematosus (SLE). However, the function of LILRA3 in development of lupus is unclear. Dysfunctional neutrophils play a pathogenic role in SLE, particularly through the release of neutrophil extracellular traps (NETs). The aim of this study was to functionally characterize the role of LILRA3 in NET formation in the TLR7-induced lupus-like model.

Methods: To functionally study the role of LILRA3 in autoimmune diseases, we constructed the *LILRA3* knock-in (KI) mice. The lupus-like disease was induced by the epicutaneous application of the TLR7 agonist imiquimod (IMQ) three times a week. The C57BL/6 wild-type and *LILRA3*-KI mice were sacrificed on day 14, 28, and 56 after treatment of IMQ. Flow cytometry was used to evaluate the proportions of neutrophils in peripheral blood (PB), spleen, and bone marrow (BW), respectively. To assess NETosis (NETs release), complementary approaches were utilized. The total extracellular DNA was quantified as relative fluorescence units upon the addition of Sytox Green by using the SYTOX Green assay. Immunofluorescence staining was applied to label the neutrophil elastase and citrullinated Histone H3(Cit-H3). Enzyme-linked immunosorbent assay was applied to detect antibodies in serum.

Results: he proportions of $CD11b^+ly6G^+$ neutrophils were significantly increased in PB, spleen and BM from IMQ-treated *LILRA3*-KI (KI-IMQ) mice, compared to IMQ-treated WT (WT-IMQ) mice and WT control mice on day 14 and 28 ($P < 0.01$). After 56 days of IMQ treatment, there was no significant difference in the proportion of PB and BM $CD11b^+ly6G^+$ neutrophils across the 3 groups, but the splenic $CD11b^+ly6G^+$ neutrophils were remarkably increased from KI-IMQ mice, compared to WT-IMQ and WT control mice ($P < 0.01$). Furthermore, BM neutrophils from KI-IMQ mice displayed an enhanced release of NETs as compared to that from WT-IMQ and WT control mice at three time points ($P < 0.01$). After phorbol myristate acetate (PMA) or Calcimycin (A23187) stimulation, a similar phenomenon was also observed for BM neutrophils from KI-IMQ mice. Concentration of serum anti-dsDNA IgG was significantly elevated in KI-IMQ mice as compared to WT-IMQ and WT control mice ($P < 0.001$).

Conclusion: Our data suggest that LILRA3 may promote lupus-like disease through excessive neutrophil activation and NET formation in TLR7-induced lupus mice.

Genome-Wide DNA Methylation and Gene Expression Signatures in Classical Monocytes from African Ancestry Patients with Systemic Sclerosis

Sarah Smith[1], Peter Allen[2], Robert Wilson[1], Jena Wirth[1], DeAnna Baker Frost[1], Gary Gilkeson[1], Melissa Cunningham[1], Devin Absher[3] and Paula Ramos[1], [1]Medical University of South Carolina, Charleston, SC, [2]University of Alabama at Birmingham, Birmingham, AL, [3]HudsonAlpha Institute for Biotechnology, Huntsville, AL

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Genetics, Genomics & Proteomics Poster (0517–0533)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Systemic sclerosis (SSc) is a multisystem autoimmune disorder that has an unclear etiology and disproportionately affects individuals of African ancestry (AA). Despite this, AA individuals are dramatically underrepresented in SSc research. Additionally, monocytes show heightened activation in SSc, and in AA relative to European ancestry (EA) individuals. Monocytes are thus a good target tissue for elucidating disease mechanisms. In this study, we sought to identify changes in genome-wide DNA methylation and gene expression levels in classical monocytes from AA SSc patients and unaffected AA controls.

Methods: Classical monocytes (CD14++CD16-) were FACS-isolated from 17 SSc cases and 18 controls. All patients met the 2013 ACR/EULAR classification criteria for SSc. All participants were self-reported AA female. DNA methylation was profiled using Illumina's MethylationEPIC BeadChip to identify differentially methylated CpGs. RNA-seq was performed to identify differentially expressed genes. Expression quantitative trait methylation (eQTM) analysis was computed to identify CpGs associated with changes in gene expression.

Results: Many of the top differentially methylated CpGs map to genes with roles in immune pathways, including T-cell surface glycoprotein *CD5,* oligoadenylate synthetase *OAS3*, and DNA repair *FANCC*. The SSc monocyte transcriptome showed an enrichment of genes in the AMPK signaling pathway, genes involved in chromatin organization, transcription factor binding, and glycogen storage diseases. The top differentially expressed genes include hepara-

nase *HPSE*, collagen *COL9A2*, and chromatin regulator *SMARCA4*. The top eQTM genes included transcriptional repressor homolog *PCGF1*, RNA helicase *DDX27*, transcription factor *E2F4*, and hydrolase *KYNU*.

Conclusion: To the best of our knowledge, this is the first study to investigate DNA methylation and gene expression signatures in classical monocytes from SSc patients of African ancestry. The relatively modest differences in DNA methylation and gene expression observed between patients and controls is consistent with prior evidence of stronger inflammatory signatures in AA relative to EA individuals. These data support a possible role for DNA methylation and gene expression differences in mediating sustained monocyte activation and susceptibility to SSc in AA individuals.

SESSION INFORMATION

Session Date: Sunday, November 7, 2021
Session Title: Genetics, Genomics & Proteomics Poster (0517–0533)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Rheumatoid Arthritis (RA) patients capable of reaching clinical remission potentially have a specific genetic profile that allows them to regain immune tolerance. The identification of these genes could provide insights into the etiology of RA, as well as immunological pathways which could serve as novel drug targets.

We set out to test the association between established RA genetic risk variants and achieving remission at 6 months.

Methods: We computed genetic risk scores (GRS) comprised of RA susceptibility variants[1] and HLA-shared epitope (SE) allele status separately in 3,984 DMARD naïve patients across 9 datasets from inception cohorts. Remission was assessed at 6 months and defined as DAS28CRP values below 2.6. Values were imputed where necessary using predictive mean matching by MICE. We first tested whether baseline DAS28CRP changed with increasing GRS using

Table 1. Summary of the data separated by disease activity after 6 months.

	All	Remission at 6 months	No remission at 6 months
N	3,984	1,577	2,407
Age, *mean (sd)*	55.25 (13.75)	55.21 (14.12)	55.27 (13.51)
Female *%*	64.61%	62.59 %	65.93 %
ACPA+ *%*	56.00%	55.61 %	56.25 %
Baseline DAS28, *mean (sd)*	4.29 (1.43)	3.74 (1.54)	4.65 (1.23)

linear regression. Next, we used logistic regression to determine the relationship between the GRS and HLA-SE alleles and 6 month DAS28CRP remission in all cohorts independently. Using inverse variance weighted meta-analysis we concatenated these results into a singular effect estimate.

Due to the known differences in genetic background of anti-CCP positive and negative RA, we also repeated the analyses in only anti-CCP positive patients.

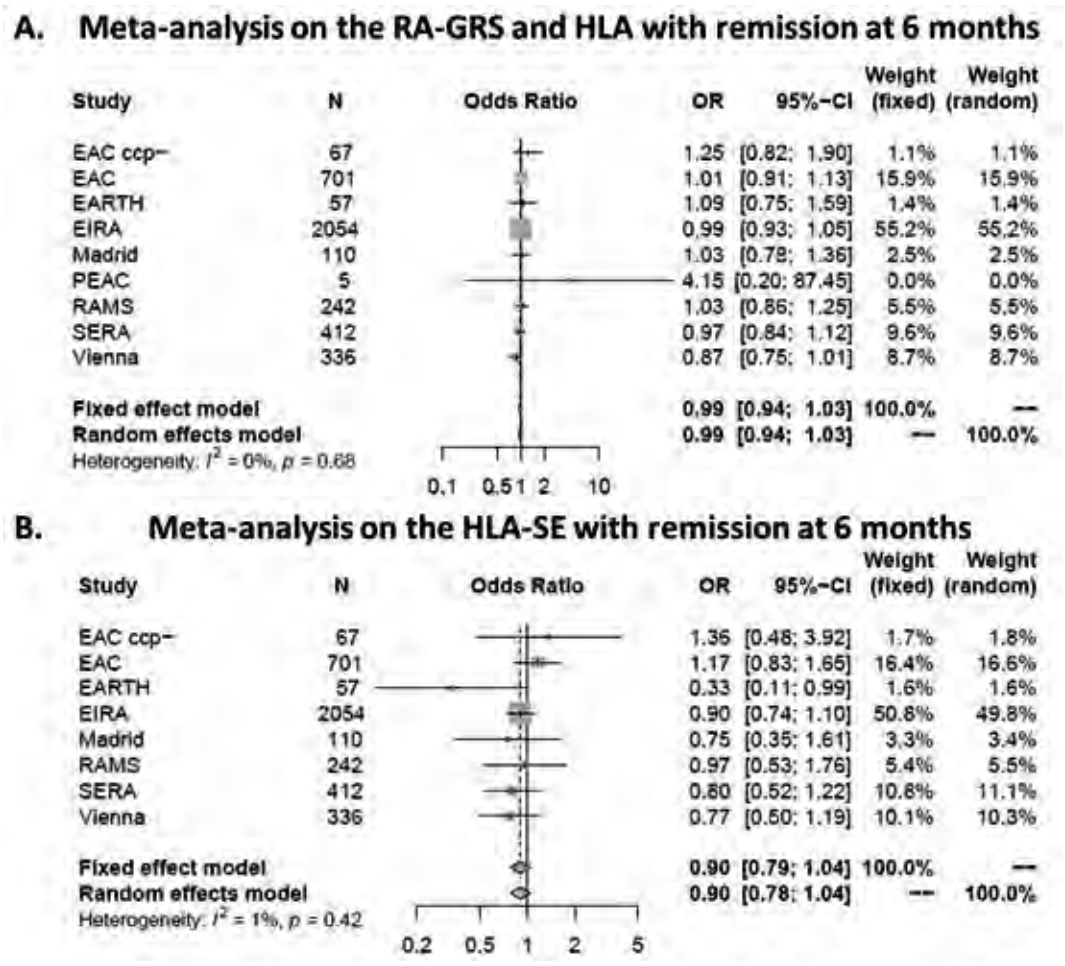

Figure 1. Inverse weighted meta-analysis of (A) the GRS + HLA and (B) the HLA-SE. Includes the dataset name (Study), sample size (N), odds ratio (OR), 95% confidence intervals (95%-CI) and the weights of the fixed and random effect models. I2 = percentage of variation across studies due to heterogeneity.

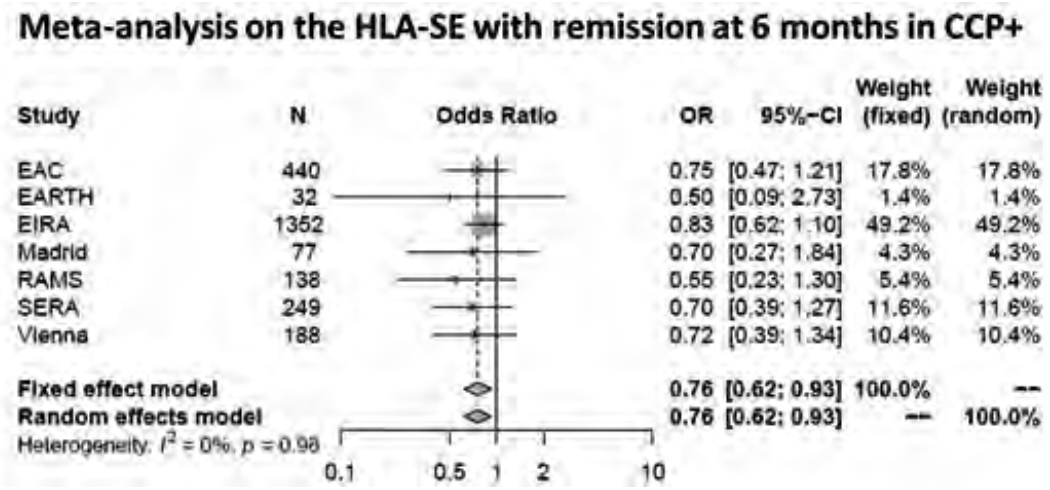

Figure 2. Inverse weighted meta-analysis of the HLA-SE in CCP positive patients. Includes the dataset name (Study), sample size (N), odds ratio (OR), 95% confidence intervals (95%-CI) and the weights of the fixed and random effect models. I2 = percentage of variation across studies due to heterogeneity.

Results: Baseline clinical variables did not differ between patients who achieved remission and those who did not (**Table 1**). Distribution of the GRS was consistent between datasets. Neither GRS nor HLA-SE alleles were associated with baseline DAS28CRP (OR 1.01; 95% CI 0.99 - 1.04). A fixed effect meta-analysis showed no significant effect of the GRS (OR 0.99; 95% CI 0.94 - 1.03) or HLA-SE alleles (OR 0.90; 95% CI 0.79 - 1.04) on remission at 6 months (**Figure 1**). In the seropositive analyses we did observe one significant association; HLA-SE alleles positivity reduced the likelihood of 6 months DAS28CRP remission in the anti-CCP positive stratum (OR 0.79; 95% CI 0.62 – 93) (**Figure 2**).

Conclusion: Of the known RA genetic risk variants only HLA-SE alleles are associated with a decreased chance of obtaining remission in the anti-CCP positive population in these combined cohorts. Studies encompassing broader genetic profiles are needed to further elucidate the genetics of RA remission.

Abstract Number: 0523

Transcriptional Subsetting of SLE Patient Cohorts Based on Metabolic Pathway Activity

Diogo Camacho, Jennifer Swantek, Keng Soh, Jurre Kamphorst, Vivek Kaimal, John Monroe and Edward Driggers, Rheos Medicines, Inc, Cambridge, MA

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Genetics, Genomics & Proteomics Poster (0517–0533)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Systemic lupus erythematosus is a highly complex, heterogeneous, autoimmune disorder, with diverse clinical presentation and innate and adaptive immune system involvement. There is a need to better understand the molecular basis for dysregulated immune system function and disease pathophysiology in SLE in order to assign individuals to more homogeneous mechanistic subsets, enabling the identification of targets for more effective, cohort-specific, therapies with a higher impact in clinical improvement. Previous studies have used whole transcriptome data to identify key molecular features in order to achieve meaningful assignment of SLE patients into subsets defined to a large extent by predominate immune cell types in peripheral blood. These studies have allowed us to make inferences as to the contribution of specific immune cells to disease in different patient groups.

Methods: As metabolic regulation of innate and adaptive immune cells is increasingly appreciated as a driver of disease phenotypes, we sought to investigate if patient heterogeneity could be revealed by focusing solely on metabolic pathways relevant to the activation state of immune cells found in the peripheral blood. We collected a set of 84 metabolic pathways and gene sets, comprised of a total of 1,692 genes, and calculated the pathway eigengenes as described elsewhere (1). We applied our methodology to the ILLUMINATE-1 clinical trial cohort transcriptomics data set (2), generated from whole blood samples collected from 879 patients. After calculating the pathway eigengenes for the patient cohort, we performed unsupervised clustering using 30 different algorithms, in order to determine the optimal number of clusters in these data (Fig 1.) Additionally, we calculated the predicted immune cell population for each patient as described elsewhere (3), enabling us to ascribe biological significance to the identified clusters. Our results show that, when comparing the patient clusters on whole transcriptome data versus on pathway eigengenes,

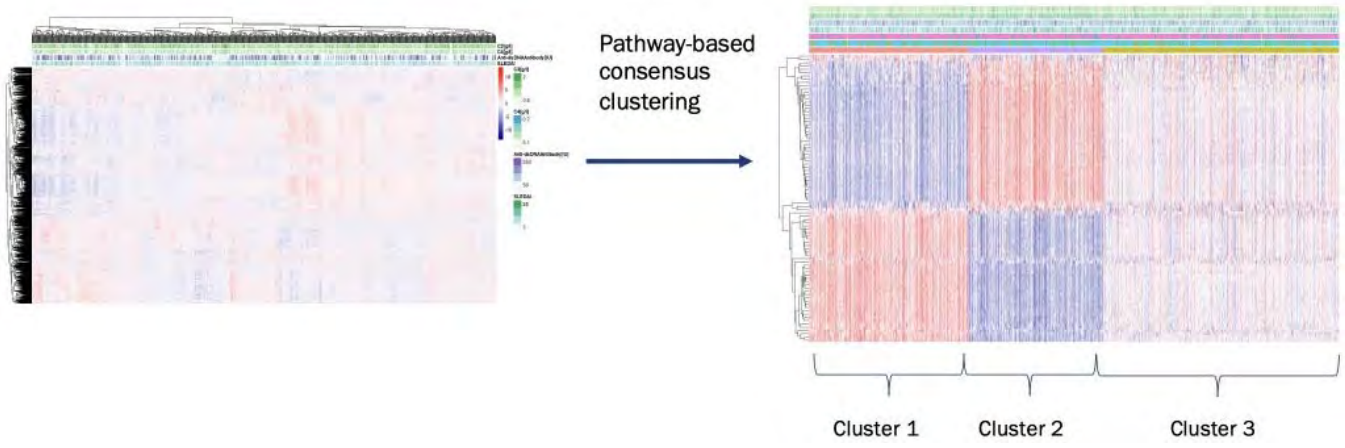

Figure 1. Metabolism-based patient sub-setting. Our approach introduces higher resolution in the understanding of patient data, allowing for a clearer definition of biologically-relevant clusters.

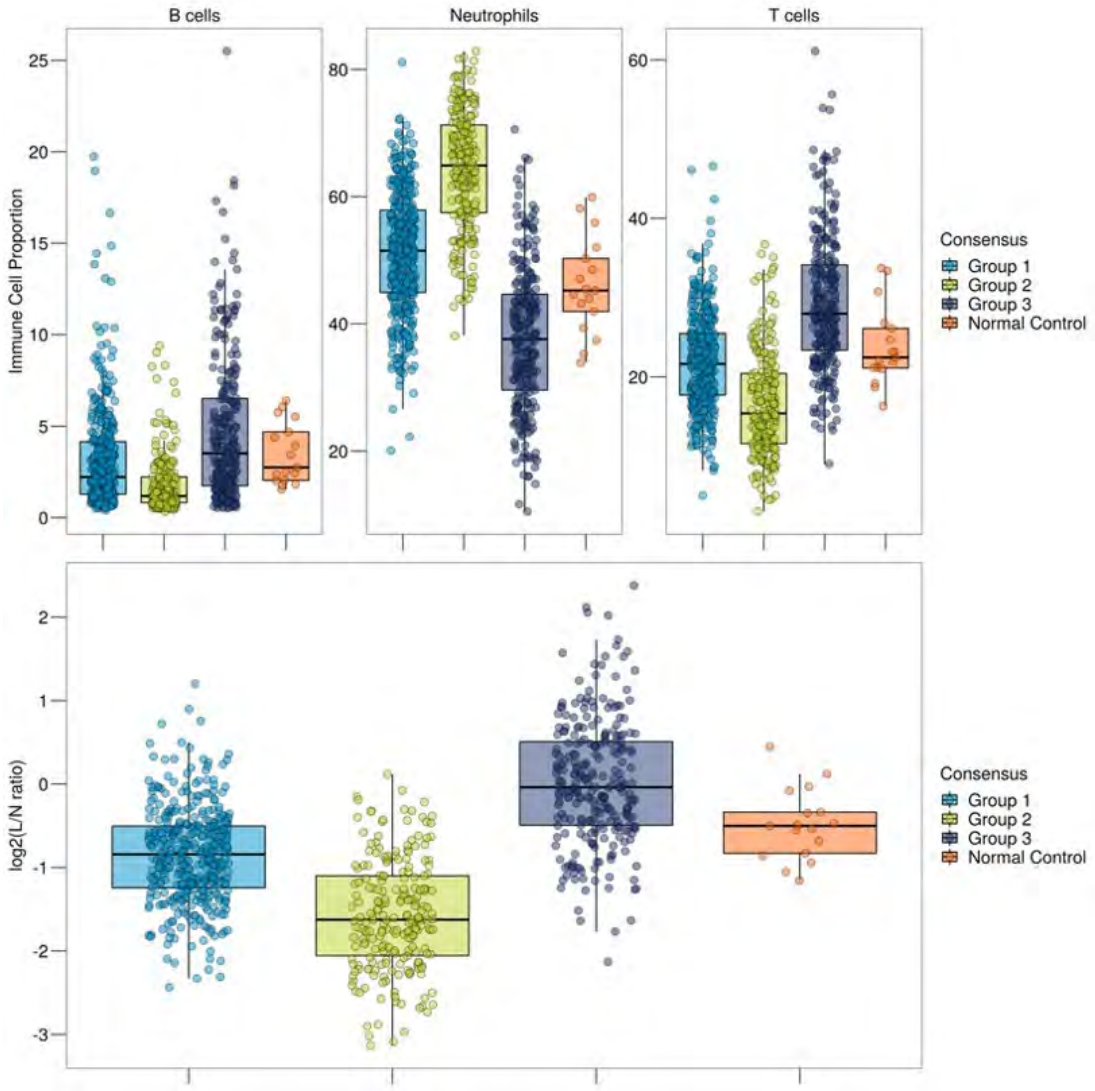

Figure 2. Immune cell population inference based on the ABIS algorithm. Using our metabolism-based patient sub-setting strategy we can clearly defined, in an unbiased manner, biologically relevant patient groups.

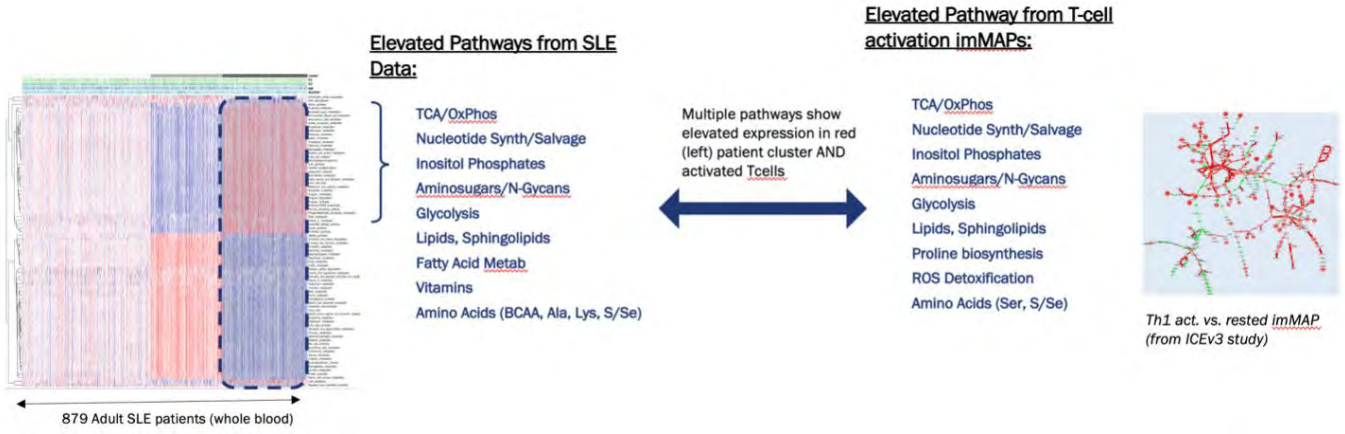

Figure 3. Patient subsets and imMAPs. We compared our unbiased clustering approach to data generated using our imMAP algorithm and we found a strong overlap between the lymphocytic cluster and the T cell activation imMAP, given further credence to our metabolism-based approach for patient subsetting.

there is an enrichment in the immune cell populations in the latter (Fig 2), reflecting not only their proportion but also their activation or effector state. Furthermore, we compared the clustering results based on the pathway eigengenes with our immunometabolism map (imMAP), an algorithm for the integration of transcriptional and metabolic profiles, run on data from primary human effector memory peripheral blood T cells activated by anti-CD3/CD28/CD2, highlighting how the high lymphocytic cluster preserves features captured by our imMAP (Fig 3.)

Results: Our results indicate that SLE patients can be differentiated based upon metabolic features with potential important biological and clinical significance, given the increasing appreciation for disease-associated immune cell metabolic reprogramming in autoimmune diseases (4, 5).

Conclusion: Insights from these studies will facilitate discovery of novel targets that impact the disease-associated metabolic programming of immune cell drivers of SLE and provide a framework for precision medicine approaches to assign individual patients to disease subgroups that would best benefit from drugs modulating those targets.

Development of Biomarker Models to Identify HLA-related Microbiome Associations in Anti-Ro+ Mothers of Children with Neonatal Lupus

Robert Clancy[1], Miranda Marion[2], Hannah Ainsworth[2], Marci Beel[3], Miao Chang[1], Carla Guthridge[3], Joel Guthridge[3], Timothy Howard[4], Peter Izmirly[5], Joseph Kheir[3], Mala Masson[1], Miles Smith[3], Judith James[3], Jill Buyon[6] and Carl Langefeld[7], [1]NYU Grossman School of Medicine, New York, NY, [2]Wake Forest University, Winston-Salem, NC, [3]Oklahoma Medical Research Foundation, Oklahoma City, OK, [4]Wake Forest University, Quakertown, NC, [5]New York University School of Medicine, New York, NY, [6]NYU School of Medicine, New York, NY, [7]Wake Forest University, Winston Salem, NC

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Genetics, Genomics & Proteomics Poster (0517–0533)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Anti-Ro autoantibody production often precedes the development of Systemic Lupus Erythematosus (SLE) or Sjogren's syndrome (SS) by years. For anti-Ro+ mothers enrolled in the Research Registry for Neonatal Lupus (RRNL), progression to SS or SLE occurs in about a quarter, while most remain asymptomatic or develop only minor rheumatic symptoms (Asym/UAS). Thus, RRNL mothers uniquely offer a promise to identify genotype-phenotype relationships that are important to preclinical autoimmunity. Since multiple SLE risk alleles from Class II HLA genes are present in anti-Ro+ mothers, we examined interactions of specific microbiome taxa with Class II HLA by independent analytic paths with the goal to identify HLA-related microbiome associations in Anti-Ro+ Mothers of Children with Neonatal Lupus.

Cluster	Asvm/UAS	SS/SLE	Total
1	4	10	14
2	9	19	28
3	8	8	16
4	2	19	21
5	4	8	12
6	2	0	2

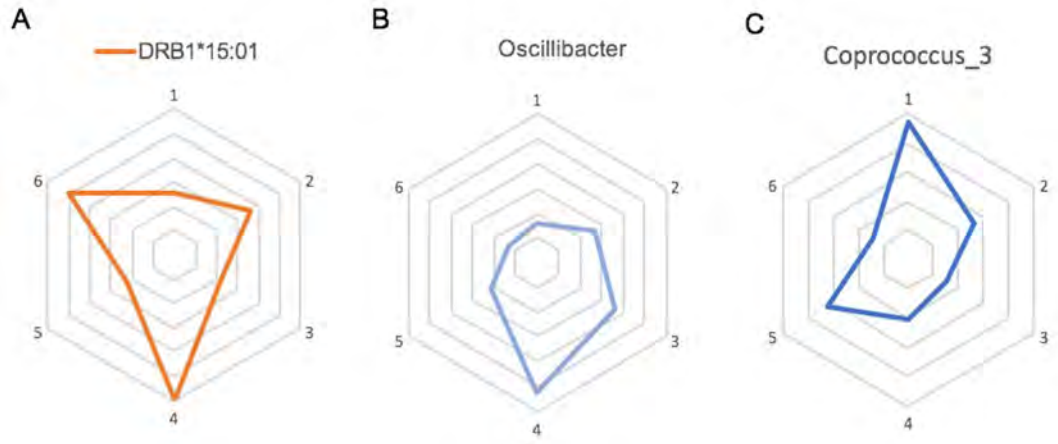

Figure 1. Distribution of subjects (anti-Ro+ mothers), HLA DRB1*15:01 and taxa of interest at clusters 1=6.

Methods: Subjects included 125 RRNL mothers and 23 healthy controls. Stool microbiomes of anti-Ro+ women in RRNL (Asym/UAS, SS/SLE), and healthy controls (HC) were processed using 16S ribosomal RNA sequencing. Sera/plasma were evaluated for cytokines and autoantibody levels. Alleles from HLA Class II genes were genotyped using NextGen sequencing of HLA region or imputed (HIBAG) from GWAS data. Independent analytic paths sought to explore associations of specific taxa and class II HLA included: 1) use of a cumulative logit model to test interactions between FDR significant genera and HLA alleles and 2) assignment of SLE, SS, UAS patients and HC to molecular phenotype clusters by Random Forest (RF), an unsupervised machine learning tool using Z-score transformed cytokine soluble mediators and autoantibody values with settings and the gap statistic that were used to estimate the

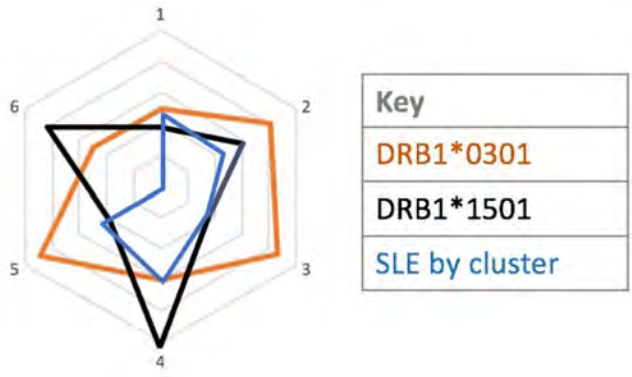

Figure 2. The distribution of DRB1*1501, DRB1*0301, and SS/SLE disease classification at cluster profiles representing evaluations of RRNL mothers.

optimal number of patients and HC within clusters. The overlapping distribution of SS/SLE, HLA alleles and taxa at clusters were then examined.

Results: Findings related to DRB1*15:01 and an interaction with genera of the *Ruminococcaceae* family were tested. *Oscillibacter*, with FDR-adjusted significance was shown to exhibit evidence of an interaction (P=0.033 (OR=0.60 (0.37-0.96)). In order to authenticate that SLE HLA risk alleles modify the strength of the association, we examined the molecular phenotype clusters from RF clustering. Radar plots were used to visualize the distribution HLA alleles and the enrichment of microbiome taxa within these clinically relevant phenotypic clusters (**Figure 1**). DRB1*1501 shows enrichment at cluster 4. Interestingly, the distribution of *Oscillibacter*, but not *Coprococcus 3* was nearly superimposable with the Class II HLA allele with enrichment at cluster 4. However, the distribution of DRB1*1501 was not enriched at cluster profiles representing evaluations of DRB1*0301 and SS/SLE disease classification (**Figure 2**) demonstrating a limitation of DRB1*1501 to predict risk for transition from benign to pathologic autoimmunity in anti-Ro+ mothers of children with neonatal lupus.

Conclusion: These data support the use of molecular phenotypes that are linked to genetic-environmental interactions to identify HLA-related microbiome associations.

STEAP3, FZD2 and EGFLAM Are Novel Genetic Risk Loci for Granulomatosis with Polyangitis: A Genome Wide Association Study from UK Biobank

Mehmet Hocaoglu[1], Jamal Mikdashi[2], Yi-Ju Chen[2], James Perry[2] and Charles Hong[2], [1]University of Maryland Medical Center, Midtown Campus, Baltimore, MD, [2]University of Maryland School of Medicine, Baltimore, MD

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Genetics, Genomics & Proteomics Poster (0517–0533)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Granulomatosis with Polyangitis (GPA) is a systemic ANCA associated small vessel vasculitis. Prior genetic studies demonstrated a strong association of HLA Class II region with GPA. The literature on the non-HLA risk loci is limited as only the minority of the multiple candidate risk loci were able to be replicated in subsequent studies. The aim of this study is to examine the role of non-HLA genetic risk factors for GPA using the genomic data from UK Biobank cohort.

Methods: Our study utilized the UK Biobank database which has over 820,000 genotyped SNPs with up to 90 million imputed variants for 500,000 volunteers from the general population in the United Kingdom (UK). The genetic information of each participant is linked with their International Classification of Diseases (ICD)-10, procedure and treatment codes. 175 patients with ICD-10 code M31.3 Granulomatosis with polyangitis were included in our study as cases. >95% of the cases had at least one other supporting clinical, treatment or procedural codes related to

Table 1. Variants outside of the MHC class II region that are associated with Granulomatosis with polyangitis (GPA).

GPA. Sex, age and ancestry matched control subjects were assigned for each case from the same cohort in a 1:20 case: control study design. Related individuals and individuals with autoimmune diseases associated with secondary vasculitis were excluded. The genome wide association analysis was performed using Plink2 methodology.

Results: We identified a total of 338 SNPs with a genome wide significance level of $< 5x10^{-8}$ and minor allele frequency of >0.5%. (Figure 1) 329 of the significant variants were located at the MHC Class II region in chromosome 6. Within the MHC Class II locus, the SNP with strongest association was rs1042169, an exonic missense variant found in *HLA-DPB1* gene. Multiple other SNPs in strong LD with our top hit were identified in *HLADPB2, RING1, MIR219A1, RXRB, RING1* and *HSD17B8* loci. Independent SNPs were also identified in the *HLADPA1 and COL11A2* loci. Outside of the MHC region, nine SNPs exceeded the threshold for genome wide significance. 7 of those were found in *EGFLAM* locus in strong linkage disequilibrium with our top hit rs2561807, an intronic variant. Two intergenic SNPs with genome wide significance level were identified in *STEAP3* and *FZD2* loci, rs6723312 and rs568915088 respectively. (Table 1) Both rs2561807 and rs6723312 demonstrated dose dependence with significantly higher prevalence in homozygotes compared to heterozygotes. (Figure 2)

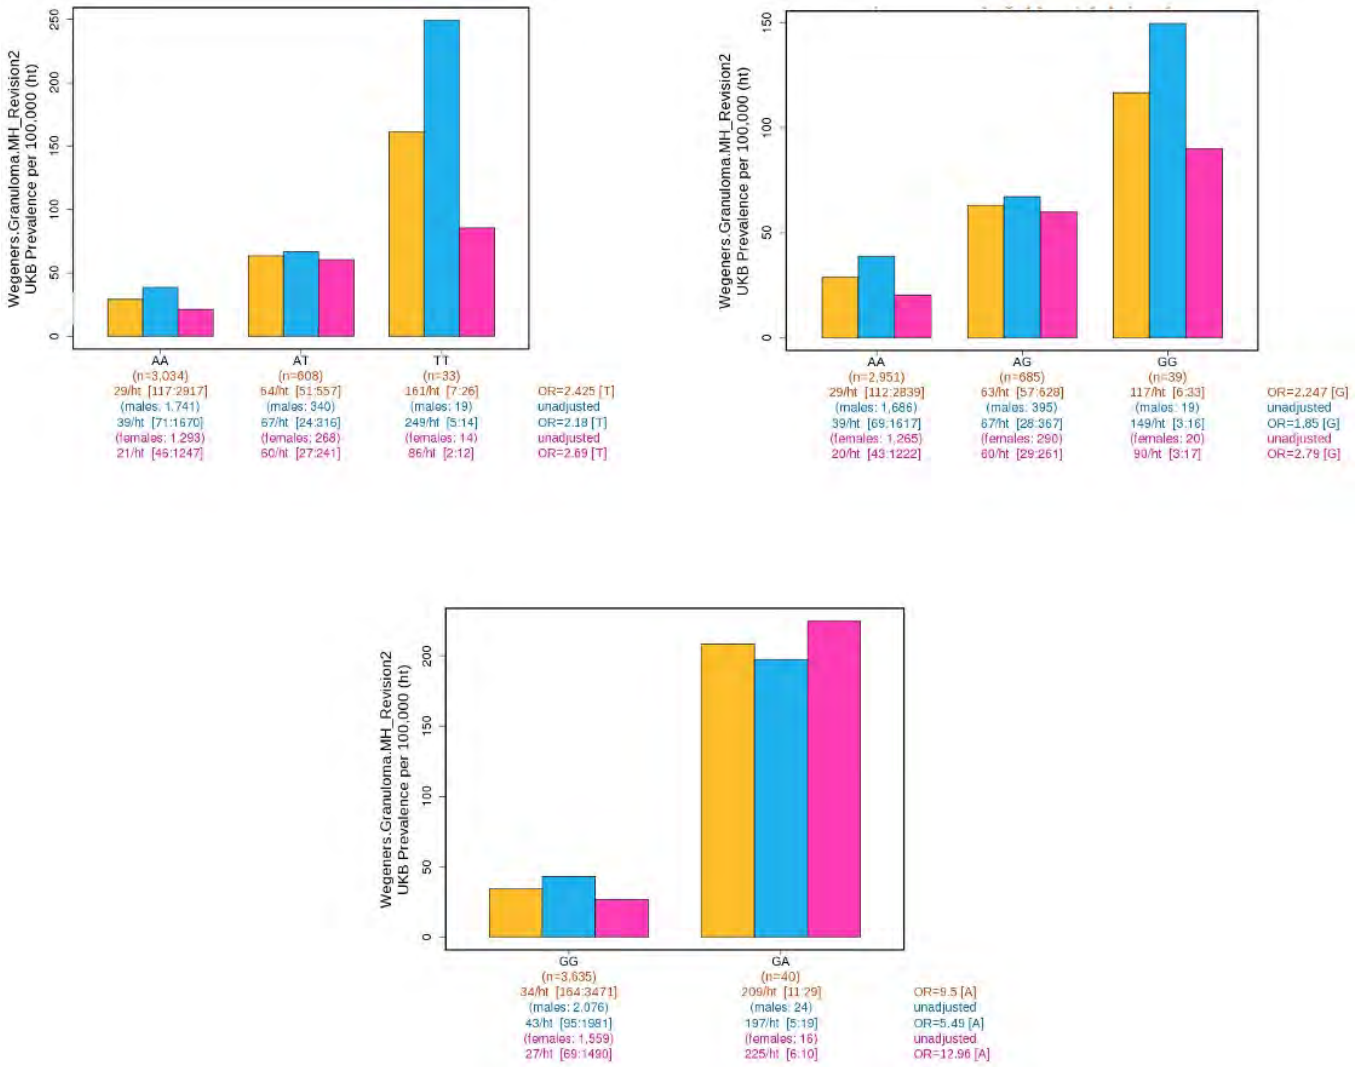

Figure 2. Prevalence of Granulomatosis with Polyangiitis (GPA) per 100,000 participants per genotype in the UK Biobank for rs6723312, rs2561807 and rs568915088 variants.

Conclusion: In this genome wide association study, we confirmed the previously reported association of HLA-DP with GPA and identified EGFLAM, STEAP3 and FZD2 as new genetic risk loci. Further research on the role of non HLA region for genetic susceptibility of GPA is warranted.

Transcriptional Factor Profiling Denotes Specific Synovial Macrophage Heterogeneity

Deborah Winter[1], Carla Cuda[2], Shang-Yang Chen[2], Anna Montgomery[3], Salina Dominguez[2], Gaurav Gadhvi[2] and Harris Perlman[2], [1]Northwestern University Division of Rheumatology, Chicago, IL, [2]Northwestern University, Chicago, IL, [3]UCL, Chicago, IL

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Genetics, Genomics & Proteomics Poster (0517–0533)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Macrophages are critical to the pathogenesis of rheumatoid arthritis(RA), but several distinct macrophage subpopulations co-exist in the synovium of joints. In steady-state, tissue-resident macrophages maintain joint integrity and are required for tissue homeostasis. On the other hand, macrophages contribute to inflammation through the production of cytokines, release of degradative enzymes, and recruitment of other immune cells. However, we currently lack specific targets to regulate macrophage function at the molecular level in the context of developing and relapsing disease.

Methods: We utilized functional genomic analysis of murine and human synovium including single cell-CITE and ATAC seq.

Results: Based on our analysis of gene expression, we characterized the 4 synovial macrophage populations as follows: MA=CX3CR1+MHCII- tissue-resident synovial lining, MB=CX3CR1+MHCII+ newly infiltrating cells; MC=CX3CR1-MHCII- tissue-resident interstitial, MD=CX3CR1-MHCII+ monocyte-derived interstitial. We then characterized the 4 subpopulations of synovial macrophages at days 0, 3, 7, 13 and 21 post serum transfer induced arthritis (STIA). We clustered the genes that were differentially expressed over the course of STIA in any subpopulation into 6 clusters (STIA I-VI). STIA I-III represent an increase in expression of inflammation and immune response genes that is most prominent in infiltrating MB. In contrast, STIA IV-VI represent a decrease in expression of homeostatic (largely interstitial MC and MD), cell cycle (MB), and tissue-resident genes (preferentially MA), respectively. To achieve better resolution on the transcriptional profile of synovial macrophages, we performed bulk RNA-seq on each subpopulation as well as classical and non-classical monocytes. We defined 5 clusters of genes that vary in expression across macrophages: c1=MA-specific; c2=tissue-resident-specific (MA and MC), c3=monocyte-derived-specific (MB and MD), c4=tissue-resident and monocyte; c5=MB and monocyte. To identify TFs that regulate each cluster, we performed motif-finding using the HOMER package. We identified that the MAFB sequence motif was associated with c3 and increased in expression from monocytes to tissue-resident macrophages supporting its role in monocyte-macrophage transition. On the other hand, the MEF2C sequence motif and gene expression suggested it played a role in tissue-residency. By performing a similar analysis on STIA time course clusters, we found that MAFB is associated with increased expression of inflammatory genes, whereas MEF2C is linked with decreased expression of homeostatic and tissue-resident genes. We also determined that macrophage sub-populations identified in mice were recapitulated in human patients from the synovial tissue of 7 RA patients. We found that patients exhibited varying macrophage composition, specifically, the proportion of MA and MC tended to be negatively correlated with disease severity, while MB and MD exhibited the opposite trend.

Conclusion: These studies established the dynamics and transcriptional regulation of monocyte-derived macrophages in inflammatory arthritis from mice and human synovium.

Abstract Number: 0527

Role of Terminal Uridylyl Transferase 7 in TNF-α-Induced Inflammation in Rheumatoid Arthritis Synovial Fibroblasts *In Vitro*

Anil singh, farheen Shaikh and Salah-uddin Ahmed, Washington State University, Spokane, WA

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Genetics, Genomics & Proteomics Poster (0517–0533)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Terminal uridylyl transferase 7 (TUT7), also known as Zcchc6, is a zinc finger domain-containing protein responsible for terminal uridylation of miRNA, implicated in pre-miRNA maturation and mature miRNA degradation. Dysregulated microRNA (miRNA) expression in human rheumatoid arthritis synovial fibroblast (RASFs) has been observed when compared to non-diseased SFs (NLSFs). Differential expression of miRNA is found to be associated with dysregulated miRNA biogenesis and degrading enzyme activity or stoichiometric differences in the amount of these proteins inside the cells. However, the role of TUT7 remains unexplored in RASFs.

Methods: Protein levels of miRNA biogenesis and degrading enzymes were compared by Western blotting in whole cell extracts prepared from RASFs and NLSFs. RASFs were treated with TNF-α for 24 h were used to evaluate changes in gene expression of miRNA biogenesis and degrading enzymes. RNA sequencing was performed in RASFs transfected with TUT7 siRNA or negative control (NC) siRNA in presence or absence of TNF-α (20 ng/ml) using an Ion Proton™ System. Effects of the loss of TUT7 were examined by gene enrichment of differentially expressed genes (DEGs) in presence or absence of TNF-α, followed by Gene Ontology analysis to determine key pathways modulated. Culture supernatants from siRNA-transfected samples were tested by ELISA to determine cytokine or chemokine production. Statistical value of $p < 0.05$ was considered significant.

Results: Western blot analysis of miRNA biogenesis machinery confirmed increased expression of Ago1 and Ago2 and decreased expression of TUT7 in RASFs compared to NLSFs (N=3 $p< 0.05$). We assessed the effects of TUT7 ablation by siRNA on TNF-α-induced synovial inflammation in human RASFs by RNA sequencing. RNA Sequencing analysis revealed that, out of 20,814 genes in the array, 218 DEGs were statistically qualified candidates altered in the absence of TUT7. Gene ontology study of DEGs revealed significant effects of TUT7 knockdown on cellular response to starvation, protein processing in ER, skeletal system development, heart development, and spliceosomal tri-snRNP complex assembly. Validation of RNA-seq data by quantitative RT-PCR analysis of response to TNF-α during transient knockdown of TUT7 confirmed the upregulated expression of matrix metalloproteinases (MMP1, MMP3), chemokines (CXCL5, IL-8) and cytokine (IL-6) transcripts in human RASFs. In corroboration of the mRNA data, ELISA results from TUT7 siRNA-transfected RASFs supernatants showed the significant upregulation of TNF-α-induced IL-6, IL-8, CXCL5, MMP-1, and MMP-3 production (N=4; $p< 0.05$).

Conclusion: This study provides novel evidence showing that loss of endogenous TUT7 in RASFs may exacerbate their hyper-responsiveness to inflammatory cytokines such as TNF-α by modulating the miRNA degradation pathway.

Interferon Pathway Lupus Risk Alleles Modulate Risk of Death from Acute COVID-19

Ilona Nln[1], Ruth Fernandez Ruiz[2], Theresa Wampler Muskardin[3], Stephanie Tuminello[2], Mukundan Attur[2], Eduardo Itturate[2], Christopher Petrilli[2], Steven B. Abramson[4], Aravinda Chakravarti[2] and **Timothy Niewold**[1], [1]Colton Center for Autoimmunity NYU School of Medicine, New York, NY, [2]NYU Grossman School of Medicine, New York, NY, [3]Colton Center for Autoimmunity, NYU School of Medicine, New York, NY, [4]New York University School of Medicine, New York, NY

SESSION INFORMATION

Session Date: Sunday, November 7, 2021

Session Title: Genetics, Genomics & Proteomics Poster (0517–0533)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Background/Purpose: Type I interferon (IFN) is critical in our defense against viral infections. Increased type I IFN pathway activation is a genetic risk factor for systemic lupus erythematosus (SLE), and a number of common alleles contribute to the genetic high IFN trait. In this study, we examine whether these common gain-of-function alleles in the type I IFN pathway are associated with protection from mortality in acute COVID-19.

Methods: We studied IFN pathway SLE risk genes in patients with acute COVID-19 admitted to NYU Langone hospitals (751 European-American and 398 African-American ancestry). The samples were genotyped using low depth sequencing and imputation, and we analyzed data from the following SNPs: IRF5 (rs2004640, rs3807306, rs10488631, rs2280714), IRF7/PHRF (rs1131665, rs4963128), IRF8 (rs17445836, rs12444486), and PRKG1 (rs7897633). Ancestral backgrounds were analyzed separately, and mortality after acute COVID-19 was the primary outcome.

Results: We observed specific IRF5 haplotypes that are protective against SLE risk were associated with increased risk of mortality in acute COVID-19 patients in European-American ancestry (OR=3.74, p=0.015). Alleles of PRKG1 were also associated with mortality from COVID-19 in the European-American ancestry cohort (OR=1.80, p=0.0057), and this risk factor was particularly strong in younger patients (OR=29.2, p=0.01 in ages 45-54). IRF8 genotype at rs1244486 was associated with protection from mortality in COVID-19 in African-American subjects aged 65 and older (OR=0.34, p=0.04).

Conclusion: We find that a number of type I IFN pathway genes associated with risk of SLE also modulate risk of death during acute COVID-19. Similar to their associations with SLE, these alleles are variably associated with COVID-19 mortality across ancestral backgrounds, suggesting ancestral differences in the genetic regulation of the IFN pathway. These data confirm the critical role of the IFN pathway in our defense against viral infections, and support the idea that some common SLE risk alleles exert protective effects in anti-viral immunity.

COPA Syndrome-associated Mutations in Lung Transplant Recipients for Interstitial Lung Disease

Sarah Beshay[1], Isabella Osuna[2], Jessica Smith[1], Justin Branch[3], Laura Muruato[3], Marietta DeGuzman[3], Pamela McShane[1], Yuelan Ren[1], Rajeev Singh[1], Manuel Silva Carmona[3], Sandeep Sahay[1] and **Tiphanie Vogel**[3], [1]Houston Methodist, Houston, [2]Rice University, Houston, TX, [3]Baylor College of Medicine, Houston, TX

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Genetics, Genomics & Proteomics Poster (0517–0533)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: COPA syndrome is a rare monogenic cause of immune-mediated lung disease, and it can mimic rheumatic diseases including rheumatoid arthritis (RA) with ILD, lupus and vasculitis. Like most genetic disease, COPA syndrome typically develops in childhood, but adult-onset cases have been reported. We recently established that a 77-year-old female who is 14 years out from double lung transplantation for a diagnosis of idiopathic pulmonary fibrosis (IPF) onset at age 60 years, her son with RA-ILD, and her granddaughter with juvenile arthritis complicated by ILD all have COPA syndrome. We then decided to determine the prevalence of COPA syndrome-associated mutations in patients with ILD who received lung transplantation.

Methods: We retrospectively reviewed 10 years of lung transplant recipients for ILD at a large transplant center

and identified patients with pulmonary fibrosis with or without a rheumatologic diagnosis. Targeted Sanger sequencing of the COPA syndrome hotspot (exons 8 and 9 of the *COPA* gene) was performed on amplified DNA extracted from explanted lung tissue.

Results: 427 transplant patients were identified; 66% were men and the mean age was 61 years. 55% received bilateral lung transplant. 62% had a diagnosis of idiopathic pulmonary fibrosis, 28% had a comorbid autoimmune condition, and 10% had other ILDs. To date, *COPA* sequencing has been completed for 147 patients and we have identified 4 patients with *COPA* mutations (2.7%), 3 with the most commonly reported variant (c.698G >A, p.R233H) and 1 with a novel variant (c.716C >T, p.A239V). The 1 female and 3 male patients had been diagnosed with RA-ILD, IPF, IPF and combined pulmonary fibrosis and edema (CPFE) as adults. All received bilateral lung transplant at an average age of 61 years (range 55-66 years). The 3 surviving patients are 11, 11 and 5 years out from transplant, however, the female patient with RA-ILD died 2 years post-transplantation secondary to chronic allograft rejection.

Conclusion: COPA syndrome is a rare entity and gaps exist in its recognition, diagnosis and management. We found that mutations in the *COPA* gene underlie some cases of severe pulmonary fibrosis labeled as other forms of adult-onset ILD. Identification and characterization of patients with such mutations will better define this rare disorder and serves as a step toward devising effective therapeutic strategies for patients with COPA syndrome.

Session Title: Genetics, Genomics & Proteomics Poster (0517–0533)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Background/Purpose: Sjögren's syndrome (SS) is an autoimmune exocrinopathy characterized by chronic salivary and lacrimal gland dysfunction. Alterations of Insulin-like growth factor (IGF) pathway has been recently linked to the development of systemic autoimmune diseases possibly through induction of apoptotic pathways and genetic variants of the IGF1 receptor (IGF1R) gene, has been shown to increase systemic lupus erythematosus (SLE) susceptibility. The aim of this study was to investigate whether genetic variations of the IGF1R contribute to SS pathogenesis and inflammasome activation, previously shown to be a contributor in SS related lymphomagenesis.

Methods: DNA was extracted from whole peripheral blood derived from 200 SS patients fulfilling the 2016 ACR/EULAR criteria and 336 HC and genotyped for the rs2229765 IGF1R polymorphism by RFLP-PCR assay. To explore potential functional implications of the IGF1R rs2229765, total RNA was extracted from minor salivary glands bi-

Table 1. Frequency of rs2229765 variant in SS patients and healthy controls

SNP rs2229765	Model	Genotype	HC (n=219) n (%)	SS (n=200) n (%)	OR [95%CI]	p-value

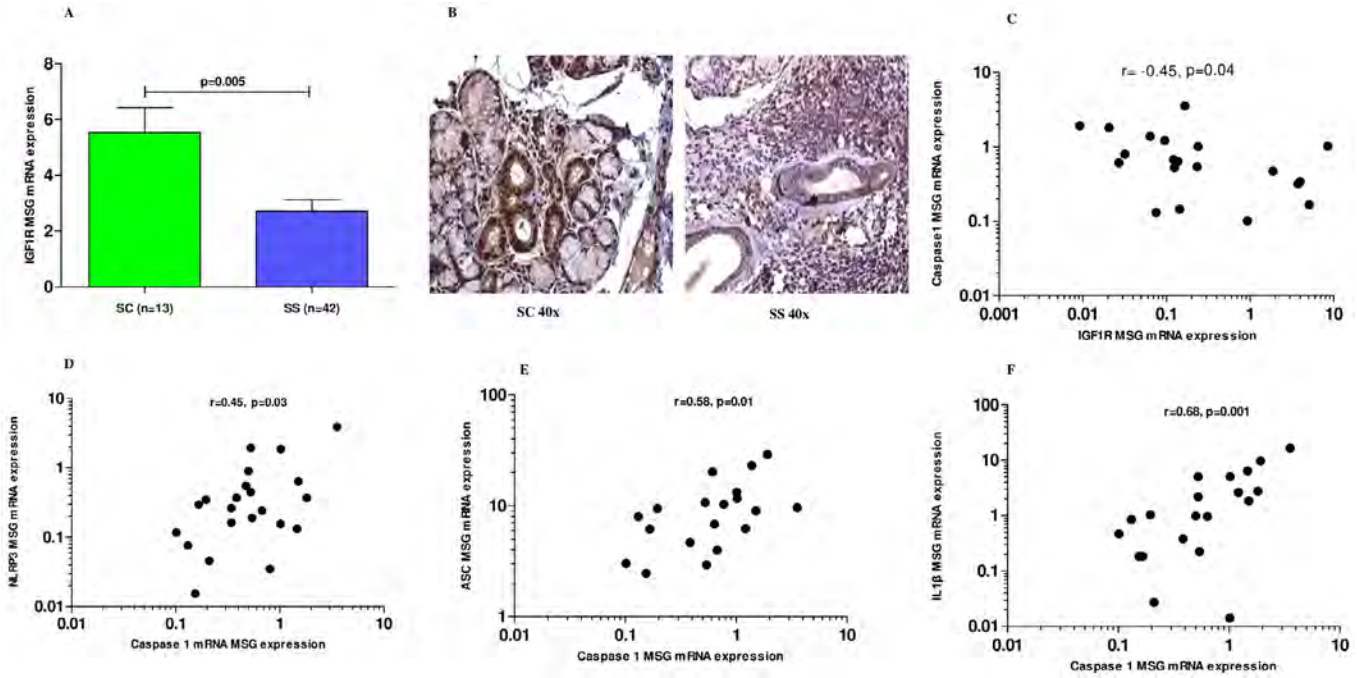

Figure 1. IGF1R mRNA and immunohistochemical expression in MSG tissues and gene expression correlations.

opsies (MSG) of 50 SS patients and 13 sicca controls (SC, presenting with ocular and /or oral dryness) and mRNA expression of IGF1R, as well as downstream inflammatory apoptotic mediators including caspases 1, 4, 5 and inflammasome components NLRP3, ASC, IL-1β, IL-18 was quantitated by RT-PCR. IGF1R immunohistochemical (IHC) expression was also assessed in formalin-fixed, paraffin-embedded MSG tissue sections derived from 5 SS patients and 5 SC. Statistical analysis was performed with GraphPad and SNPstats software. All subjects gave informed consent in accordance with the Declaration of Helsinki.

Results: Increased frequency of the AA genotype was detected in primary SS patients compared to HC (22% vs 10.7%, OR: 2.35 [1.45-3.80, 95% CI], p<0.001) (Table 1). SS patients displayed reduced IGF1R at both mRNA and protein level in MSG tissues (mainly in ductal cells) compared to SC (mean±SD=2.97±2.62 vs mean±SD=5.53±3.23, p=0.009) (Figs 1 and 2). Of interest, IGF-1R expression was negatively associated with caspase-1 transcripts (r= -0.45, p=0.04), which in turn were positively correlated with NLRP3 (p=0.45, p=0.03), ASC (r=0.58, p=0.01) and IL1β (r=0.68, p=0.001).

Conclusion: In the present study, rs2229765 IGF1R variant has been shown to increase susceptibility for primary SS. Decreased trophic signals in salivary gland epithelial cells as a result of dampened IGF1R mRNA and protein expression in salivary gland tissues could be related to increased apoptosis and subsequently to activation of inflammasome pathways in the setting of primary SS.

Molecular Heterogeneity Between Different Classes of Lupus Nephritis as Revealed by Kidney Biopsy Proteomics

Asmaa AbuMaziad[1], Abhimanyu Amarnani[2] and **Ram Singh**[3], [1]University of California Los Angeles, Los Angeles, CA, [2]Los Angeles County + University of Southern California, Los Angeles, CA, [3]University of California Los Angeles David Geffen School of Medicine, Los Angeles, CA

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Genetics, Genomics & Proteomics Poster (0517–0533)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Lupus nephritis (LN) causes substantial morbidity and mortality. LN is histopathologically divided into six classes, which currently serves as the basis for making treatment decisions. Pathogenesis underlying different classes of LN is unclear. To identify the molecular differences, we studied the quantitative protein changes across all six LN classes using tandem mass spectrometry proteomics analyses of kidney biopsies from patients.

Methods: Kidney biopsies from 48 subjects, including 10 normal donor kidneys and 38 LN kidneys, were obtained from UCLA Pathology. All biopsies were reviewed independently by two pathologists. Protein was extracted from biopsy tissues and subjected to tandem mass spectrometry proteomics analyses. We measured the peptides expression quantitatively using Orbitrap LC-MS/MS system. Peptides were annotated and the abundance of peptides was normalized. The data were presented as mean ± SD and median with range (minimum–maximum), and categorical data were presented as frequencies and proportions. Wilcoxon rank-sum test with two-tailed distribution was used in the statistical comparisons between groups unless otherwise indicated. The p-values were adjusted for multiple testing with p.adjust in R using false discovery rate. The principal component analysis based on Spearman's rank correlation coefficients between samples was performed using R. We employed a machine learning analysis with random forest classification to build a probabilistic-based prediction model of LN disease vs. healthy controls. Pathway analyses of differentially expressed peptides with absolute log2 fold change greater than one was completed with Ingenuity Pathway Analysis.

Results: Proteomics analysis identified 2190 peptides quantifiable in all 48 kidney biopsies. Of these, 655 peptides were significantly differentially expressed, including 304 upregulated peptides and 351 downregulated peptides ($p < 0.05$). In principal component analyses, all class VI biopsies clustered with the control specimens, and when class VI biopsies were excluded controls neatly separated from LN (classes I-V). Through random forest classification, we built a probabilistic-based prediction model that can discriminate LN disease (class I-V) vs. healthy controls utilizing 273 of the 655 peptides differentially expressed between the groups, which maintained a receiver operating characteristic area under the curve accuracy of 87.5% with 95% CI (0.7131, 0.9985), and an out-of-bag error rate of 3.7%. Of these 273, peptides representing VIM, ETFB, SERPINA1, BHMT, IGHG1, and MDH2 had the highest mean decrease accuracy and Gini. Next, we utilized Ingenuity pathway analysis (IPA) to seek differentially expressed proteins and pathways in individual LN classes compared to controls. While a set of proteins and pathways were significantly differentially expressed across LN classes, certain proteins and pathways discriminated individual LN classes.

Conclusion: Our data indicate the unique molecular signatures that differentiate LN classes and pave the way for defining the unique molecular pathogenesis of individual LN classes, thus introducing the basis for designing class-specific treatment in LN.

Session Title: Genetics, Genomics & Proteomics Poster (0517–0533)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Background/Purpose: There is a pressing need of identifying patients suffering the rapid progressive phenotype of Osteoarthritis (RPOA) to implement prevention strategies and to include them in clinical trials. Both nuclear and mitochondrial DNA (mtDNA) polymorphisms have been associated with susceptibility and incidence/progression of the disease. Preliminary analyses by our group showed the nuclear single nucleotide polymorphism (nSNP) rs12107036 at TP63 as a potential risk factor for RPOA of the knee.

Our objectives in the present work are:

- To analyze the influence of the interactions between mtDNA haplogroups and the nSNP rs12107036
- To apply Next Generation Sequencing (NGS) techniques to discover novel mitochondrial genetic variants to construct predictive models of RPOA of the knee.

Methods: 1102 Caucasian subjects from the Osteoarthritis Initiative (OAI) were classified into two groups:

- Rapid progressors (N=255), baseline KL grade 0-1 in at least one knee, that increases up to KL≥ 3 during 48-month follow-up; or baseline KL grade 2 in at least one knee that increases up to KL grade 4 during the follow-up.
- Non-rapid progressors (N=847), with the same baseline characteristics as rapid progressors, but with a slower or no evolution over time.

mtDNA haplogroups and rs12107036 were assigned by mini-sequencing techniques. Novel mtDNA variants were analyzed by NGS. Statistical analyses included chi-square tests followed by generalized estimating equations. Relative excess risk due to interaction (RERI) and attributable proportion (AP) was evaluated for the additive interaction between mtDNA clusters and nSNP rs12107036. Confounder variables, including gender, age, BMI, previous injury, contralateral OA and WOMAC pain, were taken into account. All the analyses were performed using SPSS Statistics v24 and epi.R package included in R software v3.6.3.

Table 1. Predictive model for the risk of RPOA phenotype of the knee. $mtDNA Clusters: group of haplogroups with a common phylogenetic origin BMI: Body Mass Index; WOMAC: Western Ontario and McMaster Universities Osteoarthritis Index; OR: Odds Ratio; CI: confidence interval; #: statistical significance declared at P < 0.05, in bold.

rs12107036 G * HV	Reference			

Results: Chi-square analyses revealed that patients carrying the allele G of rs12107036 and mtDNA cluster UK have an increased risk of developing RPOA of the knee (OR 2,013; p=0,001 vs OR 1,221; p=0,049). An excess of 70,3% of the RERI between nSNP rs12107036 and mtDNA cluster UK was detected, indicating that 47,1% (AP=0,471) of the risk is attributable to this interaction, meaning that harboring both genetic factors increase 4,7 times the risk of RPOA compared to having just one. On the other hand, the in-depth sequencing of mtDNA revealed the mt16519C variant as significantly overrepresented in the rapid-progressors group (OR 1,620; p=0,002).

In the predictive model, the interaction between rs12107036 and mtDNA cluster UK (p=0,041, OR=1,703), as well as the mitochondrial variant 16519C (p=0,004,OR=1,632), showed a significant association with RPOA of the knee, in addition to age (p= < 0,001, OR=1,056), BMI (p= < 0,001, OR=1,065), contralateral OA (p= < 0,001, OR=1,993), previous injury in the target knee (p= < 0,001, OR=1,803) and WOMAC pain (p=0,002, OR=1,090) (Table 1).

Conclusion: Our predictive model indicates that mtDNA genetic variants are useful, not only as modulators of the influence of specific nuclear polymorphisms on the risk of developing RPOA, but also as candidate genetic biomarkers of this phenotype.

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Genetics, Genomics & Proteomics Poster (0517–0533)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: ANCA-associated vasculitides (AAV) are rare but aggressive autoimmune disorders. The pathogenesis of the disorders is complex and still poorly understood; only a few genetic loci have been associated with AAV. The aim of this project was to identify and characterize novel susceptibility loci for AAV positive for myeloperoxidase (MPO) or proteinase 3 (PR3) ANCA.

Methods: Genetic association analyses were performed after Illumina sequencing of 1853 genes and subsequent replication with genotyping of candidate single-nucleotide polymorphisms (SNPs) in a total cohort of 1110 Scandinavian cases with granulomatosis with polyangiitis (GPA) or microscopic polyangiitis (MPA) and 1589 controls. A novel AAV-associated SNP was analyzed for allele-specific effects on gene expression using luciferase reporter assay.

Results: Associations between PR3-ANCA positive AAV and the *HLA-DPB1*, *HLA-DPA1* and *SERPINA1* genes and between MPO-ANCA positive AAV and the *HLA-DQB1* locus identified in previous genome-wide studies were confirmed in the present study. In addition, a novel locus on chromosome 6 was identified as associated with MPO-ANCA positive AAV. The rare allele of the novel disease-associated SNP affected downstream gene expression in a cell type specific manner.

Conclusion: This study confirms previous findings of genetic associations specific for PR3-ANCA positive and MPO-ANCA positive AAV, respectively. A novel susceptibility locus for MPO-ANCA positive AAV was identified, where the disease-associated SNP may facilitate the development of autoimmunity through a negative effect on the expression of the closest gene in specific cell types.

Session Date: Sunday, November 7, 2021
Session Title: SLE – Animal Models Poster (0534–0540)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: The lymphatic system is composed of vessels which carry fluid, soluble molecules, and cells from peripheral tissue to draining lymph nodes. Photosensitivity, an exaggerated inflammatory response in response to ultraviolet radiation (UVR), is present in most patients with Systemic Lupus Erythematosus (SLE). Lymphatic dysfunction has been shown to induce photosensitivity in wild-type models, thus we hypothesized that lymphatic dysfunction could contribute to photosensitivity in SLE.

Methods: We examined MRL/lpr lupus prone mice for lymphatic function by injecting Evan's Blue into the ear and measuring retention. Ear thickness and flow cytometric analysis were used to assess photosensitivity. This was similarly done in an inducible lupus model using chronic epicutaneous application of imiquimod on B6 mice. We then investigated the utility of improving lymphatic drainage using two approaches. First, we used manual lymphatic drainage (MLD) in the MRL/lpr mice. Second, we used the imiquimod inducible lupus phenotype in a novel mouse model with enhanced lymphatic function (inducible lymphatic endothelial cell specific PTEN KO).

Results: MRL/lpr mice had greater Evan's blue retention compared to controls suggesting lupus prone mice have impaired lymphatic drainage. MLD improved lymphatic drainage and reduced photosensitivity. Imiquimod treated PTEN KO mice had reduced photosensitivity and reduced systemic immune activation compared with imiquimod treated controls.

Conclusion: This data suggests that lymphatic dysfunction contributes to photosensitivity in murine lupus and improving lymphatic flow, even with simple MLD, can ameliorate photosensitivity. Future studies will determine the etiology of lymphatic dysfunction in murine lupus and the mechanism of lessened photosensitivity with improved lymphatic drainage. If similar immune circuitry defects are present in patients with SLE, altering lymphatics could be a novel target for new therapeutics.

Session Date: Sunday, November 7, 2021
Session Title: SLE – Animal Models Poster (0534–0540)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Neutrophils are key initiators and promoters of autoimmunity, including SLE, via the elaboration of neutrophil extracellular traps (NETs). We tested the efficacy of the biolipid mimetic, NAP1051 that has transcellular activity in the inflammatory process. NAP1051 is a lipid-based agonist of FPR2/ALXR that inhibits neutrophil migration and promotes macrophage mediated efferocytosis in SLE-prone NZM 2328 mice.

Methods: Female NZM mice 4-5 months of age (when serologic autoimmune and renal glomerulonephritis have developed) were gavaged with graded doses of NAP1051 (2.5, 5.0, 10 mg/kg/day and vehicle; n=5 per group) for 28 consecutive days and monitored for proteinuria. At study termination, blood chemistry, CBC, and immune profiles were determined. Kidneys were harvested for expression of inflammatory cytokines and markers of NETosis. The kidneys were also assessed by H&E staining and T-cell infiltration, IgG and C3 complex depositions by immunofluorescence staining.

Results: NAP1051 dramatically attenuated nephritis in a dose-dependent manner, as evidenced by reduced proteinuria, serum BUN levels, expression of inflammatory cytokines (IL-1β, TNF- α), and expression of biomarkers of NETosis (NOX-2, PAD4 and NE) in the kidney (Figure 1). Infiltrating T-cells and glomerular deposition of C3 and IgG in

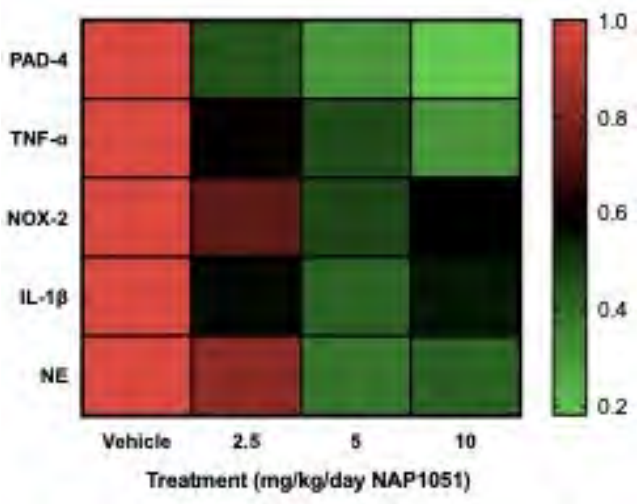

Figure 1. Heat map of gene expression of NETosis and inflammatory markers.

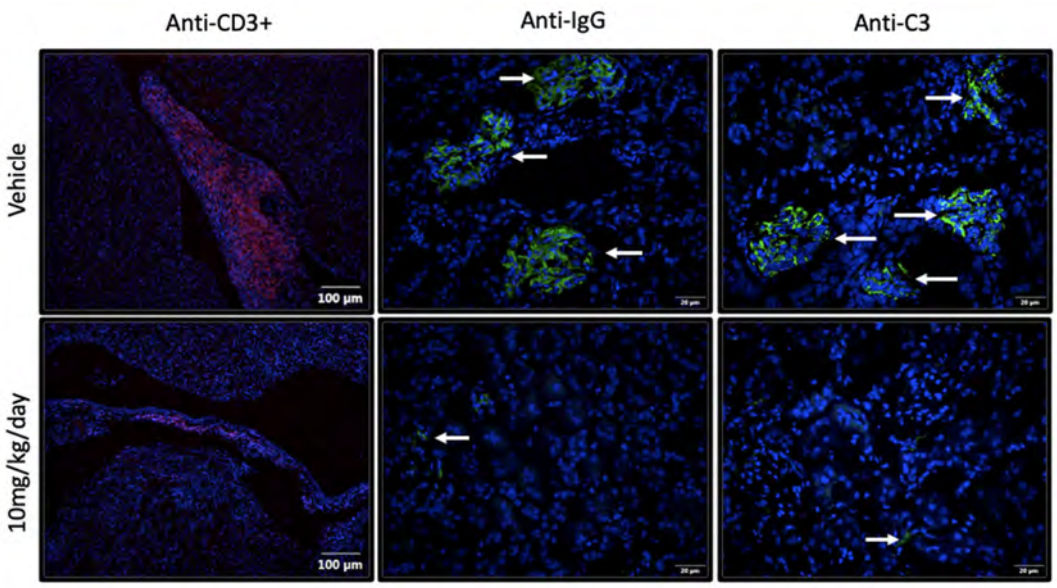

Figure 2. Immunofluorescence staining for CD3+ cells, IgG, and C3 in kidney sections from NZM 2328 mice. Top Left: Infiltrating T-cells are greater in number in the vehicle group than in the treatment group. Blue: DAPI, Red: Anti-CD3+ staining. Bottom Right: Considerably greater IgG and C3 deposition is appreciated in vehicle-treated mice than in NAP1051-treated mice. Blue: DAPI, Green: Anti-IgG staining/Anti-C3 staining. The white arrows indicate deposition of IgG and C3 complexes. Pictures for the anti-CD3+ were taken with a 10X objective and the anti-IgG/anti-C3 were taken with a 40X objective.

the kidney were also greatly reduced by NAP1051 treatment (Figure 2). Perhaps most strikingly, vehicle-treated mice developed glomerular crescents, consistent with rapidly progressive glomerulonephritis, whereas glomerular pathology was completely absent at the higher doses of NAP1051 (Figure 3). Importantly, there were no biochemical or

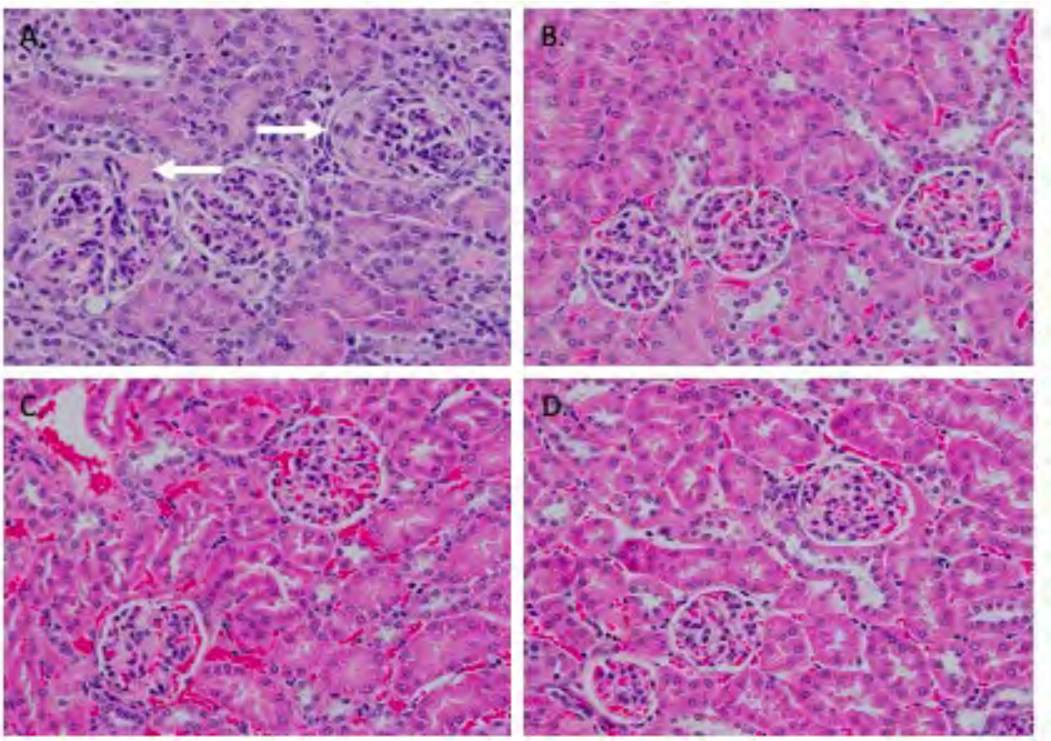

Figure 3. Kidney sections from A: Vehicle, B: 2.5 mg/kg/day, C: 5 mg/kg/day and D: 10 mg/kg/day. The white arrows point to glomerular crescents. Pictures were taken with a 40X objective.

histological signs of drug-related toxicities at any tested dose. Serological testing showed no changes in anti-dsDNA and anti-IgG levels between treatment groups.

Conclusion: NAP1051 demonstrated dose-dependent efficacy clinically and pathologically in NZM mice. NAP1051 prevented chronic glomerulonephritis, damage to the kidney tissues and reduced the expression of inflammatory markers without signs of toxicity. Interestingly, NAP1051 reduced T-cell infiltration into the kidney without affecting circulating autoantibody levels, suggesting that this compound exerts its therapeutic effect in a manner that is independent of autoantibody production. NAP1051 was also able to reduce NETosis biomarker expression in a dosage-dependent manner, suggesting that it is able to reduce PAD4 and neutrophil elastase expression. Taken together, NAP1051 exerts its activity through modulating NETosis for the treatment of SLE. Additional studies are currently underway to confirm these initial results and, if confirmed, would set the stage for evaluation in human SLE.

The EIF4 Translational Inhibitor Pateamine a Improves Immunological and Neurological Functions in *BXSB.yaa* Lupus Mice

Gonzalo Gómez-Hernández[1], Nieves Varela[1], Harini Bagavant[2], Guillermo Barturen[1], Marta E. Alarcon-Riquelme[1] and Maria Morell[1], [1]GENYO.Center for Genomics and Oncological Research, Granada, Spain, [2]Oklahoma Medical Research Foundation, Oklahoma City, OK

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: SLE – Animal Models Poster (0534–0540)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Systemic Lupus Erythematosus (SLE) is an autoimmune disease characterized by loss of tolerance and activation of the immune response. Clinical manifestations are heterogeneous and several organs can be affected including skin, joints, central nervous system and kidney. Traditional treatments include the use of hydroxychloroquine, glucocorticosteroids, immunosuppressive and more recently, biological drugs such as belimumab or rituximab. In the last decade new alternatives have been proposed based on targeting interferon and cytokines. Mouse models have been extremely helpful to test the efficacy of new SLE therapies. In this work we analyze the therapeutic potential of a natural compound, Patemina A (PatA) to treat SLE. Pat A is an inhibitor of the translation initiation process with immunosuppressive properties that has been tested successfully in cancer mouse models.

Methods: To test Pat A efficiency in SLE we used the BXSB.Yaa lupus model. Animals were treated for 8 weeks starting at the initial stages of disease (12 weeks). Sera was collected every three weeks and disease signs were followed. At the final point we performed serological analyses (cytokines and autoantibodies), flow cytometry on spleen to evaluate different cell populations, kidney histological and functional assays and behavioral tests to evaluate neuropsychiatric changes.

Results: Our data shows that Pat A treatment increases the survival rate and is able to reduce circulating levels of proinflammatory cytokines and autoantibodies. We also observed improvement of cognitive functions (learning/memory, and depression behavioral tests) together with a reduction of proinflammatory cytokines locally in the hippocampus.

Conclusion: These data suggests that translation inhibition improves lupus disease signs at the immunological and neurological levels opening a new line of research based on translation inhibition to treat lupus and other autoimmune diseases.

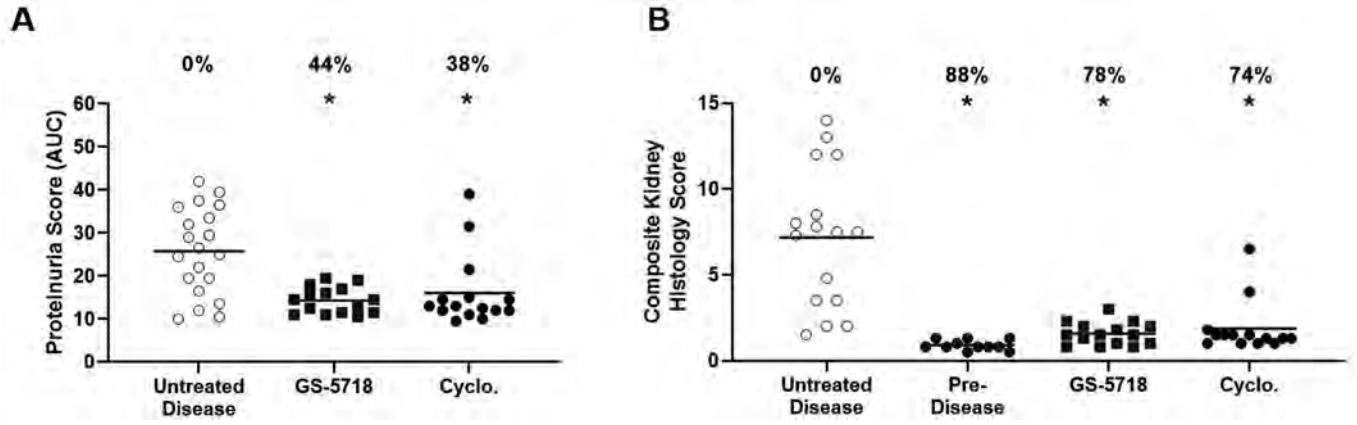
The Clinical, Oral Small Molecule IRAK4 Inhibitor, GS-5718, Improves Survival and Reduces Disease Pathologies by Modulating Multiple Inflammatory Endpoints in the Murine NZB/W Model of Spontaneous Lupus

Adam Yadon[1], Vanessa Gorney[2], Angie Hammond[3], Ethan Grant[2] and Astrid Clarke[3], [1]Gilead Sciences, Inc., Seattle, WA, [2]Gilead Sciences, Inc, Foster City, CA, [3]Gilead Sciences, Inc, Seattle, WA

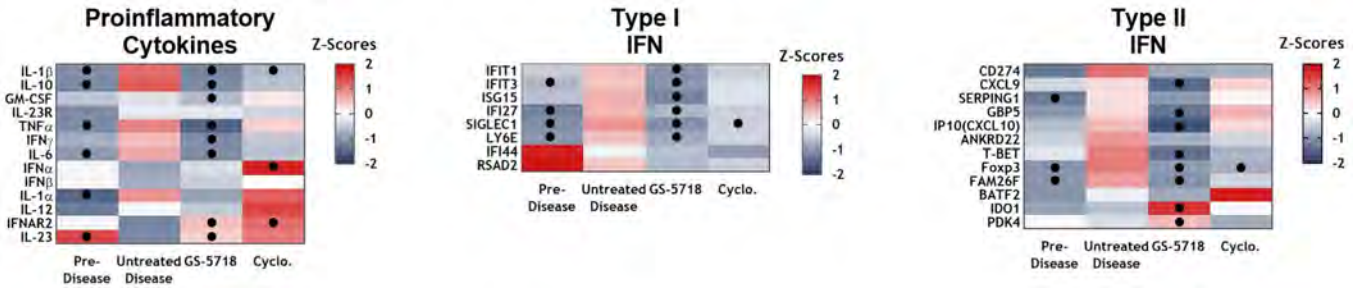
SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: SLE – Animal Models Poster (0534–0540)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Lupus is a heterogenous autoimmune disease characterized by loss of immune tolerance, production of nucleic acid:autoantibody immune complexes, immune cell hyperactivation, and increased proinflammatory cytokine and interferon production. Interleukin receptor associated kinase 4 (IRAK4) is a serine/threonine kinase that modulates proinflammatory cytokine and type I interferon production downstream of toll-like receptors (TLRs) and IL-1 receptors (IL-1Rs) in immune cells. It is well established that TLR signaling (predominately TLR7 and TLR9) plays a key role in the pathogenesis of lupus[1] and thus inhibition of IRAK4 represents a promising target for the therapeutic treatment of lupus.

The murine NZB/W model recapitulates many lupus-like disease pathologies including proteinuria, hyperactive B and T cells, high titers of autoantibodies, and splenic and kidney abnormalities[2,3]. Current standard of care treatments,



(A) Total proteinuria score (area under curve, AUC, weeks 28 to 38). (B) Composite kidney score (glomerulus, crescent, protein cast, interstitial inflammation, and vasculitis score). Cyclo., Cyclophosphamide; %, Percent change from untreated disease; *, p-value < 0.05 Kruskal-Wallis (Dunn's post-hoc) vs. untreated disease.



(A-C) Z-scores of gene expression changes (fold-change relative to untreated disease) for proinflammatory cytokines (A), type I IFNs (B), and type II IFNs (C) genes. Cyclo., Cyclophosphamide; *, p-value < 0.05 Kruskal-Wallis (Dunn's post-hoc) vs. untreated disease.

including methotrexate, cyclophosphamide, mycophenolate mofetil, and blockers of B-cell activating factor (BAFF) have demonstrated efficacy (e.g. improved survival and/or clinical pathologies) in this model[2,3]. Demonstrating beneficial effects of IRAK4 inhibition in this model would support clinical evaluation in lupus.

Methods: In this study we investigated the efficacy of GS-5718, a highly selective, competitive inhibitor of IRAK4, to improve survival and attenuate disease pathology in the murine NZB/W model of spontaneous lupus.

Results: GS-5718 treated animals displayed improved in-life disease outcomes, histological measures, and pharmacodynamically reduced multiple inflammatory endpoints. Administration of GS-5718 showed statistically significant improvements in survival and reduced proteinuria, splenomegaly, and serum cholesterol levels compared to control animals. Kidney histology revealed GS-5718 treatment decreased swelling, crescent formation and periodic acid-Schiff (PAS) staining in glomeruli, protein casts in the cortex, and perivascular infiltration. These improvements in disease pathologies were accompanied by statistically significant reductions in peripheral cytokine production, kidney cytokine and interferon gene expression, and splenic immune cell infiltration.

Conclusion: GS-5718 treatment showed statistically significant improvements in survival and disease progression in a murine NZB/W spontaneous lupus model accompanied by improvements in pharmacodynamic inflammatory endpoints. These results suggest a pathological role for IRAK4 signaling in a pre-clinical mouse lupus model and supports further evaluation of GS-5718 for therapeutic intervention in lupus patients.

Strengthening Nuclear Envelope Ameliorates UVB-triggered Skin Inflammation and Kidney Damage in Lupus Mice

Xing Lyu[1], Minghui Li[2], Ping L Zhang[3], Victoria Werth[4] and Ming-Lin Liu[4], [1]Tianjin Medical University General Hospital, Philadelphia, PA, [2]Tianjin Medical University General Hospital, Tianjin, China (People's Republic), [3]Division of Anatomic Pathology,Beaumont Laboratories, Beaumont Health, Royal Oak, MI, [4]University of Pennsylvania, Philadelphia, PA

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: SLE – Animal Models Poster (0534–0540)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Ultraviolet B (UVB) exposure triggers lupus flare by worsening skin lesions and systemic symptoms such as lupus nephritis. The effects of UVB-induced skin inflammation on kidney activity have not been well understood. NETosis has been implicated in lupus. We have seen that UVB induces neutrophil recruitment to skin with NET formation and exhibition of NET-associated proinflammatory cytokines. Our mechanistic studies revealed that nuclear envelope rupture and NET formation are driven by PKCα-mediated lamin B (lmnb) disassembly. Strengthening nuclear envelope by lamin B overexpression decreases NETosis and exhibition of NET-associated cytokines in the skin of UVB-irradiated lmnb1$^{Tg/+}$ mice. Furthermore, other studies reported that UVB can trigger an IFNα signature both in skin and kidneys, and neutrophils in the inflamed skin can migrate back to the circulation through reverse transmigration, then be recruited to the kidneys, resulting in transient proteinuria in wildtype mice. However, the involvement of NETosis in UVB-mediated lupus flare in skin and kidneys has not been studied.

Methods: We generated lupus-prone mice with lamin B overexpression by backcrossing lmnb1$^{Tg/+}$ mice with MRL/lpr (lpr) mice for 10 generations. Female MRL/lpr-lmnb1$^{Tg/+}$ mice and their MRL/lpr littermates (8-week-old) were exposed to UVB at 150 mJ/cm^2/day for 5 consecutive days. We examined skin lesions, proteinuria, infiltrates, and NET formation in the skin and kidneys of these mice.

Results: Our data show that UVB exposure induces inflammatory responses with increased skin thickness, more infiltrates and NET formation in the skin, proteinuria and increased NET formation, NET-associated IFNα, IgG deposition, and hypercellularity in the kidneys of UVB-irradiated MRL/lpr mice. In addition, our data demonstrate decreased NET formation and less skin inflammation with attenuated skin thickness and infiltrates ($p< 0.01$) in the skin, decreased proteinuria, and reduced NET formation, NET-associated IFNα, IgG deposition, and hypercellularity in the kidneys of MRL/lpr-lmnb1$^{Tg/+}$ mice as compared to those in control MRL/lpr mice after UVB exposure. Interestingly, the skin infiltrates ($r=0.57$, $p< 0.05$) or NET formation in skin ($r=0.54$, $p< 0.05$) were positively correlated with proteinuria. Importantly, NET formation ($r=0.56$, $p< 0.05$), NET-associated IFNα ($r=0.60$, $p< 0.05$), IgG deposition ($r=0.7$, $p< 0.01$), or hypercellularity ($r=0.65$, $p< 0.01$) in glomeruli were also positively correlated with proteinuria.

Conclusion: We conclude that inhibition of NET formation by strengthening the nuclear envelope integrity can ameliorate UVB-triggered skin inflammation, proteinuria, and kidney damage in young lupus-prone mice. Therefore, our results provide insights into novel therapeutics into UVB-induced lupus flare.

Session Title: SLE – Animal Models Poster (0534–0540)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Background/Purpose: Fibrosis is characterized by collagen deposition, fibro/myofibroblast accumulation, and extracellular matrix remodeling and can lead to disfiguring skin changes. In cutaneous lupus, scar formation after discoid lesion eruption may evolve from enhanced fibrotic phenotypes. Thus, understanding how fibrosis evolves in discoid lupus lesions is important to prevent morbidity and low quality of life for patients with cutaneous lupus. Recent work from our laboratory has shown that epidermal-directed overexpression of murine *Vgll3* causes severe lupus-like skin lesions reminiscent of discoid lupus erythematosus (DLE), as well as systemic autoimmune disease with end-organ damage. Given the apparent fibrotic nature of the skin lesions in transgenic (TG) *Vgll3* mice, we wanted to determine whether *Vgll3* induced fibrosis.

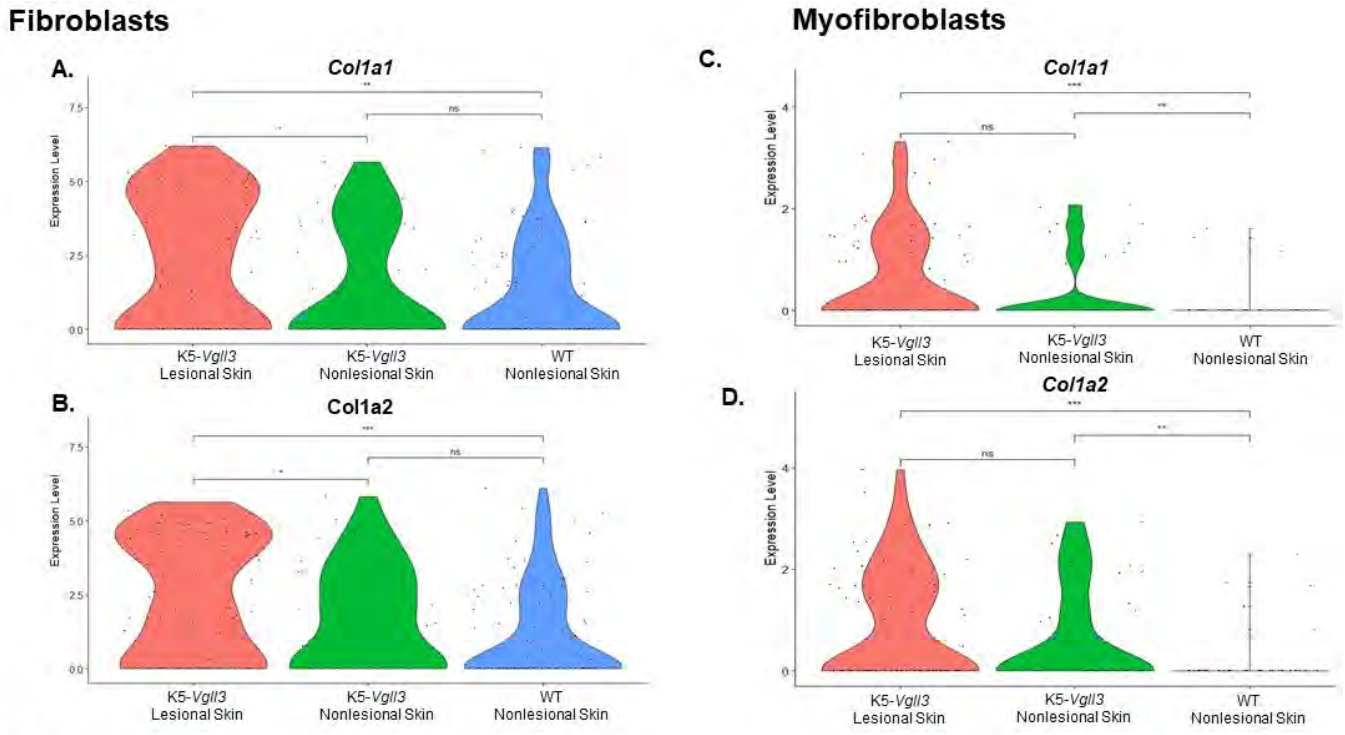

Fig. 1

A. *Col1a1* Gene expression in fibroblasts from lesional and nonlesional skin in K5-*Vgll3* mice and nonlesional skin in WT.
B. *Col1a2* expression in fibroblasts.
C. *Col1a1* Gene expression in myofibroblasts from lesional and nonlesional skin in K5-*Vgll3* mice and nonlesional skin in WT.
D. *Col1a2* expression in myofibroblasts.

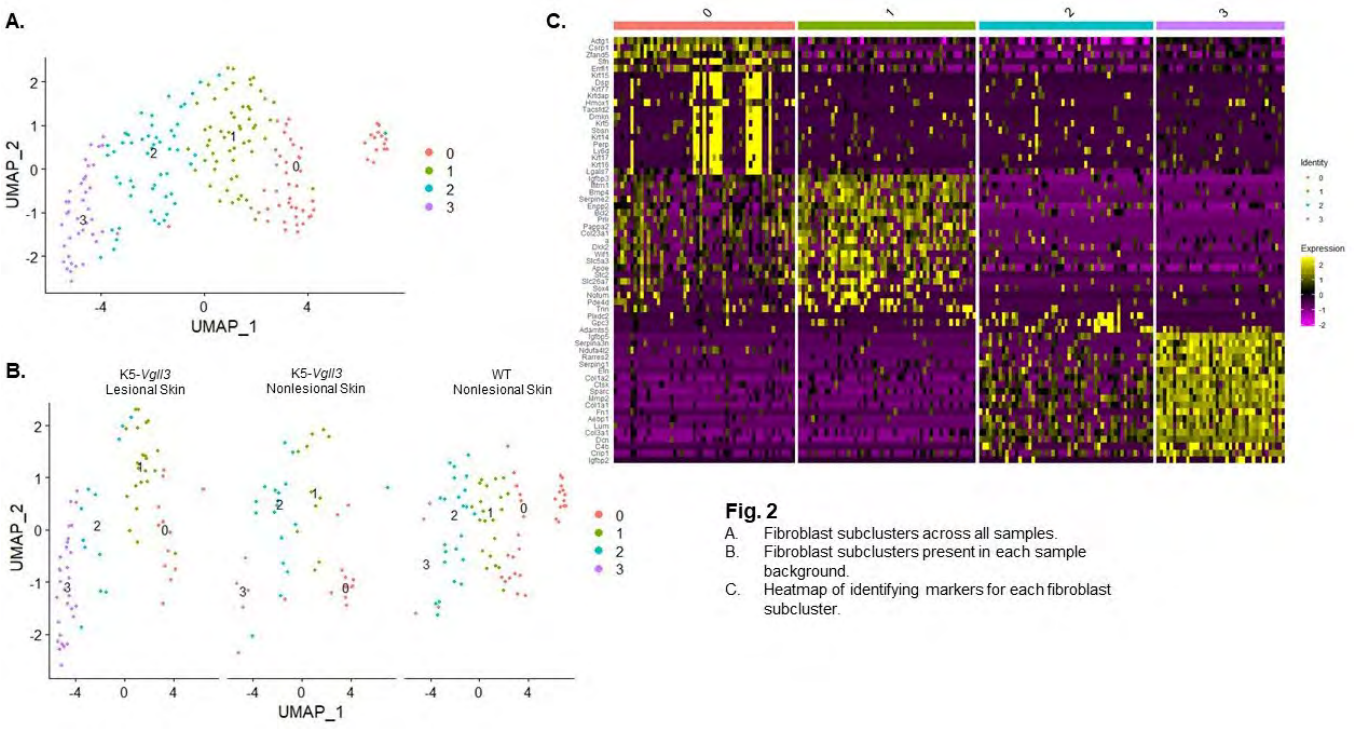

Fig. 2
A. Fibroblast subclusters across all samples.
B. Fibroblast subclusters present in each sample background.
C. Heatmap of identifying markers for each fibroblast subcluster.

Methods: 2-3 month old male and female transgenic (TG) mice overexpressing *Vgll3* in the epidermis under the K5 promoter were compared to male and female TG wild type (WT) C57Bl/6 mice (n= 3-5 per group). Fibrotic biomarkers of human DLE and scleroderma were compared via immunohistochemistry. In addition, we used single-cell RNA-sequencing (scRNA-seq) via 10x platform and bulk RNA-seq of lesional and nonlesional skin to investigate the transcriptomes of the potential cellular fibrotic players such as fibroblasts (FBs) and myofibroblasts (MYOFBs). ScRNA-seq data were analyzed using Seurat. Several subclusters of FBs, MYOFBs, and T cells were identified and fibrotic markers for each FBs subcluster were analyzed. Gene expression of fibrosis-associated genes in FBs/MYOFBs from lesional and nonlesional skin in K5-*Vgll3* mice as well as WT were identified.

Results: Epidermal *Vgll3* overexpression resulted in development of not only cutaneous inflammation but also severe fibrosis, as evidenced by trichrome staining. Immunohistochemistry identified increased infiltration of granulocytes/monocytes accompanied by significant expression of fibrotic biomarkers (*Acta2*, *Col1*, *Tgfb1*, *Ctgf)* and pro-fibrotic cytokines (*Il4* and *Il13*) in TG mice. These same markers were also seen in human DLE and scleroderma lesions compared to healthy human skin. Overall, lesional *Vgll3* TG skin exhibited higher expression of *Col1a1 and Col1a2*. ScRNA-seq of *Vgll3* TG lesional skin vs. WT skin demonstrated that the increased expression of these collagen genes was localized to fibroblast and myofibroblast populations. (**Fig. 1**). Four FBs subclusters were identified across all samples, and a unique FB subcluster (cluster 3, **Fig. 2**) in *Vgll3* TG mice was noted that uniquely exhibited higher expression of *Col1a1 and Col1a2* compared to WT mice.

Conclusion: The detection of high expression of *Ctgf* and *Tgfb1* as well as *Col1* mRNA and protein in the skin of TG mice suggests that skin-directed overexpression of *Vgll3* may impact fibrosis development. The changes in *Vgll3* TG mice are reflected in human scleroderma and DLE lesional samples, suggesting that pathways and inflammatory responses regulated by *Vgll3* may contribute to fibrosis. Further studies will elucidate the specific mechanisms that may be targetable in this pathway to better treat and prevent fibrosis in autoimmune disease patients.

Behavioral Deficits May Precede Influx of Brain-Infiltrating Macrophages in Neuropsychiatric Symptoms of Systemic Lupus Erythematosus

Hadijat Makinde, Miranda Gurra, Yidan Wang, Sara Radecki and **Carla Cuda**, Northwestern University, Chicago, IL

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: SLE – Animal Models Poster (0534–0540)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Systemic lupus erythematosus (SLE) is a complex autoimmune disease that affects many end organs including the brain. Despite a prevalence of over 50% in SLE patients depending on the attribution model, neuropsychiatric symptoms of SLE (NPSLE), including anxiety and movement disorders, are among the least understood complications. Notwithstanding the paucity of data examining underlying mechanisms, accumulating evidence points to microglia, the resident innate immune cells in the brain, as a driver of disease. The cross-talk between infiltrating monocyte-derived macrophages and microglia plays a critical role in directing microglial responses. However, the question remains whether macrophage infiltration precedes NPSLE manifestations. Here, we longitudinally investigate macrophage infiltration into the brain in two models of SLE.

Methods: B6 and SLE-prone B6.*Sle1Sle2Sle3* (B6.TC; Jackson #007228) mice underwent a battery of behavioral tasks at 2 months of age. Spleen and cervical lymph nodes were weighed as an indicator of systemic disease from female B6 and B6.TC mice spanning disease progression (n=3-5/timepoint; 2, 5, 8, 11 months of age). At each timepoint, brains were perfused and extracted, meninges were removed and live $CD45^{+}CD11b^{+}$ cells were FACSorted from pooled cell suspensions (n=3/strain/timepoint to account for biological variability) for single-cell RNA-seq (10X Genomics 3' v3.1) in conjunction with cellular indexing of transcriptomes and epitopes by sequencing (CITE-seq); analysis pending. Two additional cohorts of B6 and B6.TC mice were evaluated for brain microglia infiltration and microglial distribution via flow cytometry at 11 months of age. NPSLE-prone CReCOM mice showed behavioral deficits at 3 months of age and underwent longitudinal analyses described above.

Results: Similar to patients with NPSLE, B6.TC mice exhibited heightened anxiety, impaired motor coordination and locomotive deficits compared to control mice, suggesting B6.TC mice are a valid model for NPSLE-associated symptoms. NPSLE-prone mice showed an age-dependent increase in splenomegaly and lymphadenopathy. At 11 months of age, microglia were expanded in NPSLE-prone mice compared to their respective controls, including the recently discovered disease-associated microglia subset associated with neurodegenerative disease. Further, there was an age-dependent increase in the number of brain-infiltrating macrophages in NPSLE-prone mice. However, levels of brain-infiltrating macrophages were comparable to levels in control mice at 2 months of age, indicating that macrophage infiltration occurs between 2 and 5 months of age in NPSLE-prone mice.

Conclusion: As macrophage levels in the brains of NPSLE-prone mice are comparable to control levels at 2 months of age but behavioral deficits occur at 2-3 months of age in NPSLE-prone mice, we provide the first evidence that

macrophage infiltration may be a response to NPSLE-like disease incited by brain-intrinsic mechanisms rather than a cause. Future studies will identify the exact timing of macrophage infiltration to define their role as either disease initiators or responders and dissect macrophage heterogeneity during NPSLE progression.

N-formyl Methionine Peptide-mediated Neutrophil Activation in Systemic Sclerosis

Runa Kuley[1], Ryan Stultz[2], Bhargavi Duvvuri[2], Roger Hesselstrand[3], J Lee Nelson[4] and Christian Lood[2], [1]Division of Rheumatology, University of Washington, Seattle, WA, [2]University of Washington, Seattle, WA, [3]Lund University, Lund, Sweden, [4]Fred Hutchinson Cancer Research Center, University of Washington, Seattle, WA

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Systemic Sclerosis & Related Disorders – Basic Science Poster (0541–0559)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Systemic sclerosis (SSc) is a complex systemic autoimmune disease, and its etiology is unknown. Exaggerated neutrophil activation and formation of neutrophil extracellular traps (NETs) are reported in SSc, but its involvement in SSc pathogenesis is not clear. In the present study we assessed markers of neutrophil activation and NET formation in plasma samples from SSc patients (n=101), investigating their association with markers of inflammation and disease phenotype in SSc. Additionally, factors contributing to neutrophil-mediated inflammation in SSc remains largely unknown. Among the neutrophil activating factors, extracellular mitochondrial components have been reported in several autoinflammatory conditions, supporting inflammation and recruitment of neutrophils through among others mitochondrial-derived N-formyl methionine (fMet). The aim of the current study is to assess whether SSc patients have elevated levels of extracellular mitochondrial components and their role in neutrophil-mediated inflammation in SSc pathogenesis.

Methods: Markers of neutrophil activation (calprotectin), cell death (NETs, measured as myeloperoxidase-DNA complexes) and levels of fMet were analyzed in plasma obtained from two SSc patient cohorts (Cohort I: 81 SSc and 40 healthy controls, Cohort II: 20 SSc and 24 healthy controls) using ELISA. Neutrophil activation assays were performed in presence or absence of formyl peptide receptor 1 (FPR1) inhibitor cyclosporin H.

Results: Elevated levels of neutrophil activation markers, calprotectin and NETs were observed in SSc patients as compared to healthy controls ($P < 0.0001$) associating with a severe disease phenotype. Further, SSc patients had elevated levels of fMet in circulation as compared to healthy controls ($P < 0.0001$). Of note, levels of fMet were significantly higher in patients with diffuse versus limited SSc patients ($p< 0.04$). Consistent with a role for fMet in promoting neutrophil activation, fMet levels correlated with neutrophil activation markers calprotectin and NETs ($r=0.34$, $p=0.002$; $r=0.29$, $p< 0.01$ respectively). Additionally, plasma samples from a subset of SSc patients with high levels of fMet in circulation induced *de novo* neutrophil activation through FPR1-dependent mechanisms.

Conclusion: Our data for the first time implicates an important role for the mitochondrial component fMet in promoting neutrophil-mediated inflammation in SSc. We propose, targeting fMet-mediated inflammation pathways may provide opportunities to treat SSc patients, which is in need of novel therapeutics. Finally, our neutrophil and mitochondrial-derived biomarkers may provide for opportunities to better stratify patients and in patient management.

Functional Characterization of Glycoprotein Nonmetastatic Melanoma Protein B in Scleroderma Fibrosis

Pamela Palisoc[1], Leah Vaikutis[1], Ellen Model[1], Morgan Omara[1], Dinesh Khanna[1], **Eliza Pei-Suen Tsou**[1] and Amr Sawalha[2], [1]University of Michigan, Ann Arbor, MI, [2]University of Pittsburgh, Pittsburgh, PA

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Systemic Sclerosis & Related Disorders – Basic Science Poster (0541–0559)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Glycoprotein nonmetastatic melanoma protein B (GPNMB) is widely expressed on stromal cells and immune cells. It is involved in various cell functions such as cell adhesion, migration, proliferation, and differentiation, and has been implicated in various pathological conditions including cancer and neurodegenerative diseases. This membrane bound protein can be cleaved into a soluble form by ADAM10. By interacting with various cell surface receptors including CD44, soluble (s)GPNMB has the ability to activate various cell types, including fibroblasts. In this study, we set forth to determine the role of sGPNMB in fibroblast functions in systemic sclerosis (SSc).

Methods: Dermal fibroblasts were isolated from skin biopsies from healthy subjects and patients with diffuse cutaneous (dc)SSc. GPNMB expression was analyzed by qPCR, Western blotting, and immunofluorescence. sGPNMB was measured using ELISA. The effects of sGPNMB (0.01-100ng/ml) on fibroblast function were analyzed using Western blotting, proliferation, migration, and gel contraction assays. To induce a myofibroblast phenotype, normal fibroblasts were incubated with TGFβ for 72 hours. To determine the differences between groups, Mann–Whitney U test, Wilcoxon test, Kruskal–Wallis test, or two-way ANOVA were performed. P values of less than 0.05 were considered statistically significant.

Results: In dcSSc fibroblasts, *GPNMB* was upregulated compared to normal fibroblasts. In addition, dcSSc fibroblasts secreted higher levels of sGPNMB (147.4 ± 50.2 pg/ml vs. 84.8 ± 14.8 pg/ml, $p < 0.05$), partly due to increased ADAM10. sGPNMB (1 and 10 ng/ml) downregulated profibrotic genes, including collagen I and α-smooth muscle actin in dcSSc fibroblasts. In addition, it inhibited cell proliferation and gel contraction, while it had minimal effect on fibroblast migration. The anti-fibrotic effect of sGPNMB is, at least in part, mediated through CD44, as CD44 knockdown inhibits response to sGPNMB. GPNMB is regulated by its own soluble form and also through epigenetic mechanisms. TGFβ downregulated GPNMB and decreased the release of its soluble form in normal fibroblasts. We also confirmed the role of ADAM10 as the sheddase for GPNMB in dermal fibroblasts, as inhibition of ADAM10 decreased sGPNMB levels significantly after concomitant TGFβ treatment.

Conclusion: We showed for the first time, an anti-fibrotic role of sGPNMB in dcSSc fibroblasts. We also established the ADAM10-sGPNMB-CD44 axis in dermal fibroblasts; ADAM10 cleaves off the soluble form of GPNMB, which mediates its effect through CD44 in both paracrine and autocrine fashions. The futile anti-fibrotic effect in dcSSc fibroblasts might be due to the low levels of sGPNMB released from these cells (pg/ml range) vs. the dose needed (ng/ml range) for the anti-fibrotic effect. We also revealed a complex regulatory network for GPNMB in dcSSc fibroblasts, as it appears to be suppressed by TGFβ.

Novel Insights into Systemic Sclerosis Using a Sensitive Computational Method to Analyze Whole-genome Bisulfite Sequencing Data

Jeffrey Yu[1], Tianyuan Lu[1], Kaiqiong Zhao[1], Kathleen Oros Klein[1], Maximilien Lora[2], Ines Colmegna[3], Celia MT Greenwood[4] and Marie Hudson[2], [1]Lady Davis Institute for Medical Research, Jewish General Hospital, Montréal, QC, Canada, [2]McGill University, Montréal, QC, Canada, [3]The Research Institute of the McGill University Health Centre, Montréal, QC, Canada, [4]Epidemiology, Biostatistics and Occupational Health / Faculty of Medicine and Health Sciences / McGill University, Montréal, QC, Canada

SESSION INFORMATION

Session Date: Sunday, November 7, 2021

Session Title: Systemic Sclerosis & Related Disorders – Basic Science Poster (0541–0559)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Background/Purpose: While the etiology of systemic sclerosis (SSc) remains largely unknown, epigenetic dysregulation including abnormal DNA methylation is thought to contribute to its onset and progression. Currently, the most comprehensive assay for profiling DNA methylation is whole-genome bisulfite sequencing (WGBS), but its precision depends on read depth and it may be subject to sequencing errors. SOMNiBUS (Zhao et al. 2020) was developed to overcome some of these limitations. This one-stage method infers smooth covariate effects across regions while accounting for variable read depth, missing data patterns, sequencing errors, and confounders such as age. Using SOMNiBUS, we reanalyzed WGBS data on SSc patients and controls initially analyzed using

Figure 1. Manhattan plot of DMRs (starting position) with nCpG ≥ 60 detected by SOMNiBUS

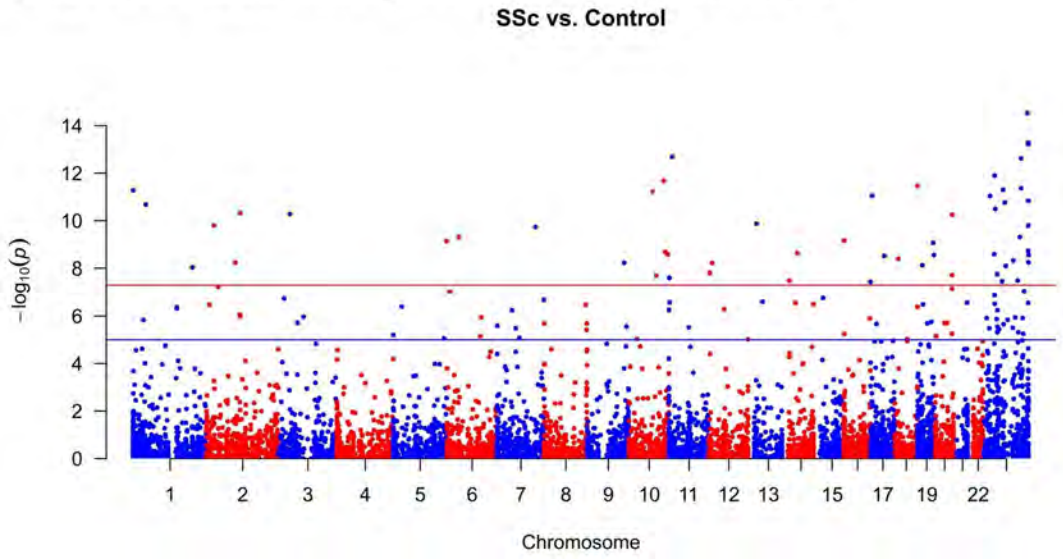

Table 1: Comparison of methods for DMR detection

Method Used	Number of DMRs		Number of Genes with DMRs within a gene's DRR	
	α = 1e-5	α = 5e-2	α = 1e-5 for DMRs	α = 5e-2 for DMRs
SOMNiBUS (p-value < α)	139	1228	161 (see Table 2)	1440
Bumphunter (q-value < α)	0	599	0	340 (34 for DMRs with > 60 CpGs)

Table 2. Genes identified by SOMNiBUS (DMR of p-value ≤ 1e-5 within the gene's DRR)

bumphunter (Jaffe et al. 2012, Aryee et al. 2014, Lu et al., 2019), a less sensitive two-stage approach that fits single CpG associations first, followed by separate coefficient smoothing based on the fitted associations. We aimed to identify novel regions of dysregulated DNA methylation, thus providing a more comprehensive understanding of SSc pathogenesis.

Methods: Purified CD4+ T lymphocytes for 9 SSc and 4 control females were sequenced using WGBS. We separated the resulting sequence into regions with cuts made when adjacent CpG sites were spaced more than 200 bp apart. 8268 regions containing ≥ 60 CpGs were retained for analysis. DMRs were inferred with SOMNiBUS region-level test, adjusted for age. Pathway enrichment analysis was performed with Ingenuity Pathway Analysis (IPA) for genes with DMRs located on the gene body or within regulatory regions. We compared the results to those obtained by bumphunter in terms of plausibility of enriched pathways and agreement in genes detected.

Results: We identified more DMRs with SOMNIBUS compared to bumphunter for both significance levels tested (Fig. 1 & Table 1). We selected all DMRs with a suggestive association defined by regional significance ≤ 1e-5 that overlapped either with a gene body or with the region 10,000 bp upstream of its transcription start site, allowing us to annotate DMRs up to the distal regulatory region (DRR), resulting in 161 differentially methylated genes (DMGs; Table 2). Changing the regional significance threshold to ≤ 0.05 for DMRs, we obtained 1,440 DMGs for SOMNiBUS compared to 340 DMGs for bumphunter (Table 1), 77 of which were identified by both methods. SOMNiBUS detected 29% of bumphunter's DMGs with DMRs of < 60 CpGs, along with 22% of bumphunter's other DMGs. In analyses stratified by autosomal and X chromosomes, the top-ranked autosomal gene was FLT4, a lymphangiogenic orchestrator previously associated with SSc (Manetti et al., 2019); 52 genes were identified on the X-chromosome (Table 2). IPA identified 10 enriched pathways for autosomal chromosomes with cell cycling as the top-ranked pathway and 5 enriched pathways for chromosomes X with antigen presentation as the top-ranked pathway (Table 2).

Conclusion: Using a novel and more powerful computational approach, we identified new and biologically plausible regions of the genome associated with SSc. These findings deepen biological insights into SSc and provide novel avenues of investigation into its pathogenesis.

Targeting CD13/aminopeptidase N as a Novel Therapeutic Approach for Scleroderma Fibrosis

Eliza Pei-Suen Tsou, M.Asif Amin, Phillip Campbell, Mikel Gurrea-Rubio, Morgan Omara, Ellen Model, Pamela Palisoc, Mustafa Ali, Sirapa Vichaikul, Jonatan Hervoso, Jeffrey Ruth, Dinesh Khanna and David Fox, University of Michigan, Ann Arbor, MI

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Systemic Sclerosis & Related Disorders – Basic Science Poster (0541–0559)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Aminopeptidase N, also known as CD13, is a Zn^{2+}-dependent membrane bound ectopeptidase widely expressed in mammalian cells including rheumatoid arthritis (RA) fibroblast-like synoviocytes (FLS), myeloid cells, and endothelial cells. CD13 exists in two forms, the membrane-binding and the MMP14 cleaved-soluble form. We previously showed that CD13 is shed from FLS. In addition, soluble (s)CD13 induces EC angiogenesis, FLS proliferation, and acute inflammatory arthritis in mice. In earlier studies we showed that sCD13 induces immune cell migration by binding to G-protein-coupled receptors. Recently we have identified bradykinin receptor B1 (B1R) as the previously unknown receptor for sCD13. We propose that CD13 is a compelling new target for scleroderma (SSc), as it induces immune cell migration and promotes fibroblast activation.

Methods: Dermal fibroblasts were isolated from skin biopsies from healthy subjects and patients with diffuse cutaneous (dc)SSc. Gene expression was analyzed by qPCR and Western blotting. sCD13 was measured using ELISA. The effects of sCD13 and B1R inhibitor on fibroblast function were analyzed using Western blotting, proliferation, migration, and gel contraction assays. To induce a myofibroblast phenotype, normal fibroblasts were incubated with TGFβ for 72 hours. The bleomycin-induced skin fibrosis mouse model was used to determine the effect of CD13 or B1R inhibition *in vivo*. To determine the differences between groups, Students t-test, Mann–Whitney U test, and Kruskal–Wallis test were performed. P values of less than 0.05 were considered statistically significant.

Results: CD13 knockout mice are resistant to bleomycin-induced skin fibrosis, as shown by significant reduction in skin thickness and hydroxyproline content after bleomycin injection compared to wild type mice. Dermal fibroblasts from SSc patients showed increased B1R expression and released significantly higher amount of sCD13 compared to healthy controls. In normal fibroblasts, *BDKRB1* (gene encoding B1R) and *MMP14* were induced by TGFβ, while *ANPEP* (gene encoding CD13) was downregulated. sCD13 induced pro-fibrotic gene expression, proliferation, migration, and gel contraction in SSc fibroblasts, and these effects were blocked by a B1R antagonist. Inhibition of B1R also prevented bleomycin-induced skin fibrosis in wild type mice.

Conclusion: We've established the pro-fibrotic properties of sCD13 in SSc fibroblasts and in an animal model of fibrosis. sCD13 exerts its pro-fibrotic effect by acting on B1R, and this in turn reinforces a myofibroblast phenotype in SSc fibroblasts. The elevated levels of B1R and sCD13 in SSc fibroblasts are mediated by TGFβ, since TGFβ increased *BDKRB1* as well as MMP14 expression, which in turn cleaves CD13 into its soluble form. Targeting the sCD13-B1R axis appears to be a promising therapeutic approach for SSc.

Abstract Number: 0545

SIRT1 Modulates the Senescent Phenotype in Scleroderma Endothelial Cells

Ellen Model, Morgan Omara, Pamela Palisoc, Dinesh Khanna and **Eliza Pei-Suen Tsou**, University of Michigan, Ann Arbor, MI

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Systemic Sclerosis & Related Disorders – Basic Science Poster (0541–0559)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Vascular abnormalities in systemic sclerosis (SSc) are characterized by injury to vascular wall and extensive damage of the microvessels. It has been shown that the endothelial cells (ECs) isolated from patient skin biopsies show dysregulated phenotypes including impaired angiogenesis, increased oxidative stress, barrier dysfunction, and endothelial-to-mesenchymal transition (Endo-MT). Interestingly, all the above-mentioned events are characteristics of the endothelial phenotype of sirtuin 1 (SIRT1)-deficient ECs. SIRT1 is a class III NAD-dependent histone deacetylase that maintains EC function by deacetylating both histones or non-histone proteins. SIRT1-deficient ECs show impaired angiogenesis, eNOS inactivation, increased oxidative stress, and accelerated senescence. It is possible that endothelial SIRT1 deficiency plays a fundamental role in endothelial dysfunction in SSc. In this study, the impact of SIRT1 on SSc EC is determined.

Methods: Dermal ECs were isolated from skin biopsies from healthy subjects and patients with diffuse cutaneous (dc)SSc. Senescence was measured by immunofluorescence, β-galactosidase assay, and senescence-associated secretory phenotype (SASP). EC functions were determined by Matrigel tube formation assay and proliferation assays. SIRT1 activators, including resveratrol, sodium hydrosulfide, or nicotinamide mononucleotide, or SIRT1 inhibitor EX527 were used to treat ECs. SIRT1 expression in ECs were modulated by siRNA knockdown or overexpression. P values of less than 0.05 were considered statistically significant.

Results: We first showed that endothelial SIRT1 was essential for normal endothelial function in human dermal microvascular ECs (HMVECs), as knockdown or inactivation of SIRT1 inhibited cell proliferation and angiogenesis while increased Endo-MT and senescence. In contrast, overexpression or activation of SIRT1 in HMVECs led to opposite observations. We found that *SIRT1* was significantly downregulated in SSc ECs. This was accompanied with increased acetylation of SIRT1-target proteins including eNOS, p53, and NF-kB p65. SSc ECs also showed increased senescence, determined by increased senescent markers and SASP, and reduced eNOS activity. Enhanced staining of senescent markers was co-localized with blood vessels in SSc skin. Overexpression or activation of SIRT1 in SSc ECs significantly enhanced cell proliferation and angiogenesis, while decreased senescence. To determine the mechanism for SIRT1 downregulation in SSc ECs, we uncovered the p53-miR34a-SIRT1 axis in these cells. We found significantly elevated levels of *TP53*, acetylated-p53, and miR34a in SSc ECs, which are key members of the regulatory loop for SIRT1 that leads to downregulation of SIRT1 and elevated levels of p21.

Conclusion: In this study, we provided a link between epigenetic regulation and endothelial senescence in SSc, and presented a novel mechanism for the dysregulated endothelial phenotype that characterizes this disease. Class III histone deacetylases also show potent anti-fibrotic effects in the skin and lungs. Our results offer a strong scientific framework for repurposing SIRT1 activators as targeted therapeutics to treat SSc patients.

Session Date: Sunday, November 7, 2021

Session Title: Systemic Sclerosis & Related Disorders – Basic Science Poster (0541–0559)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

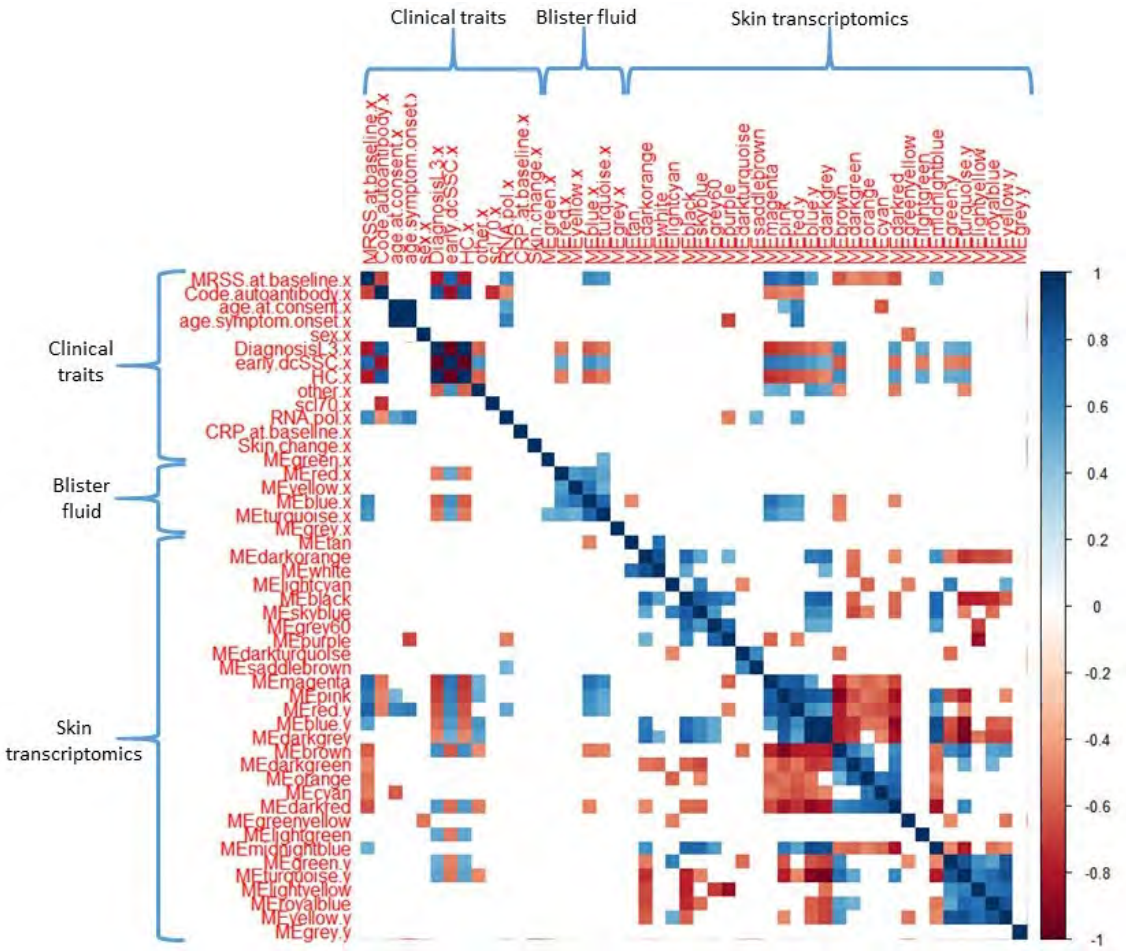

Figure 1. Correlation matrix highlighting only significant correlations between blister modules, skin transcriptomic modules and clinical traits.

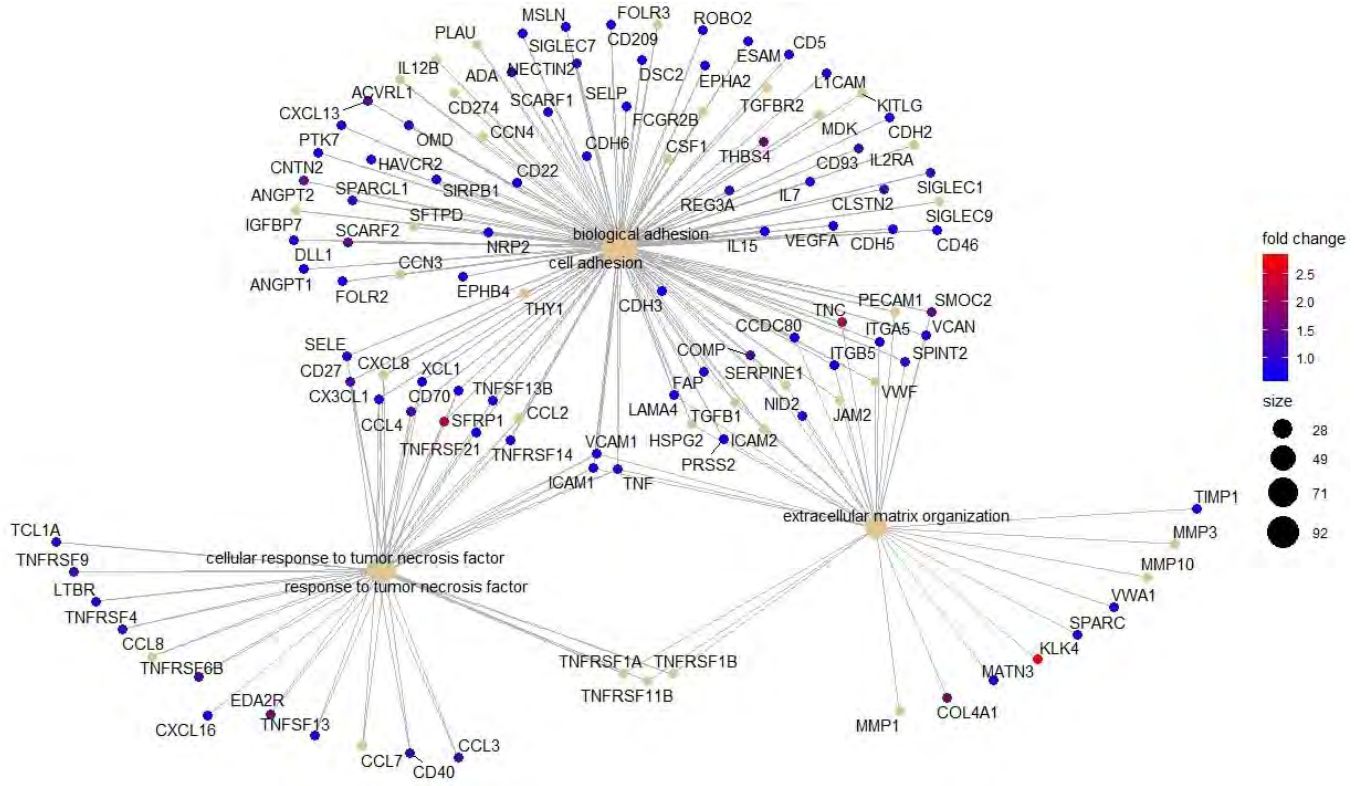

Figure 2 Network plot for skin blister "blue" module.

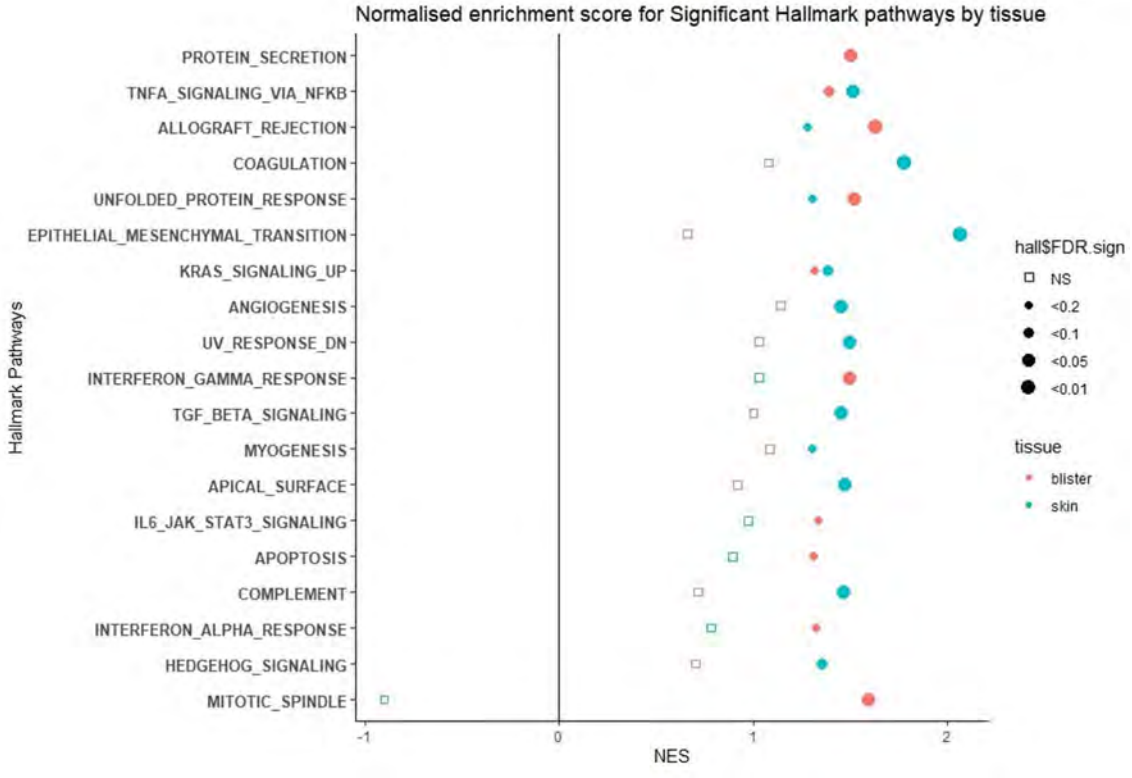

Figure 3 Cleveland plot of Hallmark pathways enriched in "blue" and "magenta" modules.

Background/Purpose: Suction blister fluid provides a unique opportunity to analyse the dermal microenvironment of SSc. We report an integrated analysis of proteomic data from dermal interstitial fluid in early dcSSc patients compared with healthy controls (HC), and genome-wide transcriptomic analysis of concurrently taken skin biopsies. Interpreting differential protein expression in the context of RNA sequencing (RNAseq) provides unique insight into potential mediators and pathways relevant to SSc.

Methods: The BIOPSY cohort recruited 21 early dcSSc patients with mean skin score (MRSS) of 21 (sd 11) and 16 HCs. Forearm skin blister fluid was obtained using the dermal suction blister method and assayed using the Olink platform (www.olink.com) (1192 proteins). Simultaneous 4mm punch biopsies were taken from all subjects, for genome-wide transcriptomic profiling by RNAseq. Integrated analysis of gene and protein expression data, together with SSc clinical and laboratory characteristics was conducted using WGCNA and clusterProfiler in R. This method clusters individual analytes into modules sharing similar expression patterns. Each module has been arbitrarily assigned as a colour. Modules with significant correlation to early dcSSc diagnosis, and with each other, were identified. Significant genes or proteins within a module were identified by a fold change of at least 1.5 compared to HCs.

Results: WGCNA identified 6 modules in blister fluid, and 30 modules from skin RNAseq data (Figure 1). The magenta module (385 genes) in the skin correlated most significantly with early dcSSc ($r=0.74$, $p< 0.001$), and MRSS at baseline ($r=0.82$, $p< 0.001$). The blue module (450 proteins) in the blister fluid correlated most strongly with early dcSSc disease ($r=0.6$, $p< 0.001$), MRSS at baseline ($r=0.63$, $p< 0.001$), and skin progression ($r=0.54$, $p=0.002$). Both modules significantly correlated with each other ($r=0.6$, $p< 0.05$).

Consistent with current concepts of SSc pathogenesis, key biological processes identified in the magenta module were angiogenesis, extracellular matrix (ECM) structure, and endothelial cell proliferation, with COMP, COL4A4, COL11A1 having the highest fold change compared to HC. The blue module consisted of proteins centred around ECM organisation, cell adhesion, and response to TNF, with upregulation of SFRP1, TNC and KLK4 in early dcSSc compared to HC (Figure 2).

Significant Hallmark pathways were compared between the two modules in each tissue modality and HCs (Figure 3). Notably, some pathways were upregulated in both skin gene expression (magenta) and blister fluid (blue) modules including NFKB signalling, allograft rejection, and KRAS signalling. Significantly activated pathways in magenta (skin gene) but not the blue module (blister fluid protein) included angiogenesis, Hedgehog and TGFβ signalling. Conversely, protein secretion, IFNγ response and mitotic spindle pathways were significantly increased only in the blue module.

Conclusion: the molecular pathology of SSc. Correlation with skin severity or progression suggests potential for developing a novel composite biomarker for skin.

Abstract Number: 0547

Autologous Haematopoietic Stem Cell Transplantation for Systemic Sclerosis Results in Sustained Changes in Immunoregulatory T and NK Cells

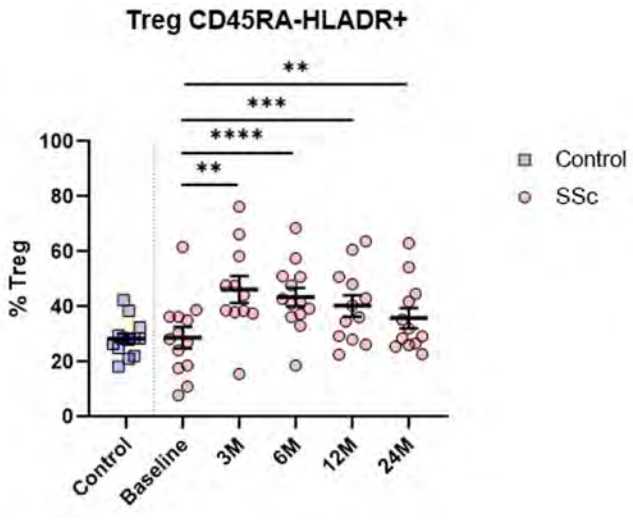
Ross Penglase, Malini Visweswaran, John Zaunders, Laila Girgis, David Ma and John Moore, St Vincent's Hospital, Sydney, Australia

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Systemic Sclerosis & Related Disorders – Basic Science Poster (0541–0559)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Autologous Haematopoietic Stem Cell Transplantation (AHSCT) is an effective treatment for severe systemic sclerosis (SSc). To date, mechanistic studies have indicated possible pro-regulatory and tolerogenic shifts in adaptive immunity. This study aims to describe the changes in key adaptive and innate immune cell populations following AHSCT, with a focus on previously undescribed T cell subpopulations in the transplant setting.

Methods: High-dimensional immunophenotyping of cryopreserved peripheral blood mononuclear cells (PBMCs) from severe SSc patients (n=13) was performed at baseline and 3, 6, 12 and 24 month timepoints post-AHSCT using two custom-designed 18-colour flow cytometry panels. Key adaptive and innate immune populations were examined along with specific subsets within the $CD4^+$ population, including markers for recent thymic egress (CD31) and potential skin-homing (cutaneous lymphocyte antigen, CLA). Data were analysed by one-way ANOVA.

Results: Following AHSCT, there was a decrease in the absolute CD4 count until 12 months, with a sustained increase in the absolute CD8 count and reversal of the CD4/CD8 ratio. $CD4^+$ conventional (Tconv) and $CD25^+CD127^-$ regulatory (Treg) cells exhibited an early proportional shift from a naïve to memory phenotype. While the percentage and absolute counts of Tregs did not change, there was early and sustained expansion of the highly suppressive $CD45RA^-HLADR^+$ Treg subset (% Treg, pre 29.8% vs 24 months 35.88% p=0.008). Furthermore, there was an early and sustained expansion of circulating skin-homing CLA^+ Tregs (% Treg, pre 28.4% vs 6 months 39.8% p< 0.001).



CD45RA-HLADR+ Tregs as a percentage of total Tregs (CD4+CD25+CD127-).

Recent thymic emigrant ($CD45RA^+CD31^+$) $CD4^+$ Tconvs and Tregs recovered by 24 months, indicative of resumed thymic output of both populations. The percentage of $CD19^+$ B cells increased significantly by 6 months (pre 3.3% vs 6 months 5.9% p=0.02). There was an early and sustained increase in the percentage of NK cells to 12 months, particularly the putatively immunosuppressive $CD56^{hi}$ subpopulation (pre 0.5% vs 12 months 1.1% p=0.005). There was no change in circulating basophils or the proportions of activated, intermediate or classical monocytes.

Conclusion: AHSCT results in both early and long term kinetic shifts in adaptive and innate immune cell populations in SSc patients. Although the overall proportion of circulating Tregs does not change, the early and sustained expansion of Tregs with a highly-suppressive phenotype and skin-homing potential may contribute to the clinical remission following AHSCT. In the long term, there is resumption of thymic output of $CD4^+$ Tregs. Harnessing these mechanistic data may inform future targeted therapies for SSc.

Abstract Number: 0548

Rapamycin Blocks the Profibrotic Effects of Fli1 Downregulation in Scleroderma Myeloid Cells

Fatima El-adili, Grace Marden, Maria Trojanowska and Andreea Bujor, Boston University School of Medicine, Boston, MA

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Systemic Sclerosis & Related Disorders – Basic Science Poster (0541–0559)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Systemic sclerosis (SSc) is an autoimmune fibrotic disease with unclear pathogenesis and no effective therapies. Increased proportion of CD163-positive, profibrotic macrophages has been described in SSc, but its contribution to SSc pathogenesis is unclear. Activation of the mammalian target of Rapamycin (mTOR) pathway has been linked to SSc fibrosis, and was also previously shown to induce a profibrotic phenotype in macrophages. We have recently demonstrated that Fli1, a member of the Ets family of transcription factors, is underexpressed in SSc myeloid cells. Co-culture of human dermal fibroblasts and Fli1 depleted myeloid cells resulted in potent induction of CD163 and other profibrotic genes in myeloid cells, and abundant collagen deposition by fibroblasts, which

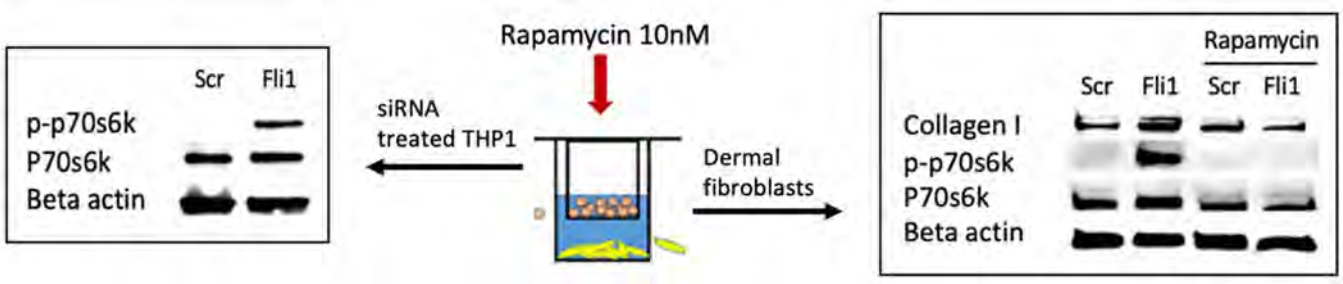

Figure.1. Myeloid cells with low Fli1 induce mTORC1 activation. Western blot analysis of protein extracts from Thp1 (left) and fibroblasts (right) after 48 h of coculture with siRNA treated THP1 cells in the presence and absence of Rapamycin. n>3 each, representative data shown.

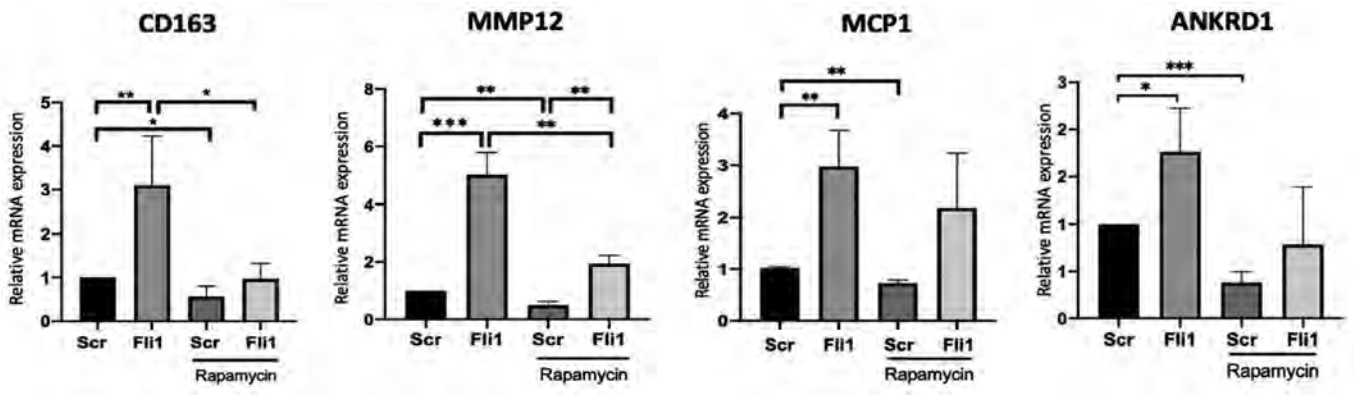

Figure 2. Inhibition of the mTOR signaling via Rapamycin blocks the elevation in CD163, MMP12, MCP1 and ANKRD1 in myeloid cells with low Fli1. n= 3 each * P ≤ 0.05, ** P ≤0 .01, *** p ≤ 0.001

was independent of TGFβ pathway activation.[1] The aim of our study was to evaluate the mechanism by which deletion of Fli1 in myeloid cells exerts its profibrotic effects.

Methods: Primary human dermal fibroblasts were isolated from skin biopsies and were co-cultured with THP1 cells using inserts. Fli1 was depleted via siRNA in THP1 cells using Lipofectamine, and Rapamycin (10nM) was used to treat the co-cultures. Western blot was used to assess the protein levels of collagen and P-p70S6K (Thr^{389}), and qRT-PCR was used to measure mRNA expression of CD163, MCP1, MMP12 and ANKRD1.

Results: Co-culture of human dermal fibroblasts and Fli1 depleted macrophages resulted in activation of the mTOR pathway, with increased phosphorylation of p70S6K (Thr^{389}) in THP1 cells and dermal fibroblasts. Rapamycin treatment blocked the increase in collagen deposition by fibroblasts cocultured with Fli1 depleted myeloid cells (Fig.1). Furthermore, blockade of the mTOR pathway using Rapamycin in THP1 cells alone, in the presence or absence of siRNA against Fli1, reversed the effects of Fli1 inhibition on the mRNA levels of CD163, MCP1, MMP12 and ANKRD1 in these cells (Fig.2).

Conclusion: Fli1 deletion in myeloid cells triggers activation of a profibrotic phenotype, with increased fibroblast collagen deposition, via activation of the mTOR signaling pathway. Myeloid Fli1 deficiency may contribute to SSc pathogenesis, and Rapamycin may be a potential therapeutic option for SSc fibrosis.

Upregulation of Prostanoid EP2 Receptors and Meditation of Treprostinil Anti-Proliferative Effects in Scleroderma Smooth Muscle Cells

Yongqing Wang[1], Nezam Altorok[2] and **Bashar Kahaleh**[2], [1]University of Toledo Medical Center, Toledo, OH, [2]University of Toledo, Toledo, OH

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Systemic Sclerosis & Related Disorders – Basic Science Poster (0541–0559)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Progressive functional and structural vascular disorder is one of the hallmark features of Systemic Sclerosis (Scleroderma, SSc). Vascular dysfunction leads to dysregulated vascular tone control and activation of vascular smooth muscle cells (vSMCs) resulting in enhanced vasospasm and intimal hyperplasia. We previously reported downregulation of the prostacyclin receptor (IP) in SSc skin and vSMCs. In this study we examined IP signaling in SSc and control vSMCs using an IP-specific agonist. Also, it is now clear that in conditions where IP expression is repressed, as in Pulmonary Arterial Hypertension (PAH) or in experimental IP knockdown, the prostacyclin analog treprostinil may engage other receptors including PPARs, EP1, EP2, EP4, or DP1 to mediate its effects. Thus, we examined the role of these receptors in mediating treprostinil effects.

Methods: vSMCs were isolated from involved SSc skin (no=5) matched healthy subjects. cAMP levels were measured by ELISA after the addition of treprostinil or the specific IP agonist MRE 269, before and after the addition of the epigenetic inhibitors 5-Aza 2 deoxycytidine (Aza) and trichostatin (TSA). Cell proliferation was measured by MTT assay. Treprostinil inhibition of proliferation was tested after the addition of specific antagonists to EP1, EP2, EP4, DP1, PPAR α, δ, and ɣ.

Results: Treprostinil stimulated cAMP expression in SSc and control cells to the same degree, while MRE 269 stimulated cAMP in control cells but failed to stimulate SSc cells. The addition of epigenetic inhibitors Aza and TSA restored MRE 269 ability to stimulate cAMP in SSc cells to a level equal to control values. Treprostinil inhibited vSMCs proliferation in a dose-dependent fashion. The addition of the specific antagonist to EP1, EP4, DP1, PPAR α, and δ to SSc and control vSMCs did not influence the degree of treprostinil mediated inhibition of vSMCs proliferation. The addition of PPAR ɣ antagonist had modest effects on treprostinil mediated inhibition of SSc vSMCs proliferation, while the addition of EP2 antagonist significantly diminished treprostinil inhibition of SSc vSMCs proliferation. The expression levels of EP2 were upregulated 9 folds in SSc vSMCs and PPARɣ 3 folds over levels in control cells. There was no difference in the expression levels of PPAR α, β/ δ, EP1, and EP4 between SSc and control vSMCs and DP1 expression level was significantly repressed in SSc cells.

Conclusion: We identified defective IP receptor signaling in SSc cells that were reversed by the addition of the epigenetic inhibitors confirming the involvement of epigenetics in the repression of IP expression in SSc cells. Moreover, treprostinil stimulated cAMP in SSc and normal cells equally suggesting that treprostinil uses other receptors to mediate its effects. Using specific antagonists, we show that treprostinil engages mainly EP2 in it is effects and to a much less extent PPARɣ. mRNA expression data showed a significant increase expression of EP4 and PPAR- γ in SSc cells when compared to normal cells.

Treatment Regimens and Outcomes in Systemic Sclerosis-associated Pulmonary Arterial Hypertension

Hilde Jenssen Bjørkekjær[1], Håvard Fretheim[2], Helene Marjavara Inselseth[3], Øyvind Midtvedt[4], Imon Barua[4], Torhild Garen[5], Helle Bitter[1], Arne Andreassen[6], Øyvind Molberg[4], Kaspar Broch[6] and Anna-Maria Hoffmann-Vold[4], [1]Department of Rheumatology, Sørlandet sykehus HF, Kristiansand, Norway, [2]Oslo University Hospital, Oslo, Norway, [3]University of Oslo, Oslo, Norway, [4]Department of Rheumatology, Oslo University Hospital, Oslo, Norway, [5]Department of Rheumatology, Oslo University Hospital, Oslo, Nepal, [6]Department of Cardiology, Oslo University Hospital, Oslo, Norway

SESSION INFORMATION

Session Date: Sunday, November 7, 2021
Session Title: Systemic Sclerosis & Related Disorders – Basic Science Poster (0541–0559)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Pulmonary arterial hypertension (PAH) is a major clinical challenge in systemic sclerosis (SSc). It is associated with impaired quality of life and high mortality. In 2015, the treatment recommendations changed, recommending upfront combination therapy from the time of diagnosis. The objective of this study was to assess the impact of upfront dual combination therapy versus monotherapy on PAH progression and mortality.

Methods: We included all patients with SSc who had right heart catheterization (RHC) between 2005 and 2018 at Oslo University Hospital, and who were diagnosed with PAH, defined as a mean pulmonary arterial pressure (mPAP) ≥ 25 mmHg and a pulmonary artery wedge pressure ≤ 15mmHg in the absence of interstitial lung disease (ILD). Longitudinal clinical characteristics including treatment were assessed; vital status were available in all patients. To study treatment regimens over time, patients were categorized into three subgroups in regard to diagnostic periods. To secure that all patients had at least 3 years of follow up, group 1 consisted of patients diagnosed between 2005 and 2009, group 2 of patients diagnosed between 2010 and 2014, and group 3 of patients diagnosed between 2015 and 2018. Treatment was initiated as soon as PAH had been confirmed, and included (1) an endothelin-1 receptor antagonist (ERA) and/or (2) a phosphodiesterase-5 inhibitor (PDE5 inhibitor). To assess the impact of treatment regimens on mortality and PAH progression, two outcomes were assessed, including (1) death and (2) PAH-progression defined as a) intensified PAH treatment, b) increasing respiratory symptoms and/or c) hemodynamic progression defined as reduction in the cardiac index (CI) to less than 2.5 l/min/m^2, or mixed venous oxygen saturation (SVO2) < 65%. We constructed Kaplan-Meier plots and performed time-to-event analyses.

Table 1. SSc: systemic sclerosis; PAH: pulmonary arterial hypertension; lcSSc: limited cutaneous systemic sclerosis; ACA: anti-centromere antibodies; NYHA: New York Heart Functional Classification; mPAP: mean pulmonary arterial pressure; PVR: pulmonary vascular resistance; PAWP: pulmonary artery wedge pressure; SvO2: mixed venous oxygen saturation; ERA: Endothelin-1-inhibitor; PDE5 inhibitor: Phosphodiesterase-5-inhibitor

PAH progression 3 year follow up, n (%)	31 (61 %)	10 (83 %)	14 (61 %)	7 (44 %)

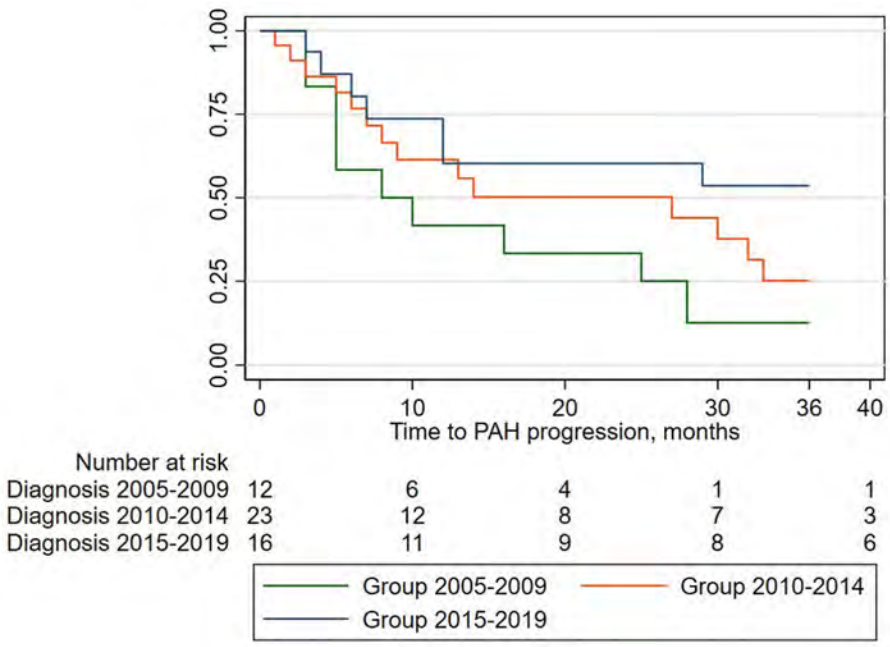

Figure 1. Kaplan Meier curve showing time to PAH progression in SSc-PAH patients segregated by the time of PAH diagnosis.

Results: In total, 191 patients had RHC in the study period, whereof 56 (29 %) SSc patients had a PAH diagnosis. Mean age at SSc-diagnosis was 59 years, mean age at PAH-diagnosis 66 years; 80 % were female and 93 % had limited cutaneous SSc (table 1). None of the patients in group 1 started upfront combination therapy compared to 53 % of patients in group 3. Event-free survival was better in group 3 compared to groups 1 and 2 as shown in the table and figure (p=0.05). 3-year survival increased numerically across groups 1 through 3, from 54% via 62% to 78% (p= 0.148).

Conclusion: We show that upfront dual combination therapy for SSc-PAH has been used more frequently after 2015 in Norway. This shift is associated with less progression of PAH and increased survival in patients with SSc-PAH. This may indicate that there is a benefit of upfront dual combination therapy in SSc-PAH patients in addition to higher awareness and better monitoring strategies.

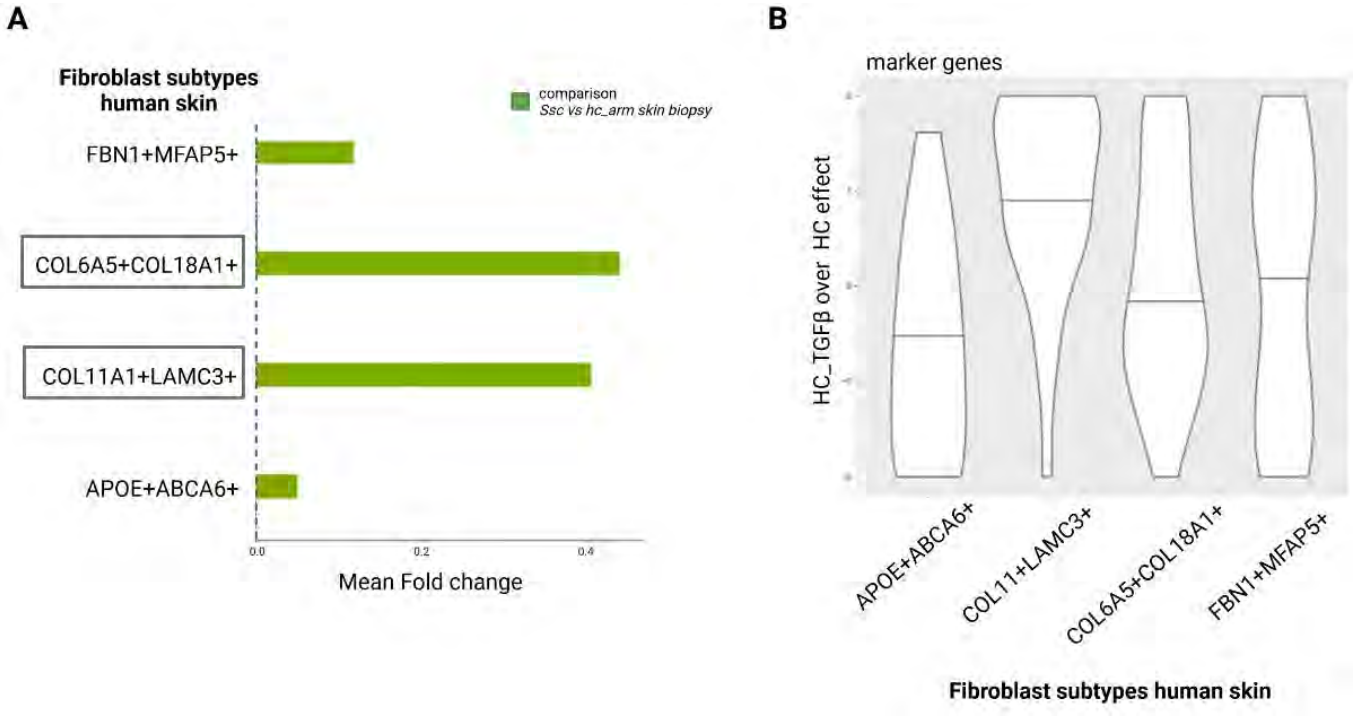
Session Date: Sunday, November 7, 2021

Session Title: Systemic Sclerosis & Related Disorders – Basic Science Poster (0541–0559)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Background/Purpose: Metabolic perturbations drive fibroblast-to-myofibroblast reprogramming and tissue fibrosis. Restoring perturbed metabolism might represent a new antifibrotic strategy. Here we explored the capacity of



(A) Expanded inflammatory fibroblasts and myofibroblasts in SSc skin. (B) TGFβ upregulates COL11+LAMC3+ myofibroblast marker genes in DF.

dimethyl-alpha-ketoglutarate (dm-aKG), a core cell metabolite, to regulate myofibroblast function and skin fibrosis in SSc.

Methods: To discover dysregulated genes, pathways, and cell types in SSc skin, we integrated skin transcriptomes of 76 SSc patients and 26 healthy controls (HC) from three different cohorts (GSE:45485, 59785, 9285/32413) using limma and GSEA. We deconvoluted cell types in bulk skin transcriptomes using human skin single-cell RNA-seq data[1]. We compared the dysregulated genes in SSc skin with RNA-seq data from cultured TGFβ-treated healthy human dermal fibroblasts (DF) and validated gene dysregulations with RNA-seq data from skin biopsies of the PRESS cohort with 48 early diffuse SSc patients and 33 HC. We studied the effects of dm-aKG on myofibroblast differentiation and pro-fibrotic activation in 2D and 3D cultures of SSc and HC DF treated or not with TGFβ. We analyzed gene (RNA-seq, qPCR) and protein (Western blot, ELISA) expression and contractile (collagen gel contraction), migratory (wound scratch assay, DF spheroids) and invasive (collagen gel invasion in DF spheroids) cell functions. Statistical significance was set at $p< 0.05$.

Results: Our deconvolution of skin transcriptomes demonstrated an enrichment of specific fibroblast populations in SSc vs. HC skin: COL6A5+COL18A1+ inflammatory fibroblasts and COL11+LAMC3+ myofibroblasts were highly abundant in SSc skin (Fig. 1A). TGFβ increased the expression of several marker genes of the COL11+LAMC3+ myofibroblasts (Fig. 1B). Meanwhile, dm-aKG decreased the TGFβ-induced *LAMC3* and *COL11* mRNA expression in cultured DF, suggesting that TGFβ might facilitate, while dm-aKG could repress the COL11+LAMC3+ myofibroblast expansion in SSc skin. We uncovered dysregulation of several aKG-associated metabolic pathways in SSc skin transcriptomes, such as mitochondrial respiration and oxidoreductase activity. Dm-aKG repressed the TGFβ-regulated pro-fibrotic responses and myofibroblast differentiation of DF as measured by procollagen-1, fibronectin and aSMA protein reduction. Furthermore, dm-aKG reversed the TGFβ-induced increase of genes regulating cytoskeleton organization (*NEXN, CAP2, ANTXR1, LIMCH1, TGM2)*, cell contraction *(ANKRD1, OXTR, FZD2, DYSF, CSRP2)* and extracellular matrix dynamics (*COL10A1, COL11A1, MMP14, MMP3, ADAMTS4, MATN3, SULF1, HAPLN1)*. These genes were all upregulated in skin from early diffuse SSc patients (PRESS cohort). Most importantly, functional experiments confirmed the core role of dm-aKG in suppressing contractile, migratory and invasive properties of TGFβ-activated DF.

Conclusion: Dm-aKG reverses the dysregulated expression of myofibroblast-linked gene signatures of the SSc skin and potently represses core myofibroblast functions. Thus, dm-aKG could represent a new therapy to combat skin fibrosis in SSc.

Session Date: Sunday, November 7, 2021

Session Title: Systemic Sclerosis & Related Disorders – Basic Science Poster (0541–0559)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Background/Purpose: Long non-coding RNAs (lncRNAs) are non-coding transcripts involved in the regulation of gene expression; their role in disease development, to date, remains largely under investigation. Recently, we showed that lncRNA H19X is pivotal in the regulation of TGFβ driven fibrosis in SSc. Here, we aimed to characterize the functional relevance of H19X in endothelial cell (EC) activation, a crucial mechanism in SSc vasculopathy.

Methods: Single-cell RNA-sequencing (scRNA-seq) was performed on 27 dcSSc and 10 healthy controls (HC) skin biopsies. After library preparation (10X Genomics protocol) and sequencing (Illumina NextSeq-500 platform), the reads were examined by quality metrics and transcripts mapped to reference human genome (GRCh38). Data analysis was performed using Seurat package in R (v. 3.0). A total of 4981 EC (1583 from HC and 3398 from SSc patients, 59-342 EC per subject), characterized by enrichment of EC markers of *CLDN5*, *VWF* and *PECAM1,* were identified and analyzed for the expression of H19X and specific EC activation markers. The function of H19X was analyzed in Human Dermal Microvascular EC (HDMEC). H19X expression was analyzed by qPCR after HDMEC stimulation with different proinflammatory cytokines at biologically relevant concentrations. HDMEC were transfected using locked nucleic acid antisense oligonucleotides (LNA GapmeRs). Western Blot (WB) and qPCR were used to analyze the effects of H19X silencing on endothelial adhesion molecules.

Results: scRNA-seq data from skin biopsies showed a significant upregulation of H19X in SSc compared to healthy EC (p=0.0095), which was observed also for various EC subclusters. Identified subclusters included arterial (characterized by *SEMA3G*, *HEY1*), capillary (*CA4*, *RGCC*), venous (*ACKR1*, *VCAM1*) and lymphatic (*PROX1*, *LYVE1*) EC. Two additional clusters, proliferating (*TOP2A*, *MKI67*) and injured (*HSGP2*, *APLNR*) EC, were represented almost exclusively in SSc ECs. Specifically, the highest expression of H19X was found in injured SSc EC and capillary SSc EC. Overall, 1.5% of the SSc EC, about 51 cells, expressed detectable levels of H19X. In HDMEC (n=3), H19X was consistently induced by IFNα, IFNβ and IFNγ as well as by different IFN combination stimulations (IFNα+β+γ and α+γ). Time curve analysis demonstrated that the strongest induction was observed between 48h and 72h. Importantly, H19X knockdown lead to a consistent and significant decrease of mRNAs of the adhesion molecule VCAM1, both in untreated HDMEC (n=4, p=0.006) as well as after IFN stimulation. A decrease of VCAM1 could be also demonstrated by WB analysis (untreated, n=4, p=0.01, semiquantitative analysis). Furthermore, co-expression analysis of the scRNA-seq data from skin biopsies confirmed a higher expression of several adhesion molecules in EC expressing H19X, including ICAM, VCAM1 and JAM3.

Conclusion: H19X is overexpressed in SSc endothelium and is stimulated by IFNs. Our results point to a role of H19X as a regulator of adhesion molecules in EC, thus suggesting its potential involvement in the pathogenesis of SSc vasculopathy.

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Systemic Sclerosis & Related Disorders – Basic Science Poster (0541–0559)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Antinuclear antibodies are frequent in systemic sclerosis (SSc). While recognized as potent biomarkers, their pathogenic role is much more debated. This study explored the effect of purified IgG from SSc patients on the phenotype and function of healthy dermal fibroblast (FB) using an innovative and unbiased multi-omics approach.

Methods: Normal dermal FB were cultured in the presence of purified IgG from patients with diffuse cutaneous SSc (dcSSc), limited cutaneous SSc or healthy controls (HC). FB proteome and transcriptome were explored using mass spectrometry coupled with liquid chromatography (LC-MS/MS) and microarray assays, respectively.

Results: Proteomic analysis identified 3310 differentially expressed proteins (DEP). SSc sera and purified IgG induced singular modifications FB protein profiles. These FB proteome changes were dependent of SSc serotype, especially pronounced with purified IgG from anti-topoisomerase I antibodies (ATA) positive patients (**Figure 1**). The enriched Gene Ontology (GO) terms upregulated in IgG purified SSc were involved in macroautophagy, positive regulation of protein transport and cell adhesion molecule transport. Transcriptomic analysis distinguished 764 differentially expressed genes and confirmed that IgG from dcSSc can induce profibrotic changes in genes profiles of FB. IgG from ATA positive patients induced singular changes: 629 DEP were identified in dcSSc ATA+ purified IgG and GO terms analysis showed enrichment in focal adhesion, cadherin binding, cytosolic part or lytic vacuole. Filamin A was the most strongly overexpressed protein in the presence of purified IgG compared to HC (**Figure 2**).

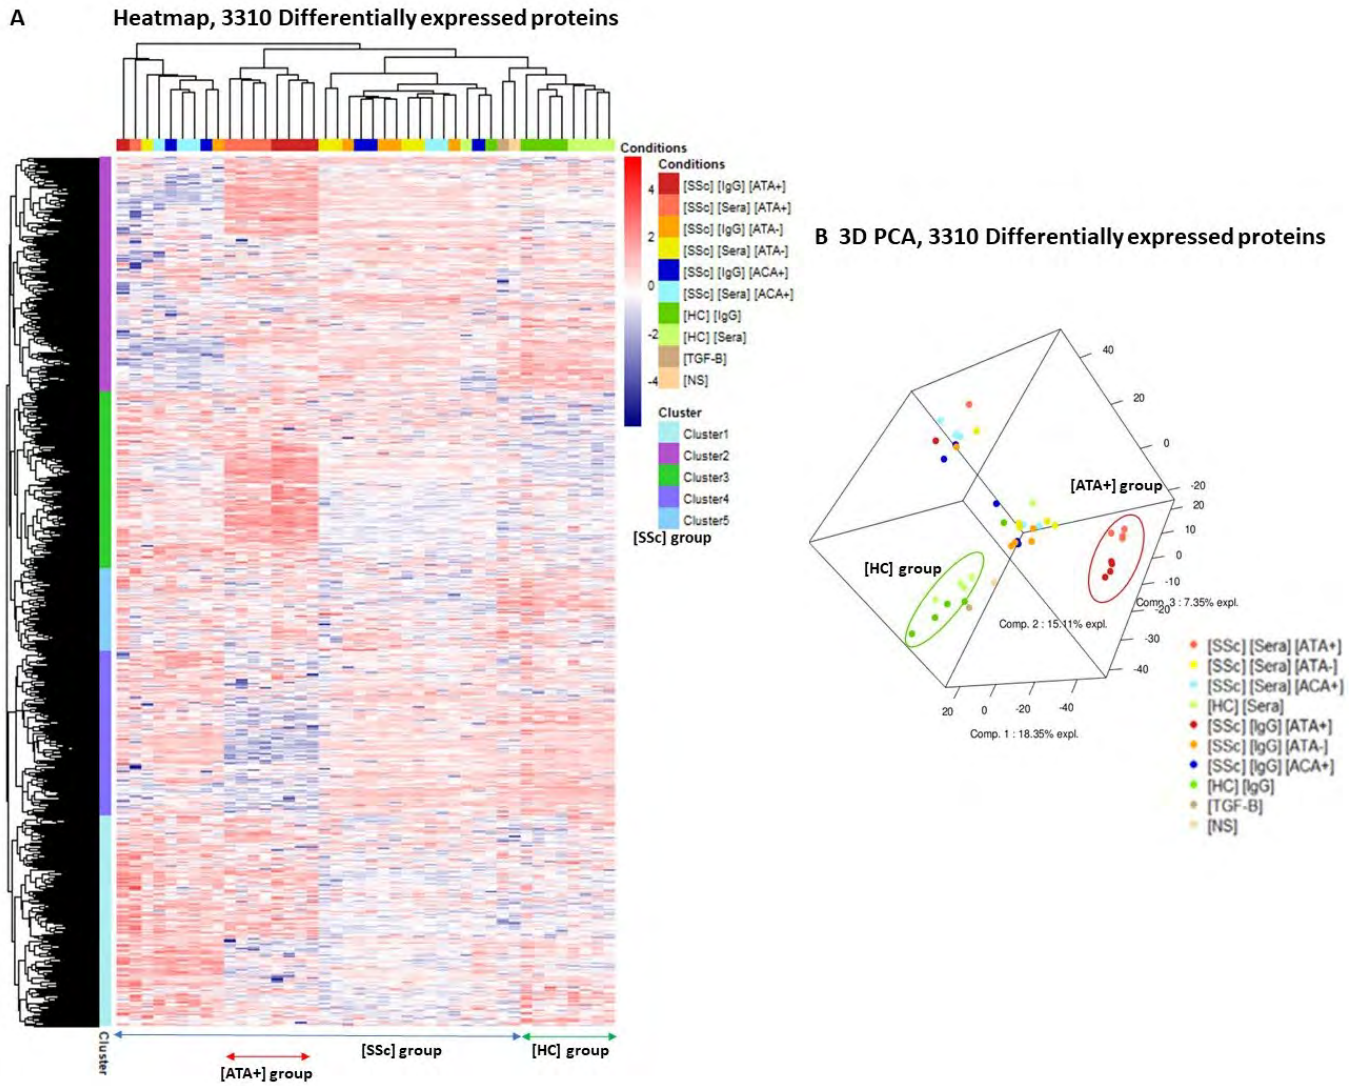

Figure 1 legend: 1.A: heatmap representing 3310 differentially expressed proteins in proteomic analysis by Liquid chromatography–mass spectrometry (LC-MS/MS). Supervised clustering identified 5 different cluster of protein expression profile. 803, 894, 673, 626, 314 proteins were respectively found in cluster1, 2, 3, 4 and 5. 1.B: PCA of differentially expressed proteins. PCA highlights proteins expression by the FB according to SSc serotype. [ATA+] seemed to induce a singular protein expression profile compared to others SSc and SSc. PCA: principal component analysis. [HC] [Sera]: sera from healthy control; [HC] [IgG]: IgG from healthy control; [SSc] [Sera] [ATA+]: Sera from diffuse systemic sclerosis anti-Topoisomerase-I positive antibodies; [SSc] [IgG] [ATA+]: IgG from diffuse systemic sclerosis anti-Topoisomerase-I positive antibodies; [SSc] [Sera] [ATA-]: Sera from diffuse systemic sclerosis anti-Topoisomerase-I negative antibodies; [SSc] [IgG] [ATA-]: IgG from diffuse systemic sclerosis anti-Topoisomerase-I negative antibodies; [SSc] [Sera] [ACA+]: Sera from limited systemic sclerosis anti-centromere positive antibodies; [SSc] [IgG] [ACA+]: IgG from limited systemic sclerosis anti-centromere positive antibodies; [TGF-B]: fibroblast stimulated in the presence of TGF-**β**; [NS]: non stimulated fibroblast.

Conclusion: We identified that purified IgG from SSc can modify the phenotype of normal dermal FB. This effect seems dependent of the serotype. Purified IgG from dcSSc exhibited profibrotic properties with a singular profile of proteins expression and mRNA in patients with ATA.

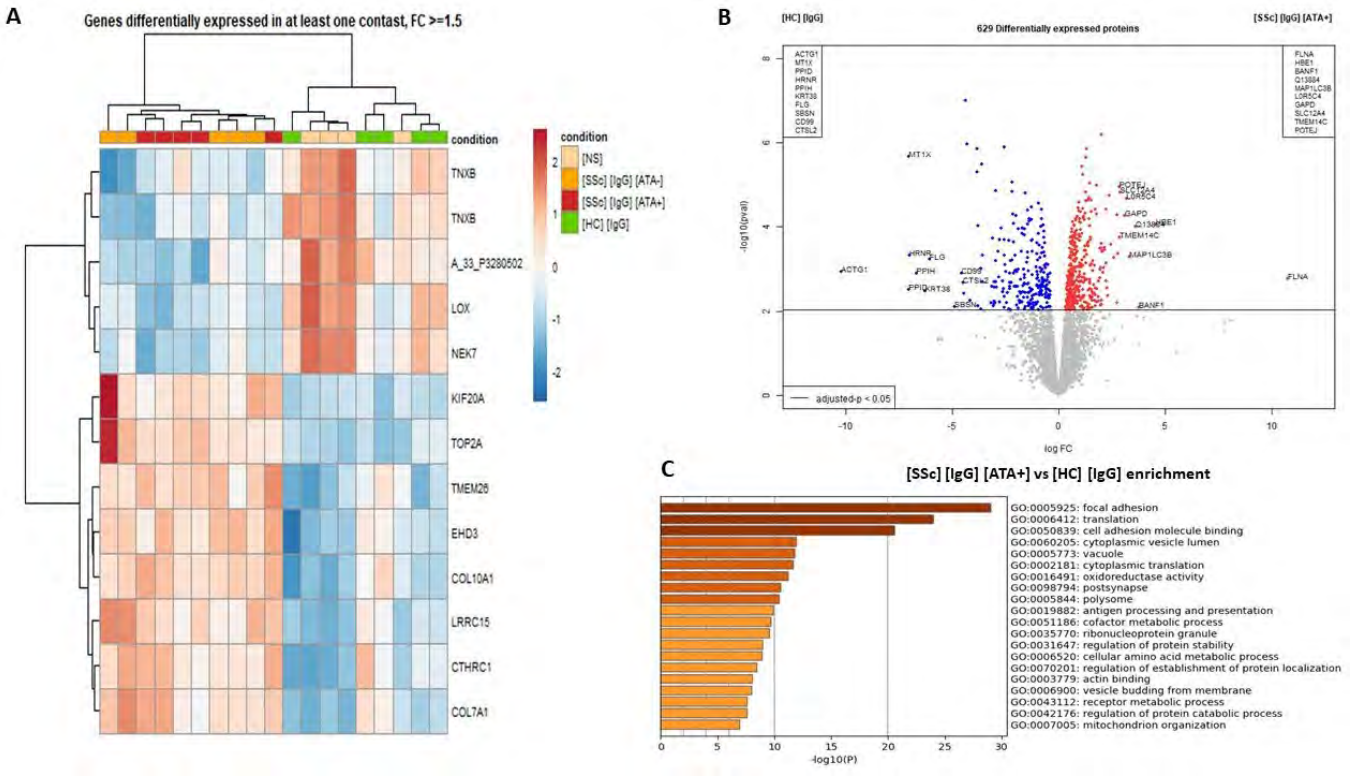

Figure 2 legend: A: heatmap (transcriptomic analysis) represented genes dysregulated in at least one contrast with FC>1.5 in the DNA probes dysregulated in proteomic analysis; B: Volcanoplot (proteomic analysis) represented the comparison [SSc] [IgG] [ATA+] vs [HC] [IgG]; proteins with adjust p-value <0.05 and Log Fold Change >1.4 or <-1.4 were considered; C: Enriched clusters GO terms in the comparison [SSc] [IgG] [ATA+] vs [HC] [IgG] according to upregulated proteins, analysis done with Metascape; [HC] [IgG]: IgG from healthy control; [SSc] [IgG] [ATA+]: IgG from diffuse systemic sclerosis anti-Topoisomerase-I positive antibodies; [SSc] [IgG] [ATA-]: IgG from diffuse systemic sclerosis anti-Topoisomerase-I negative antibodies; [SSc] [IgG]: IgG from systemic sclerosis patients; [NS]: non stimulated fibroblast.

Session Date: Sunday, November 7, 2021

Session Title: Systemic Sclerosis & Related Disorders – Basic Science Poster (0541–0559)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

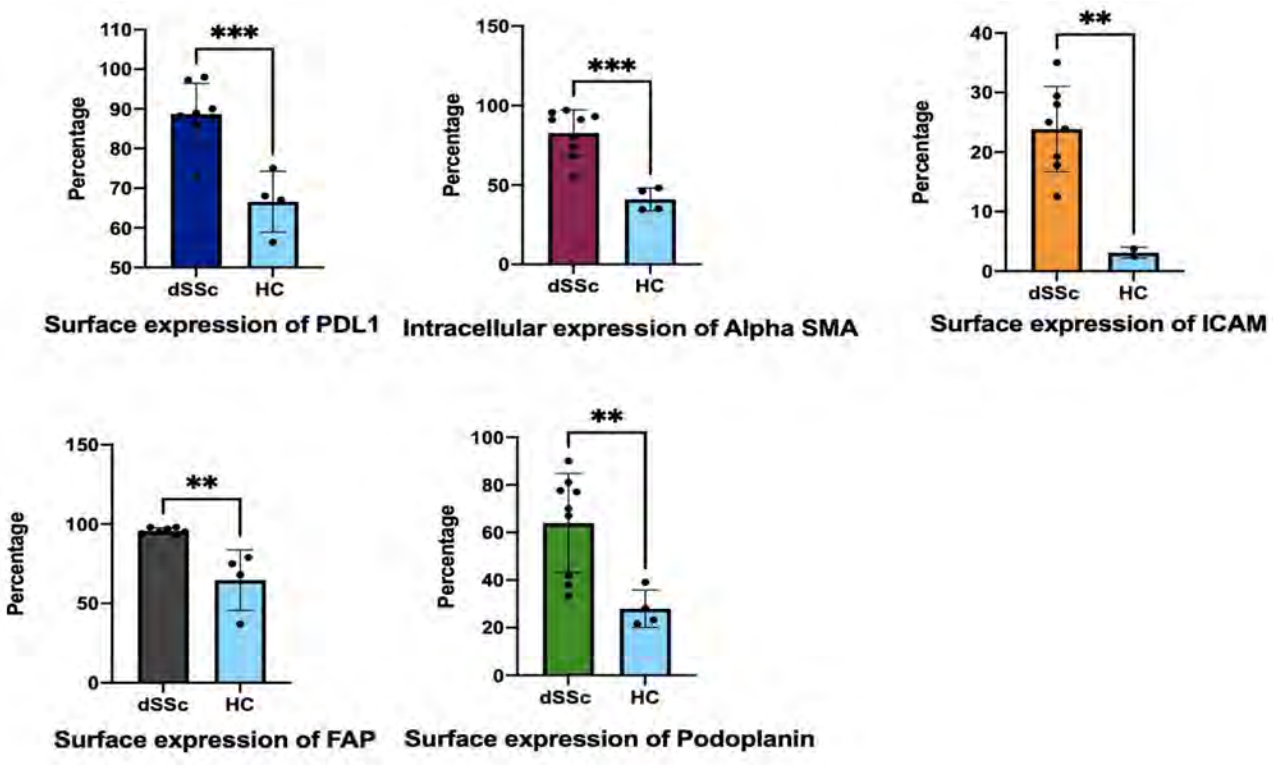

Figure 1. Fibroblast from dSSc fibroblasts increased PD-L1, a-SMA, ICAM-1, FAP and PDPN compared with HC after stimulation with TGFb for 48h.

Background/Purpose: The PD-1/PD-L1 pathway has been implicated in Systemic Sclerosis (dSSc). This disease is dominated by increased extracellular matrix deposition initiated by myofibroblasts. We therefore examined the PD-1/PD-L1 pathway in dSSc myofibroblasts and its influence on fibrosis.

Methods: Dermal fibroblasts were isolated from the skin from patients with dSSc (n=9) and compared with dermal fibroblasts from healthy controls (HC)(n=4). Cells were stimulated with TGF β for 48 hours and analyzed by flow cytometry for expression of the surface proteins CD45, Thymocyte differentiation antigen-1 /(CD90 Thy-1), podoplanin (PDPN), Programmed Death Protein Ligand-1(PD-L1), Fibroblast activation Protein (FAP),and Intercellular adhesion molecule-1 (ICAM-1) and alpha smooth muscle actin (α- SMA). Supernatants were analyzed for the production of Type 1 Procollagen and IL-6. Parallel to this, dcSSc fibroblasts, were stimulated with IFNγ (10ng/ml) for 48 hours followed by addition of anti-PD-L1 antibody (atrezolizumab, 5ug/ml) and soluble, recombinant PD-1 (RPD-1;1ug/ml). Supernatants were harvested after 48 hours and analyzed for production of Type 1 Procollagen and Fibronectin.

Results: $CD45^{neg}$ fibroblasts, from both dSSc as well as HC could be identified by their expression of Thy-1 and Podoplanin. Upon stimulation with TGFβ, fibroblasts from dSSc patients increased the percentages of myofibroblasts expressing PD-L1, α- SMA, ICAM-1, FAP and Podoplanin when compared to HC fibroblasts.(Figure 1) All $p < 0.05$, Figure 1. Upon concatenating and analyzing this data by tSNE, we could demarcate a distinct populations of the myofibroblasts that had a high expression of PD-L1 together with ICAM-1 (Figure 2). Compared with HC, dcSSc fibroblasts were characterized by an increased production of Type 1 Procollagen and IL -6, this was highly increased by stimulation with TGFβ, still most pronounced in dSSc (Figure 3a). To explore the role of PD-L1 in fibrosis, we added an anti-PD-L1 monoclonal antibody, or rPD-1 to fibroblasts. Both increased the production of Type 1 Pro-collagen, whereas fibronectin was only increased by adding the anti-PD-L1 antibody(Figure 3b).

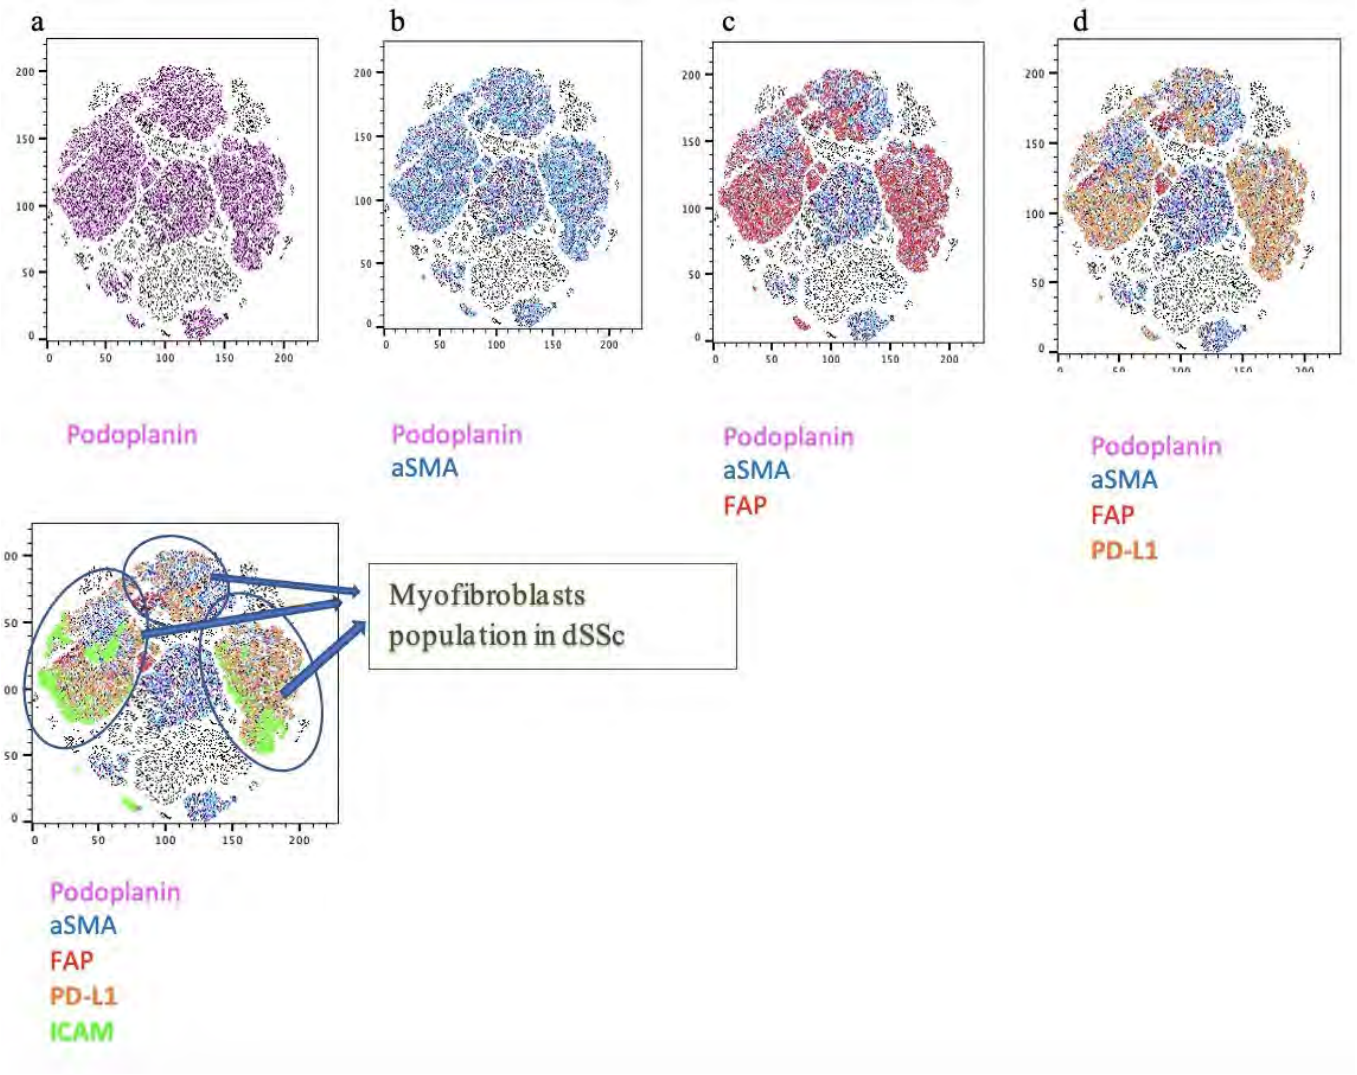

Figure 2. A t-SNE analysis of concatenated dSSc fibroblasts populations that were CD90 positive with overlay of markers of fibroblast activation such as Podoplanin, FAP and intracellular expression of Alpha SMA. A distinct myofibroblast population could be identified that express the above markers together with PD-L1 and ICAM-1.

Conclusion: dSSc fibroblasts are distinct from dermal fibroblasts from HC, both in their phenotype and functionality. The myofibroblast population can thus be defined as a subset within the dSSc fibroblasts with high and co-expression of PD-L1, FAP, Podoplanin, and ICAM. PD-L1 plays an important role in regulating fibrosis, and inflammation in dSSc and our results supports the notion that PD-L1 does this through reverse signaling.

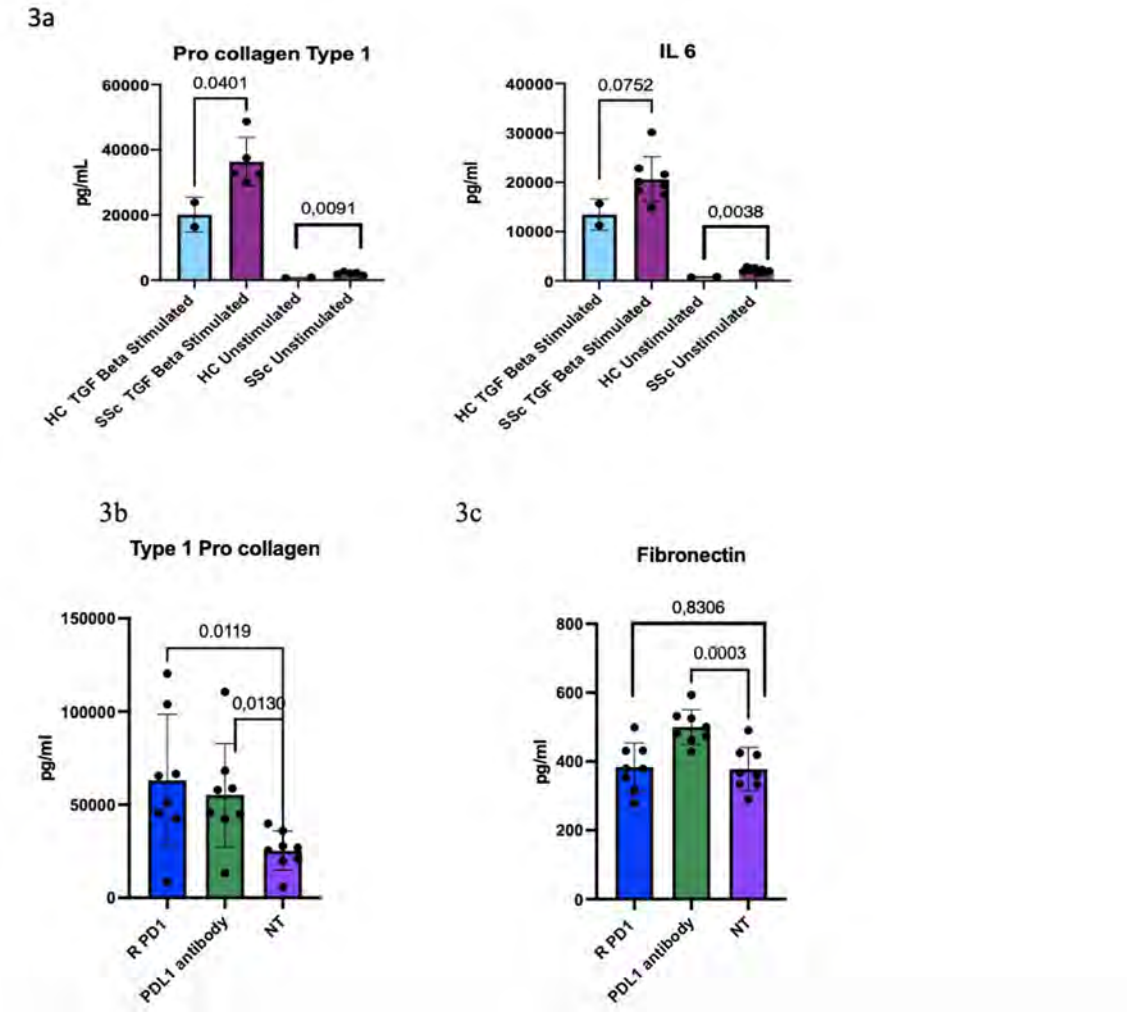

Figure 3. Increased type 1 collagen production (a) and IL-6 (b) by dSSc fibroblasts when compared with healthy controls (HC), with or without stimulation by TGFb. Type 1 procollagen (c) and fibronectin (d) production after addition of an anti-PD-L1 antibody or sPD-1 in dSSc fibroblasts.

Pathway-Driven Drug Repositioning in Systemic Sclerosis from Omics Data

Dillon Popovich[1], Tamar Abel[1], Noelle Kosarek[2], Monica Espinoza[3], Rezvan Parvizi[4], Jonathan Garlick[5] and Michael Whitfield[4], [1]Geisel School of Medicine, West Lebanon, NH, [2]Dartmouth Geisel School of Medicine, Hartford, VT, [3]Geisel School of Medicine, Hanover, NH, [4]Geisel School of Medicine, Lebanon, NH, [5]Tufts University School of Dental Medicine, Boston, MA

SESSION INFORMATION

Session Date: Sunday, November 7, 2021

Session Title: Systemic Sclerosis & Related Disorders – Basic Science Poster (0541–0559)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Background/Purpose: Omic analyses of systemic sclerosis (SSc) skin biopsy datasets identified distinct sets of patients that respond differently to treatment. The goal of this study was to use the Connectivity Map (CMAP) library of gene expression profiles from drug treatments of cell lines to identify pathways and small molecules (perturbagens) that would normalize the aberrant gene expression profiles in SSc patients back to that of healthy controls.

Methods: CMAP 2.0 data was processed with RMA, quantile normalized, and fit to a multichip linear model. Probes were collapsed as average intensity and formatted for gene fold-change as the ratio of treatment to control intensities. DNA microarray data from SSc patient skin were obtained from Milano et al (GSE9285) and Pendergrass et al (GSE32413) then analyzed by Gene Set Variation Analysis (GSVA) in R for single-sample enrichment scores. Enrichment scores significant for each intrinsic subset of SSc patients were determined and perturbagens that have potential to regulate these pathways were chosen for further study. 3D skin-like tissues were constructed with dermal fibroblasts from ATCC, treated with selected perturbagens, and analyzed with H&E or Sirius Red for visualization.

Results: We focused on analyses on the inflammatory and fibroproliferative pathogenic subsets. Pathways specific to these two subsets were selected from publicly available gene expression data from SSc and control skin through single-sample GSVA. We identified 608 pathways enriched for upregulation in the inflammatory subset and 667 pathways enriched for upregulation in the fibroproliferative subset. Using single sample GSVA, we identified all CMAP perturbagens predicted to modulate the pathways in the inflammatory or fibroproliferative subsets. A parallel analysis using the BASE algorithm was also performed and perturbagens identified in both analyses were chosen for further study. EGFR inhibitors were shown to regulate gene set pathways from the inflammatory subset of SSc patients. We determined that PI3K inhibitors modulated gene set pathways from the fibroproliferative subset of SSc patients. Experimental validation of the PI3K inhibitor decreased collagen 1 expression of fibroblasts grown in 2D cell culture. Inhibitors were also analyzed in self-assembled (SA) 3D skin-like tissues containing only normal dermal fibroblasts, with and without TGFB stimulation. The PI3K inhibitor showed decreased extracellular matrix deposition, likely as a result of reduced collagen expression within the tissue environment. The EGFR inhibitor showed less significant changes in either tissue thickness or collagen deposition.

Conclusion: Multiple small molecule inhibitors have been identified that regulate gene set pathways that are specific to two molecular subsets of SSc patients determined by gene expression profiling. Testing these perturbagens within cell culture and 3D skin like tissues showed that PI3K inhibitors may inhibit multiple aspects of SSc disease progression in dermal fibroblasts.

Investigating the Heterogeneity of Skin Macrophages in Systemic Scleroderma

Hadijat Makinde[1], Salina Dominguez[1], Monique Hinchcliff[2], Deborah Winter[3] and Harris Perlman[1], [1]Northwestern University, Chicago, IL, [2]Yale School of Medicine, Westport, CT, [3]Northwestern University Division of Rheumatology, Chicago, IL

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Systemic Sclerosis & Related Disorders – Basic Science Poster (0541–0559)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: The etiology and pathogenesis of systemic sclerosis (SSc) are poorly understood; however, an increasing body of evidence supports an early inflammatory phase that precedes fibrosis. Macrophages have been implicated in the inflammatory process that leads to the reorganization of the extracellular matrix (ECM) leading to the development of end-organ fibrosis. Macrophages also contribute to disease progression by production of reactive oxygen species, matrix-degrading enzymes, as well as by antigen presentation. However, macrophages are heterogeneous thus individual subsets may have differential functions in a tissue- and disease-specific context. Here we evaluate the transcriptional heterogeneity of macrophages present in the skin of SSc patients.

Methods: $CD45^+$ immune cells were sorted from skin biopsies using multiparameter fluorescence-activated cell sorting (FACS) from early diffuse cutaneous (dc) SSc patients (630 cells from 5 patients). Cellular Indexing of Transcriptomes and Epitopes by Sequencing (CITE-Seq) was performed, and samples were processed using the 10X Genomics 3' v3.0 pipeline and analyzed using the Seurat package with modifications when needed.

Results: Six individual clusters were resolved from immune cells isolated from SSc skin. Differentially expressed genes between clusters identified at least two distinct macrophage subsets that comprise one-third of all immune cells, including a monocyte-derived macrophage subset (LYV^+ $CD68^+$; 20% of all cells) and Langerhans cells ($CD1a^+$ $CD207^+$; 13% of all cells) that are associated with distinct pathways. Macrophage subsets identified by RNA expression were confirmed via antibody-derived tags and show heterogeneity in their gene and protein expression of CD11b, CD11c, and CCR2, among other key identifying features, that directly relate to their functional capabilities. These macrophage subsets also displayed differences in their expression of HLA-antigens, indicating distinct antigen presentation capabilities.

Conclusion: These data show for the first time that macrophages within fibrotic skin of patients with SSc come in many flavors corresponding to distinct functions. This highlights the importance of precisely identifying immune cells within an affected organ and their corresponding mechanisms contributing to the pathogenesis of SSc. Only then can we target specific immune cell populations that drive the inflammatory process, which may be more beneficial than the current approach of broadly targeting immune cells during disease progression. Future directions include interrogating how these macrophage subsets differ compared to those found in the skin of control patients as well as delving into potentially pathogenic lymphocytic populations.

The Beta Secretase BACE1 Induces Systemic Sclerosis (SSc) Fibroblast Activation Through the Regulation of the Pro-Fibrotic Notch Signalling Pathway

Christopher Wasson[1], Eva Clavane[2], Rebecca Ross[1], Paul Meakin[2] and Francesco Del Galdo[3], [1]LIRMM University of Leeds, Leeds, United Kingdom, [2]LICAMM University of Leeds, Leeds, United Kingdom, [3]University of Leeds, Leeds, United Kingdom

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Systemic Sclerosis & Related Disorders – Basic Science Poster (0541–0559)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Extensive work in the Alzheimer's field has shown BACE1 plays an important role in amyloid beta processing. Additionally, there is evidence showing BACE1 regulating Notch signalling and disrupting angiogenesis in the context of Alzheimer's. Given the known role of Notch signalling and disrupted angiogenesis in Systemic Sclerosis (SSc), in this study we investigated the role of BACE1 in the profibrotic phenotype of dermal fibroblasts from SSc skin.

Methods: Dermal fibroblasts were obtained from full thickness skin biopsies from early-diffuse cutaneous SSc patients. Protein was collected from the fibroblasts and BACE1 protein levels were assessed by western blot. SSc patient fibroblasts were treated with the BACE1 inhibitor M3.

Results: BACE1 protein levels were found to be expressed at significantly higher levels in SSc patient fibroblasts compared to healthy controls (1.9-Fold). Inhibition of BACE1 with the specific small molecule inhibitor led to reduced myofibroblast marker (Collagen type 1, alpha smooth muscle actin and CTGF) expression in SSc fibroblasts. Further analysis found inhibition of BACE1 could block the morphogen (TGF-b, Sonic hedgehog and Wnt-3a) mediated fibroblast activation. The BACE1 inhibitor reduced alpha smooth muscle actin expression in TGF-b stimulated fibroblasts by 50%, in sonic hedgehog stimulated cells by 65% and in Wnt-3a stimulated cells by 35%. Finally, treatment of SSc fibroblasts with the BACE1 small molecule inhibitor resulted in reduced expression of the active form of Notch1 and downstream targets Hes1 and GLI2, suggesting BACE1 contributes to SSc fibroblast phenotype through the activation of Notch signalling pathway.

Conclusion: We have identified a novel role for BACE1 in SSc myofibroblast activation through Notch1. This further strengthen the important role Notch signalling plays in SSc. Furthermore, this study highlights BACE1 as a potential novel antifibrotic target for therapeutic intervention which could be investigated with a number of BACE1 inhibitors currently in clinical trials for Alzheimer's.

The Systemic Sclerosis (SSc) Risk Gene A20 (TNFAIP3) and Its Repressor DREAM Determine Susceptibility to Fibrosis

Swarna Bale[1], Wenxia Wang[2], Roberta G Marangoni[3], Erica Herzog[4], Bettina C Schock[5], Swati Bhattacharyya[1] and Varga John[1], [1]University of Michigan, Ann Arbor, MI, [2]Northwestern University, Chicago, IL, [3]University of Rochester, Rochester, NY, [4]Yale University School of Medicine, New Haven, CT, [5]Wolfson Institute for Experimental Medicine, Queens University, Belfast, United Kingdom

SESSION INFORMATION

Session Date: Sunday, November 7, 2021

Session Title: Systemic Sclerosis & Related Disorders – Basic Science Poster (0541–0559)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Background/Purpose: The ubiquitin-editing enzyme A20, encoded by TNFAIP3, is genetically implicated in autoimmune and inflammatory diseases. A20 plays a pivotal role in regulating inflammatory cellular pathways, and is tightly regulated by the downstream regulatory element antagonist modulator (DREAM) and other factors. Variants of TNFAIP3 are also associated with SSc and lung fibrosis in multi-ethnic cohorts. However, it remains unclear how genetic factors contribute to pathogenesis, and which cell types drive pathology due to SSc-specific genetic alterations. We therefore characterized the expression, function and role of A20 and DREAM in SSc and disease models

Methods: A20 and DREAM were measured in transcriptome datasets, skin and lung biopsies, and skin fibroblasts from SSc patients and healthy controls. The hypothesis that loss of A20 might play a direct pathogenic role in fibrosis was tested in A20 haploinsufficient mice that have reduced A20 comparable to humans harboring A20 risk alleles; and in mice with fibroblasts-specific deletion of A20 or DREAM. The role of A20 in myofibroblast transition was directly examined in skin and lung fibroblasts, dermal vascular endothelial cells (DMVE), adipose-derived stem cells (ADSC) and preadipocytes. A selective AdipoR1/R2 agonist was used to modulate A20 expression in skin fibroblasts and *in vivo* models of dermal fibrosis

Results: Unbiased transcriptome analysis of skin and lung biopsies indicated decreased A20 in SSc, whereas the negative A20 regulator DREAM was significantly elevated and anti-correlated with A20. In a variety of human and mouse mesenchymal cells, A20 potently inhibited profibrotic gene expression, myofibroblast transition and other fibrotic responses via blocking multiple SSc-linked signaling pathways. Mice haploinsufficient for A20, or harboring fibroblasts-specific A20 deletion, recapitulated major pathological and genomic features of SSc. In contrast, mice lacking DREAM (and showing elevated A20 expression) were protected from fibrosis. AdipoRon, an orally active small molecule targeting cellular adiponectin receptors, stimulated A20 expression *in vitro* in wild type but not in A20-deficient fibroblasts, potentially accounting for its anti-fibrotic activity

Conclusion: We provide first evidence that in addition to its well-established role in regulating inflammatory responses, A20 has a novel function in mitigating fibroblast activation. Together with DREAM, A20 thus constitutes a critical cell-intrinsic regulatory circuit governing fibrotic processes. Dysregulation of this circuit might be implicated in SSc pathogenesis, and represents a druggable target for fibrosis therapy

Targeting NNMT as a Novel Metabolic Approach to Treat Systemic Sclerosis

M.Asif Amin[1], Bo Shi[2], Pei-Suen Tsou[1], Swarna Bale[1], Phillip Campbell[1], Mikel Gurrea-Rubio[1], Mark Eckert[3], Ernst Lengyel[3], Johann Gudjonsson[4] and Varga John[1], [1]University of Michigan, Ann Arbor, MI, [2]Nothwestern university, Chicago, IL, [3]University of chicago, Chicago, IL, [4]Department of Dermatology, University of Michigan, Ann Arbor, MI

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Systemic Sclerosis & Related Disorders – Basic Science Poster (0541–0559)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Fibrosis, the hallmark of systemic sclerosis (SSc), is associated with metabolic and epigenetic alterations that are incompletely characterized. Our laboratory had previously implicated dysregulated nicotinamide adenine dinucleotide (NAD) metabolism associated with upregulation of the NAD hydrolase CD38 in SSc *pathogenesis*. Nicotinamide N-methyl transferase (NNMT) is a cellular enzyme with key roles in NAD homeostasis via de novo NAD generation through the salvage pathway. By irreversibly methylating the NAD precursor nicotinamide (NAM) and reducing its availability for NAD salvage synthesis while also depleting the universal methyl donor S-adenosylmethionine, NNMT uniquely links cellular energy consumption and epigenetic modifications. Moreover, NNMT promotes stromal cancer-associated fibroblast differentiation, and elevated NNMT is implicated in metastasis. In this study, we sought to examine the expression and role of NNMT in SSc fibrosis.

Methods: Gene expression in SSc skin biopsies was determined by bulk and single cell RNA-Seq and immunolabelling. To investigate the impact of NNMT, human skin fibroblasts in cultures were incubated with transforming forming growth factor (TGF-β) and NNMT inhibitors followed by PCR, immunolabelling, immunofluorescence (IF), NAD assays and migration assays using Incucyte™ Live Cell Imaging. Genomewide transcript level changes and chromatin remodeling were determined.

Results: NNMT expression is significantly elevated in SSc skin biopsies, and in explanted skin fibroblasts. NNMT mRNA levels in the skin are positively associated with TGF-β activity in multiple SSc datasets. Moreover, NNMT levels are strongly associated with CD38 levels in SSc skin biopsies, and a combined gene score for NNMT plus CD38 robustly correlated with the skin score (MRSS). The number of NNMT-immunopositive interstitial cells was elevated in both papillary and reticular dermis from SSc patients. TGF-β strongly increased the expression of NNMT in normal fibroblasts. Targeted pharmacological inhibition of NNMT markedly attenuated TGF-β-induced cellular fibrotic responses.

Conclusion: NNMT, which represents a nexus linking cellular energy metabolism and epigenetic chromosome modeling, is highly expressed in explanted SSc fibroblasts and SSc skin biopsies. NNMT is inducible by TGF-β and directly contributes to the induction of fibrotic cellular responses, while its pharmacological blockade mitigates fibrosis *in vitro*. The profibrotic effects of NNMT potentially implicate altered NAD metabolism as well as changes in DNA methylation and related epigenetic mechanisms. Targeting NNMT with selective inhibitors therefore represents a novel therapeutic approach for fibrotic diseases such as SSc.

Session Title: Epidemiology & Public Health Poster II: Inflammatory Arthritis – RA, SpA, & Gout (0560–0593)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Background/Purpose: Tofacitinib is a Janus kinase inhibitor, which is orally applied and is approved for rheumatoid arthritis among other indications. ESCALATE-RA is the first prospective, non-interventional study with tofacitinib in Germany. The first patient was enrolled end of 2017 and results of the first interim analysis were published in 2020.

Table. 1. Demographics, Clinical Data at Baseline and Tofacitinib Treatment Persistence (M12- and M24-population).

	M12 (N=862)	M24 (N=466)
	n/n_{tot} (%)	n/n_{tot} (%)

*An AE is any untoward medical occurrence in a patient administered a medicinal product
AE, adverse event; BL, baseline; CRP, C-reactive protein; DAS28-4, disease activity score in 28 joints based on 4 variables; ESR, erythrocyte sedimentation rate; FACIT, Functional Assessment of Chronic Illness Therapy; FFbH, Functional Ability Questionnaire Hannover; M12/M24, visit after 12/24 months of treatment; HCP, healthcare professional; N, Number of patients with M12/M24 visit; n_{tot}, Number of patients with available data; SAS, Safety Analysis Set; SD, standard deviation

Methods: The enrollment of the planned 1500 patients takes place Germany-wide (87 recruiting sites as of 08 May 2021). Adult patients eligible for tofacitinib therapy are documented quarterly in a standardized manner from the first tofacitinib intake up to 24 months and remain within the study even after switching to another DMARD or combination of DMARDs. This second interim analysis (cut-off date 29 Jan 2021) describes patients, who reached visit M12 after 12 months as well as patients who reached the final visit M24 after 24 months. Missing observations were not taken into account. Since this is an ongoing study, small changes in numbers may occur after the final data quality checks.

Results: At data cut-off, 1227 patients were enrolled, 862 (70.3%) patients reached M12 and 466 (38.0%) patients reached M24. In both populations mean age was 59 years, approx. three quarters of patients were female and over 60% were seropositive. 52.5% of M12- and 54.7% of M24-population were treated with a bDMARD immediately prior to enrollment. Tofacitinib treatment persistence was 56% after 1 year in M12-population and 53% after 2 years in M24-population (Table 1).

A reduction of disease activity and morning stiffness was observed in both populations over time while functional ability according to FFbH (Functional Ability Questionnaire Hannover, German short questionnaire for the assessment of patient functional capacity in the context of basic everyday activities (range: 0-100% functional capacity) [1]) increased in both populations. The mean change from BL of disease activity and morning stiffness as well as functional ability was somewhat more pronounced in M12- than in M24-population. Functional remission was achieved by more patients in the M24- (40.5%) than in M12-population (35.4%). Furthermore, patients in both populations showed a comparable improvement in self-reported quality of life and the majority of patients in both populations were satisfied or extremely satisfied with tofacitinib treatment (Table 2).

AEs occurred in 66.9% (M12-population), and 73.8% (M24-population) of patients, respectively. Approx. half of the M12- as well as the M24-population had AEs related to tofacitinib, less than one-third of patients in both populations discontinued study drug due to AE but remained in the study. Two deaths were reported in M12-population (Table 2).

Conclusion: This second interim analysis shows a good effectiveness and an increased quality of life with tofacitinib therapy. Safety results were consistent with the known safety profile of tofacitinib. These results are in line with those of the first interim analysis.

Abstract Number: 0561

Enhancing the Identification of Rheumatoid Arthritis-Associated Interstitial Lung Disease in Electronic Health Records Through Text Mining of Computerized Tomography Reports

Brent Luedders[1], Brendan Cope[2], Matt Devries[2], W. Scott Campbell[2], James Campbell[2], Ted Mikuls[3], Jeffrey Curtis[4], Daniel Hershberger[3] and Bryant England[3], [1]University of Nebraska Medical Center, Omaha, NE, United Kingdom, [2]University of Nebraska Medical Center, Omaha, [3]University of Nebraska Medical Center, Omaha, NE, [4]Division of Clinical Immunology and Rheumatology, Department of Medicine, Department of Epidemiology, University of Alabama at Birmingham, Birmingham, AL

SESSION INFORMATION

Session Date: Sunday, November 7, 2021

Session Title: Epidemiology & Public Health Poster II: Inflammatory Arthritis – RA, SpA, & Gout (0560–0593)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Background/Purpose: Interstitial lung disease (ILD) is an extraarticular manifestation of RA that leads to increased morbidity and mortality. Algorithms incorporating multiple diagnostic and procedure codes as well as treating provider specialty have been developed to identify RA-ILD patients in administrative data sources. Positive predictive values (PPV) for such algorithms range between 70-85%. In this study, we adapted these RA-ILD algorithms to electronic health record (EHR) data and used text mining to capture ILD terms within chest CT reports.

Methods: We identified possible RA-ILD cases at a large academic medical center by searching the EHR for patients with at least one ICD-9/10 or SNOMED Clinical Terms code for both RA and ILD. Detailed medical record review was performed to validate RA-ILD diagnoses (reference standard). When available, chest CT images were separately reviewed by an expert in ILD for the presence/absence of ILD, blinded to the clinical data. We applied previously validated RA-ILD administrative algorithms with various combinations of ICD-9/10 codes for ILD, CPT codes for chest CT or lung biopsy, and provider specialty (pulmonology or rheumatology). Subsequently, we used text mining by automated regular expressions to identify ILD related terms (e.g. ground glass, honeycombing) and variations of these terms in chest CT reports within the EHR. We tested the performance of the aforementioned algorithms with/without these ILD terms.

Results: Of the 114 possible RA-ILD cases, 77 were validated by record review (**Table 1)**. Patients were on average 67.4 years old and most commonly white (82.3%), female (66.7%), and seropositive (82.6%). Among the validated

Table 1. Patient characteristics

	Overall cohort*	Validated RA-ILD cases
Number	114	77
Age, years	67.4	68.7
Female sex	76/114 (66.7%)	46/77 (59.7%)
White race	93/113 (82.3%)	61/77 (79.2%)
Seropositive[x]	81/98 (82.6%)	60/70 (85.7%)
Current/former smoker	54/97 (55.7%)	38/66 (57.6%)

Values mean (SD) or n (%) of non-missing
** patients with ≥1 ICD-9/10 code for both RA and ILD*
[x] As determined by lab values when available, or provider documentation when labs not available

Table 2. Performance of RA-ILD algorithms with and without text mining for ILD terms from CT reports

	Algorithm search criteria*	PPV (95% CI)	RA-ILD cases identified, n (% referent to algorithm 1)	Change in PPV with text phrase searching
Administrative RA-ILD algorithms				
Algorithm 1	≥ 1 ICD for ILD	70.6 (61.1, 79.0)	77 (100)	n/a
Algorithm 2	≥ 1 ICD for ILD plus specialty code	83.3 (72.7, 91.1)	60 (77.9)	n/a
Algorithm 3	≥ 1 ICD for ILD plus specialty code or CT/biopsy	78.1 (68.5, 85.9)	75 (97.4)	n/a
Algorithm 4	≥ 2 ICD for ILD	85.5 (75.6, 92.5)	65 (84.4)	n/a
Algorithm 5	≥ 2 ICD for ILD plus specialty code	90.5 (80.4, 96.4)	57 (74.0)	n/a
Algorithm 6	≥ 2 ICD for ILD plus specialty code or CT/biopsy	87.7 (77.9, 94.2)	64 (83.1)	n/a
Algorithms plus ILD term searching of CT reports				
Algorithm 1T	Algorithm 1 plus ILD term search^T	84.2 (68.7, 94.0)	32 (41.6)	13.6
Algorithm 2T	Algorithm 2 plus ILD term search^T	95.8 (78.9, 99.9)	23 (29.9)	12.5
Algorithm 3T	Algorithm 3 plus ILD term search^T	88.9 (73.9, 96.9)	32 (41.6)	10.8
Algorithm 4T	Algorithm 4 plus ILD term search^T	96.3 (81.0, 99.9)	26 (33.8)	10.8
Algorithm 5T	Algorithm 5 plus ILD term search^T	95.8 (78.9, 99.9)	23 (29.9)	5.3
Algorithm 6T	Algorithm 6 plus ILD term search^T	96.3 (81.0, 99.9)	26 (33.8)	8.6

** All algorithms additionally required ≥1 ICD or SNOMED CT code for rheumatoid arthritis*
T: search of CT reports for ≥1 of the following: 'honeycomb', 'honey comb', 'interstitial lung disease', 'pulmonary fibrosis', 'ground glass opacit', 'groundglass', 'reticular opacit', 'reticulation', 'rheumatoid lung'
Abbreviations: ICD = International Classification of Diseases; ILD = interstitial lung disease; CT = computed tomography; PPV = positive predictive value; 95% CI = 95% confidence interval; n/a = not applicable

RA-ILD cases, 56 had CT images available with 50 expertly read as RA-ILD (5 indeterminate). Administrative algorithms (Algorithms 1-6) had positive predictive values (PPVs) for RA-ILD ranging from 70.6 to 90.5% (**Table 2**). Algorithm 5 (≥2 ICD for ILD plus specialty code) had the highest PPV, but identified fewer RA-ILD cases (57/77). The addition of ILD terms extracted through text mining increased the PPV compared to similar administrative algorithms by 5-13%. Notably, adding an ILD term from chest CT to the simplest administrative algorithm (Algorithm 1T) yielded a PPV similar to the most complex administrative algorithms (Algorithms 5 and 6). Fewer RA-ILD cases were identified with ILD term searching (range 23 to 32), since many patients did not have available CT reports. Findings were similar in sensitivity analyses that considered expert read of available CTs the reference standard.

Conclusion: An ILD algorithm initially derived and validated in administrative claims data had similarly high validity when applied to EHR data. Incorporating ILD related terms from chest CT reports substantially increased the PPV, but reduced sensitivity. Declines in sensitivity due to the unavailability of CT reports may be attenuated in integrated health care systems and as data sharing across EHRs improves. Our findings demonstrate how existing administrative algorithms can be improved to better identify RA-ILD for comparative effectiveness and outcomes research that utilizes EHRs.

Inpatient Epidemiology and Resource Utilization of Ankylosing Spondylitis: National Inpatient Sample 2018

Patompong Ungprasert[1], Thanat Chaikijurajai[2], Karn Wijarnpreecha[3] and Paul Kroner[3], [1]Cleveland Clinic, Cleveland Heights, OH, [2]Cleveland Clinic, Cleveland, OH, [3]Mayo Clinic Florida, Jacksonville, FL

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Epidemiology & Public Health Poster II: Inflammatory Arthritis – RA, SpA, & Gout (0560–0593)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Little is known about inpatient epidemiology, economic burden and resource utilization of patients with ankylosing spondylitis (AS). The current study aims to describe those characteristics using a nationwide database.

Methods: Patients with AS were identified from the National Inpatient Sample (NIS), the largest inpatient database in the United States (US) consisting of over 4,000 non-federal acute care hospitals, using ICD-10 CM codes. The rest of patients in the database without diagnostic codes for AS were used as comparators. Data on demographics, reasons for hospitalization, length of stay, mortality, morbidity and total hospitalization charges were extracted and compared between patients with and without AS. A multivariate logistic regression model was constructed to adjust for confounders. All analyzed data was extracted from the database of the year 2018.

Results: A total of 19,130 admissions with AS were identified. The inpatient prevalence of AS was 53.9 cases per 100,000 admissions. Sepsis (27.4%), hip and knee arthroplasty (18.8%), pneumonia (7.5%), acute kidney injury (6.8%) and non-ST elevated myocardial infarction (6.2%) were the most common reasons for hospitalization. After adjusting for potential confounders, hospitalizations among patients with AS were significantly associated with longer length of stay (0.37 more days; 95% confidence interval (CI), 0.44 – 0.89) and risk for admission to intensive care unit with adjusted odds ratio (aOR) of 1.23 (95% CI, 1.11 – 1.37). Other inpatient outcomes, including inpatient mortality, shock and multiorgan failure were not significantly different between patients with and without AS. Hospitalizations of patients with AS were associated with higher cost as demonstrated by an adjusted additional mean of $4,685 (95% CI, $3,715 - $5,655) for total hospital cost and an adjusted additional mean of $19,097 (95% CI, $12,675 – $25,519) for total hospitalization charges when compared to patients without AS.

Conclusion: Inpatient prevalence of AS was higher than what would be expected from prevalence in general population. Infection and arthroplasty were the main reasons for the need for inpatient care. Hospitalizations of patients with AS were associated with longer length of stay, need for admission to ICU and cost.

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Background/Purpose: The FRAX tool, launched by the World Health Organization Collaborating Centre at the University of Sheffield in 2008 (https://www.sheffield.ac.uk/FRAX/), is widely used to quickly and reliably estimate an individual's fracture risk, outputting the ten-year probability of major osteoporotic fracture (thoracic/lumbar vertebra, proximal femur, distal forearm, or proximal humerus) and the ten-year probability of hip fracture. The FRAX algorithm accounts for the influence of several risk factors, including rheumatoid arthritis (RA), as individuals with RA are known have an excess burden of fractures. However, the use of FRAX specifically within RA populations to estimate fracture risk has not been widely studied. Therefore, the purpose of this study was to determine the accuracy of FRAX risk predictions for US individuals with RA.

Methods: In this retrospective cohort study, all patients aged 40-90 years within a geographically defined region who fulfilled the 1987 American College of Rheumatology criteria for RA from 1980 to 2007 were identified and followed until death, migration, or last medical record review. Each RA patient was matched 1:1 on age and sex to a patient of the same region without RA. The date of RA criteria fulfillment served as the baseline date for RA patients and matched subjects. Ten-year predictions for major osteoporotic and hip fractures were estimated using the FRAX tool.

Table 1. Comparison of observed and predicted fracture risk in RA and non-RA patients

Subgroup	N		Fractures*		SIR (95% CI)
			Observed	Predicted	
RA	662	*Osteoporotic:*	76	67.0	1.13 (0.91-1.42)
		Hip:	21	23.3	0.90 (0.59-1.38)
Males	220	*Osteoporotic:*	20	15.8	1.27 (0.82-1.97)
		Hip:	4	5.0	0.80 (0.30-2.12)
Females	442	*Osteoporotic:*	56	51.3	1.09 (0.84-1.42)
		Hip:	17	18.2	0.93 (0.58-1.50)
Age 40-59	334	*Osteoporotic:*	20	17.2	1.16 (0.75-1.80)
		Hip:	2	2.0	1.01 (0.25-4.02)
Age 60-79	270	*Osteoporotic:*	44	37.2	1.18 (0.88-1.59)
		Hip:	14	13.8	1.01 (0.60-1.71)
Age 80+	58	*Osteoporotic:*	12	12.6	0.95 (0.54-1.67)
		Hip:	5	7.5	0.67 (0.28-1.61)
Non-RA	658	*Osteoporotic:*	46	40.5	1.14 (0.85-1.52)
		Hip:	10	10.1	0.99 (0.53-1.84)
Males	218	*Osteoporotic:*	6	8.8	0.68 (0.31-1.52)
		Hip:	1	1.9	0.54 (0.08-3.82)
Females	440	*Osteoporotic:*	40	31.7	1.26 (0.92-1.72)
		Hip:	9	8.2	1.09 (0.57-2.10)
Age 40-59	339	*Osteoporotic:*	9	10.6	0.85 (0.44-1.63)
		Hip:	1	0.8	1.26 (0.18-8.92)
Age 60-79	265	*Osteoporotic:*	25	22.8	1.10 (0.74-1.62)
		Hip:	6	5.9	1.01 (0.45-2.25)
Age 80+	54	*Osteoporotic:*	12	7.0	1.70 (0.97-3.00)
		Hip:	3	3.4	0.89 (0.29-2.76)

*Number of patients with a fracture

FRAX prediction scores (without bone mineral density) were calculated from patient age, sex, body mass index, and the following dichotomous risk factors: RA, previous fracture, secondary osteoporosis, glucocorticoid use, smoking status, and alcohol use. Fractures were ascertained through follow-up, truncated at 10 years. Standardized incidence ratios (SIR) and 95% confidence intervals (CI) were calculated to compare observed and predicted fractures.

Results: The study included 662 RA patients and 658 non-RA comparators. RA and non-RA subjects were predominantly white females (67% female; RA: 95% white, non-RA: 94% white) with a mean age of 60.6 and 60.5 years at baseline, respectively. Individuals with RA had increased occurrence of all other dichotomous risk factors compared to non-RA comparators, with the exception of previous fractures, which was similar between RA and non-RA groups. Among RA patients, 76 major osteoporotic and 21 hip fractures were observed during follow-up (median follow-up: 9.7 years, IQR: 5.7, 10.0 years) compared to the predicted 67.0 major osteoporotic fractures (SIR: 1.13, 95% CI: 0.91-1.42) and 23.3 hip fractures (SIR: 0.90, 95% CI: 0.59-1.38). The observed and predicted major osteoporotic and hip fracture risks were similar for RA and non-RA patients, with no significant differences among sex and age subgroups. For non-RA patients over the age of 80 years, the observed risk for major osteoporotic fracture was slightly elevated (SIR: 1.70, 95% CI: 0.97-3.00), but this difference did not reach significance.

Conclusion: The findings of this study support that the FRAX tool is an accurate method for estimating major osteoporotic and hip fracture risk in individuals with RA.

Abstract Number: 0564

Associations of Sinusitis, Pharyngitis, and Respiratory Tract Disease Burden with Incident Rheumatoid Arthritis

Vanessa Kronzer[1], Weixing Huang[2], Alessandra Zaccardelli[2], Cynthia Crowson[3], John Davis[1], Robert Vassallo[1], Tracy Doyle[4], Elena Losina[2] and Jeffrey Sparks[2], [1]Mayo Clinic, Rochester, MN, [2]Brigham and Women's Hospital, Boston, MA, [3]Mayo Clinic, Eyota, MN, [4]Brigham and Women's Hospital, West Roxbury, MA

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Epidemiology & Public Health Poster II: Inflammatory Arthritis – RA, SpA, & Gout (0560–0593)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Increasing evidence implicates respiratory mucosa in the pathogenesis of rheumatoid arthritis (RA). However, individual respiratory tract diseases, especially of the upper airways, sinuses, and pharynx, have remained relatively understudied for RA risk. We aimed to determine whether specific respiratory tract diseases are associated with rheumatoid arthritis RA development.

Methods: This case-control study was performed within a large, single center biobank. We matched newly diagnosed RA cases to three controls on age, sex, and electronic health record (EHR) history. We identified RA using a validated algorithm incorporating diagnosis codes, medications, and natural language processing, and then confirmed cases by medical record review. We confirmed date of RA diagnosis by medical record review and obtained RA serostatus from clinical laboratory results. "Seropositive" RA included positivity for rheumatoid factor and/or anti-citrullinated protein antibodies. Respiratory tract disease exposure required one inpatient or two outpatient codes two years before index date of RA or matched date (mean positive predictive value 86%). We obtained covariates including

Table 1. Associations between preceding respiratory tract diseases (at least two years before index date) and incident RA

	Number (%)		Adjusted* Odds Ratio for RA (95% CI)

BMI = body mass index, CI = confidence interval, COPD = chronic obstructive pulmonary disease, RA = rheumatoid arthritis
*Reference was individuals with no respiratory tract disease codes prior to index date. Adjusting for age, sex, EHR history, enrollment year, race/ethnicity, education, BMI. Bold values are statistically significant.
**Model did not converge due to few outcomes in the reference group

CI:1.03,1.87) were associated with increased risk of RA diagnosis (Table 1). Acute respiratory tract disease burden during the pre-index exposure period was also associated with increased RA risk (OR 1.30 per 10 diagnosis codes, 95% CI:1.08,1.55). Acute pharyngitis was associated with seronegative RA (OR 1.68, 95% CI:1.02,2.74) but not seropositive RA; chronic rhinitis/pharyngitis was associated with seropositive RA (OR 2.46, 95% CI:1.01,5.99) but not seronegative RA. Respiratory tract diseases tended towards higher associations with RA in smokers, especially >10 pack-years (OR 1.52, 95% CI:1.02,2.27; p 0.10 for interaction; Table 2).

Conclusion: We identified novel associations of acute/chronic sinusitis, pharyngitis, and acute respiratory tract disease burden with RA risk. These results suggest that the mucosal paradigm of RA pathogenesis may not only involve the lower respiratory tract, but also the upper respiratory tract.

Abstract Number: 0565

Increased Risk for Inflammatory Arthritis in Veterans with Depression or Anxiety

Brian Breviu[1], Shaobo Pei[1], Matthew Kirkpatrick[2], Bingjian Feng[1] and Jessica Walsh[3], [1]Salt Lake City Veteran Affairs and University of Utah Medical Centers, Salt Lake City, UT, [2]University of Utah, Salt Lake City, UT, [3]Salt Lake City Veteran Affairs Medical Center (VAMC)/University of Utah Hospital, Salt Lake City, UT

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Epidemiology & Public Health Poster II: Inflammatory Arthritis – RA, SpA, & Gout (0560–0593)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Depression and anxiety are common in patients with inflammatory arthritis (IA), and have been reported as risk factors for various inflammatory diseases. The study objective was to estimate the risk of IA in patients with newly diagnosed depression or anxiety (mental health disorders [MHD]), relative to matched controls.

Methods: The MHD population consisted of veterans with ≥2 International Classification of Diseases (ICD) codes for a MHD between 1/1/2007-12/31/2019, with at least 2 years of active VA system use prior to date of their initial MHD ICD code (index date). Control group patients had no MHD ICD codes and were matched to the MHD patients on gender, age, and date of VA enrollment. Control group patients were assigned the same index date as their corresponding match. Patients were excluded if they had an ICD code for IA (rheumatoid arthritis, psoriatic arthritis, or ankylosing spondylitis) prior to their index date. The cumulative IA incidence was depicted with Kaplan-Meier analysis. Hazard ratios (HR) were adjusted by race, ethnicity, body mass index, smoking status, Charlson Comorbidity Index, and socioeconomic status.

Results: The population consisted of 1,378,462 veterans (689,231 MHD & 689,231 controls). The mean age was 61.1, and 92.5% were male. The cumulative incidence of IA increased linearly for up to 13 years after the initial MHD diagnosis (Figure). The incident rate per 1000 patient years was higher in the MHD group than the control group for all IA (2.74 vs. 1.71) and for subsets with RA (2.09 vs 1.32), PsA (0.35 vs 0.22), and AS (0.29 vs 0.16) (Table 1). The

Natural Language Processing of Electronic Health Record Notes Captures Forced Vital Capacity in Rheumatoid Arthritis-Associated Interstitial Lung Disease

Punyasha Roul[1], Yangyuna Yang[1], Daniel Hershberger[1], Ted Mikuls[1], Jorge Rojas[2], Jeffrey Curtis[3], Joshua Baker[4], Brian Sauer[5] and **Bryant England**[1], [1]University of Nebraska Medical Center, Omaha, NE, [2]VA Puget Sound, Seattle, WA, [3]Division of Clinical Immunology and Rheumatology, Department of Medicine, Department of Epidemiology, University of Alabama at Birmingham, Birmingham, AL, [4]University of Pennsylvania, Philadelphia, PA, [5]University of Utah, Salt Lake City, UT

SESSION INFORMATION

Session Date: Sunday, November 7, 2021

Session Title: Epidemiology & Public Health Poster II: Inflammatory Arthritis – RA, SpA, & Gout (0560–0593)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Background/Purpose: Rheumatoid arthritis-interstitial lung disease (RA-ILD) has a poor long-term prognosis, including premature mortality. Longitudinal monitoring of patients in clinical and clinical trial settings includes the routine measurement of forced vital capacity (FVC) from pulmonary function tests (PFT). However, the availability of PFT data in real-world datasets is highly variable, limiting examination of this key outcome in long-term observational studies. Natural Language Processing (NLP), an artificial intelligence method, has been used to transform unstructured text from the electronic health record (EHR) to structured clinical data. We aimed to develop a NLP program to capture FVC values from EHR notes.

Methods: We identified patients in the Veterans Health Administration (VA) with RA-ILD between 2000 and 2020 by ICD-9/10 codes for RA and ILD, based on previously validated RA-ILD algorithms. We developed a NLP program to capture FVC values from all available notes from the EHR using MS SQLServer, based on a program for FEV1 values (Akgun et al. *PLoS ONE*, 2020). We identified FVC string patterns and extracted numeric values in proximity to these strings. Subsequently, we performed several processing steps to account for variability in note type and structure, related PFT output (e.g. FEV1/FVC ratio), and values copied across multiple notes. Dates were assigned to FVC values by cross referencing EHR note dates with the most recent date accompanying CPT codes for PFTs. FVC values derived by the NLP program were compared to observed FVC values recorded directly from PFT equipment and available as structured data in the VA Corporate Data Warehouse (CDW). These represent a subset of all PFTs completed in the VA due to PFT compatibility.

Results: We developed and tested the NLP program in a cohort of 7,485 patients with RA-ILD. In the VA CDW, there were 6,002 FVC values for 1,843 unique patients. The NLP program increased the yield of FVC values by >2.6-fold, extracting 15,983 FVC values for 4,849 patients. Among 3,037 date matched FVC values from NLP and CDW, mean

Values mean (SD), P value by paired t-test

Mean 5.2 years between FVC measurements in NLP and 4.8 years in CDW

Abbreviations: CDW, Corporate Data Warehouse; FVC, forced vital capacity; NLP, natural language processing; PFT; pulmonary function test; RA-ILD, rheumatoid arthritis-interstitial lung disease; VA, Veterans Affairs

(SD) FVC was 3.0 (0.9) L from both sources, and 80% of NLP values were within 0.1L of CDW values. The mean difference in FVC between NLP and CDW values was 0.03L with no systematic bias in NLP derived FVC values seen on Bland-Altman plot (**Figure 1**). NLP and CDW FVC values strongly correlated (**Figure 2**, r=0.89, p< 0.001). A total of 3,325 RA-ILD patients had at least two FVC values captured by NLP. Comparing the first and last FVC values, there was a mean decline in FVC of -0.30 (SD 0.86) L over a mean follow-up of 5.2 (SD 4.6) years (p< 0.001 by paired t-test) (**Table 1**). Similar changes in FVC (mean -0.29 [SD 0.66] L) were observed using CDW data, but this data source captured fewer RA-ILD patients (n=1,181).

Conclusion: NLP of EHR notes substantially increases the capture of longitudinal FVC values among patients with RA-ILD. These values are highly accurate compared to the gold standard of direct output from PFT equipment which may not always be available in structured format. Use of this NLP program can facilitate clinical and epidemiologic research studies in RA-ILD by capturing longitudinal changes among one of the most critical outcomes measures in RA-ILD.

Determinants of Health-Related Quality of Life in Spondyloarthritis and Comparison with Chronic Low Back Pain – Results from a Nation-Wide Study

Helena Santos[1], Ana Rita Henriques[2], Ana Maria Rodrigues[3], Jaime Branco[3] and Helena Canhao[3], [1]Portuguese Institute of Rheumatology, Lisbon, Portugal, [2]EpiDoC Unit, Comprehensive Health Research Centre (CHRC), Lisbon, Portugal, [3]EpiDoC Unit, CEDOC, NOVA Medical School, Comprehensive Health Research Centre (CHRC), Lisbon, Portugal

SESSION INFORMATION

Session Date: Sunday, November 7, 2021
Session Title: Epidemiology & Public Health Poster II: Inflammatory Arthritis – RA, SpA, & Gout (0560–0593)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Spondyloarthritis (SpA) causes pain, fatigue, stiffness, loss of physical function and impaired health-related quality of life (HRQoL).

This study aims to: 1) to compare HRQoL in patients with SpA, chronic low back pain (CLBP) and subjects with no rheumatic disease (noRMD), and 2) to evaluate determinants of HRQoL in SpA patients, in a population-based setting.

Methods: Data from EpiReumaPt, a national health survey with 10 661 adult participants, randomly selected, that were screened for rheumatic and musculoskeletal diseases (RMDs) was used. Subjects were asked about socio-demographic data, lifestyle habits, chronic non-communicable diseases and HRQoL. SpA diagnosis was based on a positive expert opinion (rheumatologist) combined with predefined criteria; SpA disease activity was also collected. CLBP was established by predefined criteria and noRMD by expert opinion. Univariate and multivariate linear regressions were performed to explore factors associated with QoL assessed by EuroQoL- 5 Dimensions 3L (EQ-5D).

Results: We included 92 SpA, 1376 CLBP and 679 with noRMD. The mean age was 48.4 years (SD=13.7) for SpA, 58.8 years (SD=14.6) for CLBP and 45.9 years (SD=15.6) for noRMD. The 3 groups had a female predominance (64.1%, 70.3% and 53.9%, respectively). SpA and CLBP had similar HRQoL reflected by EQ5D-3L index (ß=-0.03, p-value=0.33), much lower when compared to subjects noRMD (ß=-0.14, p-value< 0.001) (table I), Patients with SpA had lower scores in all EQ-5D dimensions, similar in patients with CLBP, but much higher than in participants noRMD. Pain, was reported in almost 60% of SpA adults, followed by limitations in mobility. In our cohort, SpA adults showed similar individual perception of health than adults with CLBP by EuroQoL visual analogue scale (ß=0.03, p-value=0.989), that was much lower (higher score=better health) when compared to adults noRMD (ß=-7.49, p-value=<

	0-2	Ref			
	≥ 3	-0.18	0.05	**<0.001**	[-0.24; -0.03]
Disease activity	Inactive	Ref			
	Active	-0.13	0.06	**0.036**	[-0.29; -0.05]

Std. error: Standard error; CI: Confidance Interval
Residual standard error: 0.2033 on 79 degrees of freedom
Multiple R-squared: 0.3543, Adjusted R-squared: 0.3298
F-statistic: 14.45 on 3 and 79 DF, p-value: 1.362e-07

0.001) (table I). Considering the factors associated with HRQoL in SpA, multimorbidity (³3 chronic non-communicable diseases) (ß=-0.18; p-value< 0.001) and an active disease (ß=-0.13; p-value=0.036), were associated with worse HRQoL; on the other hand, regular physical exercise was significantly associated with better HRQoL (ß=0.18; p-value< 0.001) (table II). Our model can explain 35.43% of the variance of HRQoL in SpA subjects.

Conclusion: In this nation-wide study, SpA showed a similar impact in HRQoL than CLBP. An active disease, multimorbidity and regular physical exercise are largely responsible for HRQoL in SpA.

Session Title: Epidemiology & Public Health Poster II: Inflammatory Arthritis – RA, SpA, & Gout (0560–0593)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: The Department of Veterans Affairs (DVA) provides comprehensive medical care at minimal or no cost to 9 million veterans annually through 170 medical centers and 1074 outpatient clinics across the United States. In 1999, the DVA established a national, fully integrated electronic health record (EHR), which now includes approximately 24 million veterans. However, few studies have used Veterans Affairs (VA) EHR data to examine the validity of diagnoses of RA. We developed a validated, national database of patients with RA who received VA care

Table 1: Proportion of patients with a valid RA diagnosis[1] as a function of RF and aCCP laboratory results

[1]Diagnosis given by the treating rheumatologist.
[2]No test results available or test results available but without normal range values.
[3]1,253 patients without available or interpretable RF or aCCP excluded from initial cohort.
[4]Percentage of 553 charts reviewed confirmed as RA.
[5]Poss RA = Possible RA. Patients met our inclusion criteria but the treating rheumatologist never made a definitive diagnosis of RA or alternative diagnosis (from 553 charts reviewed).

since the introduction of International Classification of Diseases, tenth revision (ICD-10) coding in 2015. This Veterans Affairs National Rheumatoid Arthritis Database (VANRAD) will provide infrastructure for retrospective and prospective research to address the 'real-world' care of patients with RA.

Methods: Patients with the following criteria were identified from the VA EHR as of October 2, 2020: (a) ≥1 ICD-10 diagnosis code of RA; (b) treatment with ≥1 DMARD; (c) ≥2 VA rheumatology clinic visits; and (d) ≥1 RF and/or anti-CCP (aCCP) antibody test result. From this group, 553 EHRs were randomly selected for review. The 'gold standard' for the diagnosis of RA was the treating rheumatologist's diagnosis, documented in the EHR.

Results: A total of 27,482 patients met eligibility criteria. Sociodemographic characteristics were: 85.6% male; mean age of 69.7 years (y) (standard deviation [SD]=10.9 y; range=21.9 y to 100.5 y); 76.4% white, 17.0% African American; and mean VA care for 14.1 y (SD=5.3 y, range=0.04 y to 20.0 y).

For patients with ≥1 RF or aCCP test, the positive predictive value (PPV) for RA ranged from 65.3% (RF-/aCCP-) to 95.8% (RF+/aCCP+); rheumatologists' likelihood of a 'possible' diagnosis was higher if the aCCP test result was negative or not available (Table 1). Excluding patients with a second rheumatologic diagnosis did not improve PPV results (data not shown).

The percentage of RA-confirmed patients with 1 test not available, and whose complementary test was negative (RF0/aCCP- or RF-/aCCP0), was greater than the percentage of patients for whom both tests were negative (RF-/aCCP-). This suggests our data extraction methods may have been incomplete or that unidentified bias may have been present, and warrants further study.

Conclusion: Our methodology for constructing an RA database by selecting patients with ≥2 rheumatology clinic visits, an ICD-10 diagnosis of RA, treatment with ≥1 DMARD, and a minimum of 1 RF or aCCP test result has high positive predictive value for RA. Positive RF and aCCP test results were strong predictors of rheumatologists' diagnostic certainty for an RA diagnosis. Thus, the VANRAD and the associated EHR provide opportunity for a wide range of retrospective observational and prospective longitudinal studies based on 'real-world' patient care.

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

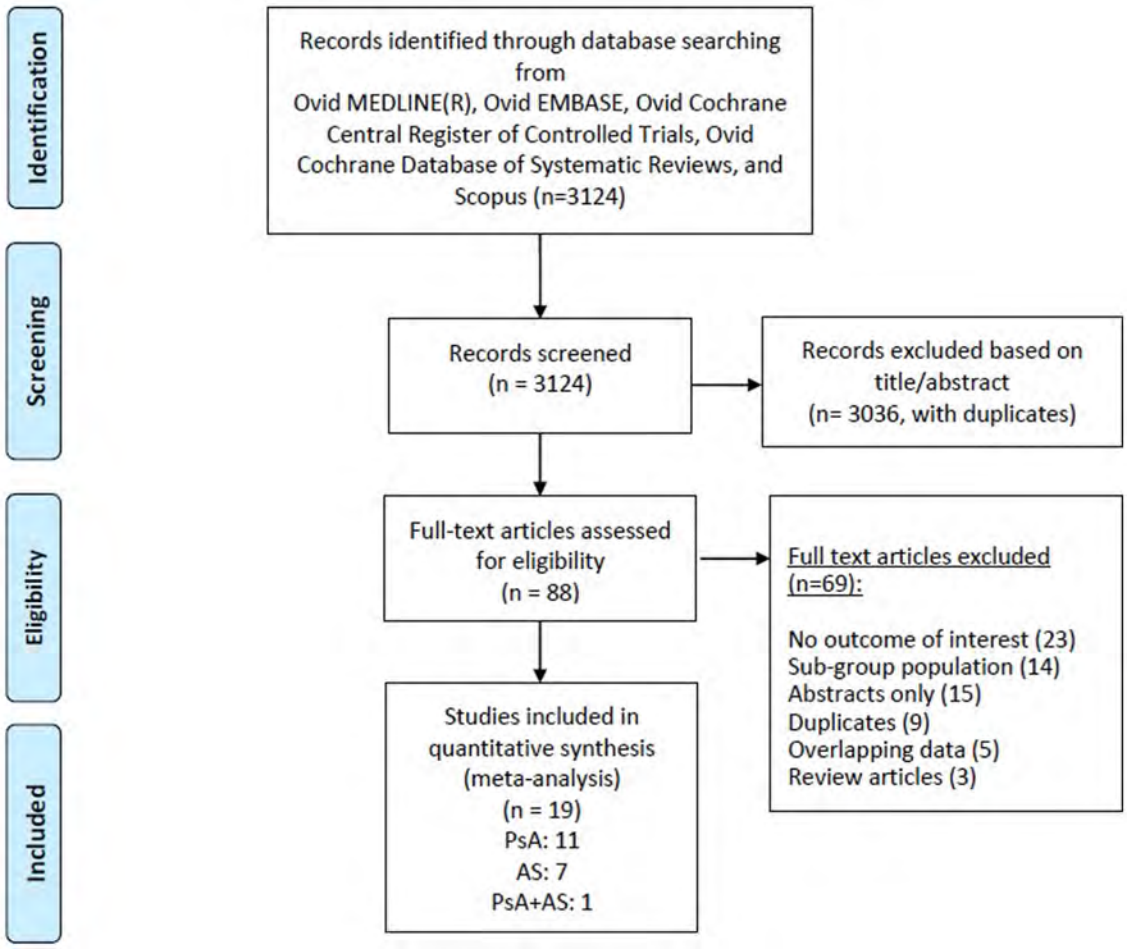

Figure 1. Prisma Flow Diagram

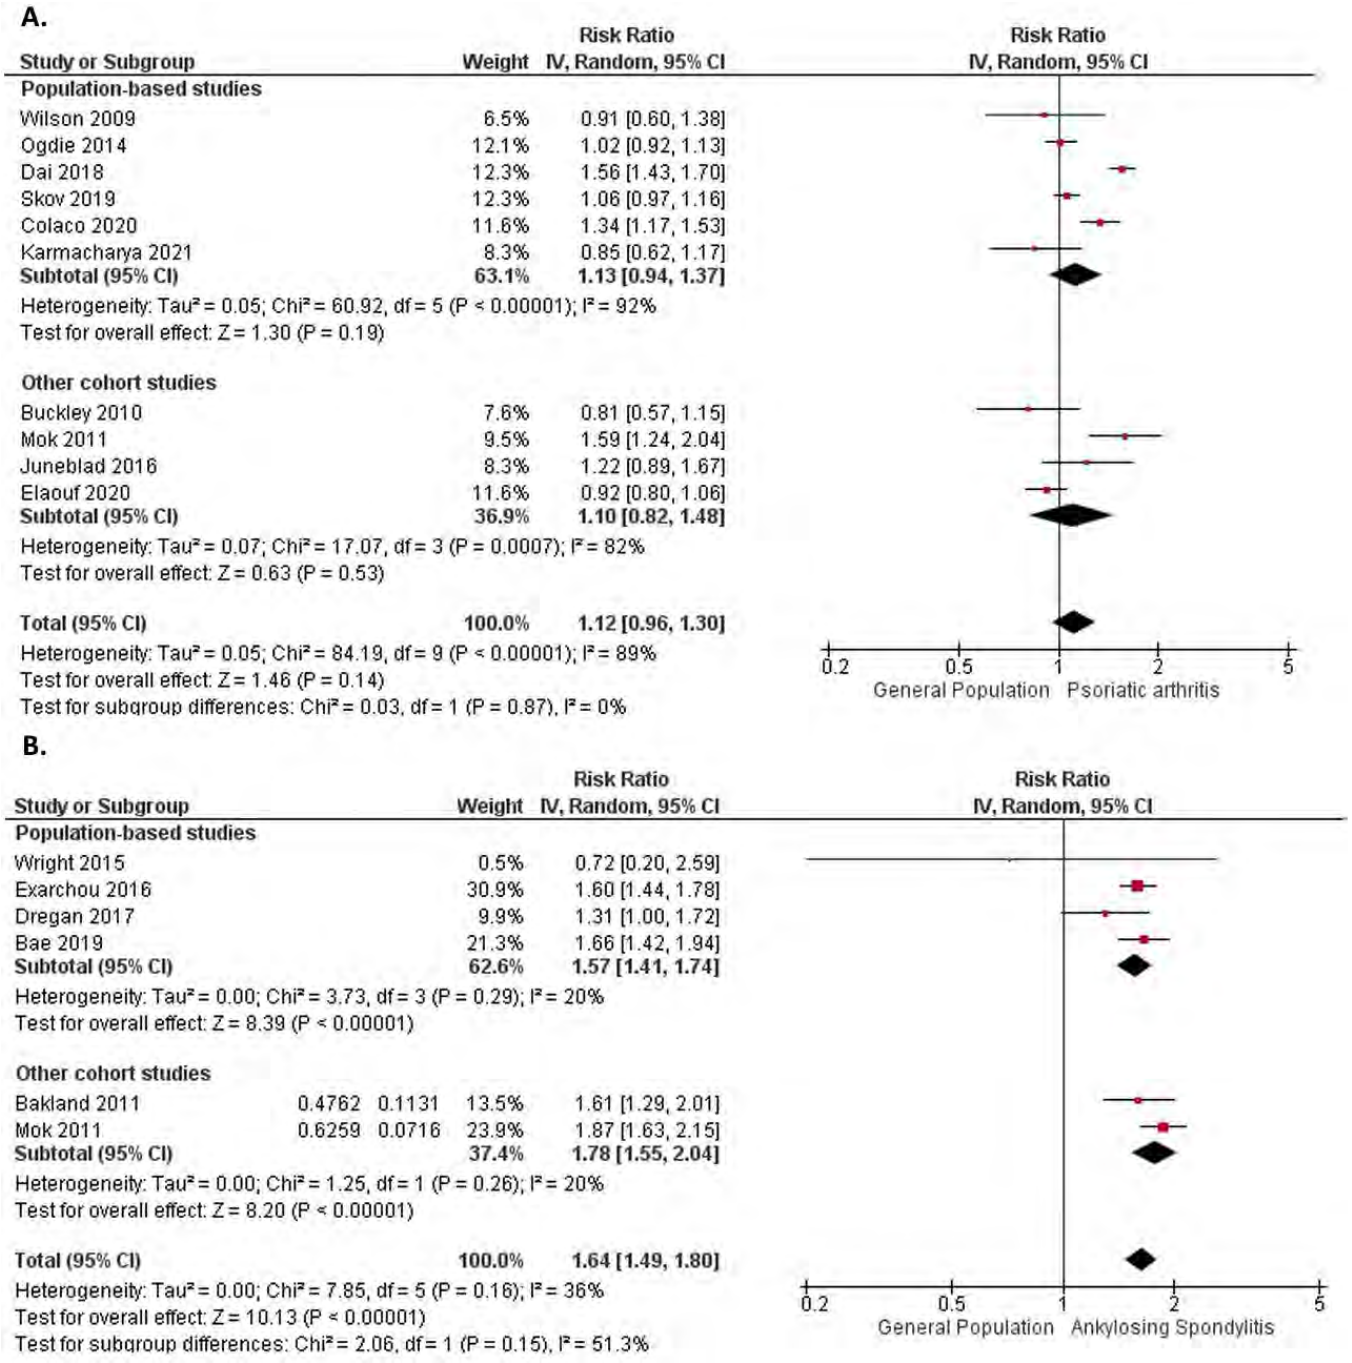

Figure 2. Forrest Plot for All-cause mortality in A)Psoriatic Arthritis B)Ankylosing Spondylitis

Background/Purpose: Spondyloarthritides (SpA) represent a group of chronic inflammatory diseases associated with a higher risk of cardio-metabolic comorbidities compared to the general population. It is unclear how these comorbidities are associated with mortality in SpA, and studies on mortality in SpA have shown inconsistent results. We performed a systematic review and meta-analysis of all-cause and cause-specific mortality in psoriatic arthritis (PsA) and ankylosing spondylitis (AS).

Methods: A comprehensive database search was performed for studies reporting all-cause or cause-specific mortality in patients with PsA and AS compared with the general population. Pooled relative risks (RRs) were calculated using random-effects model.

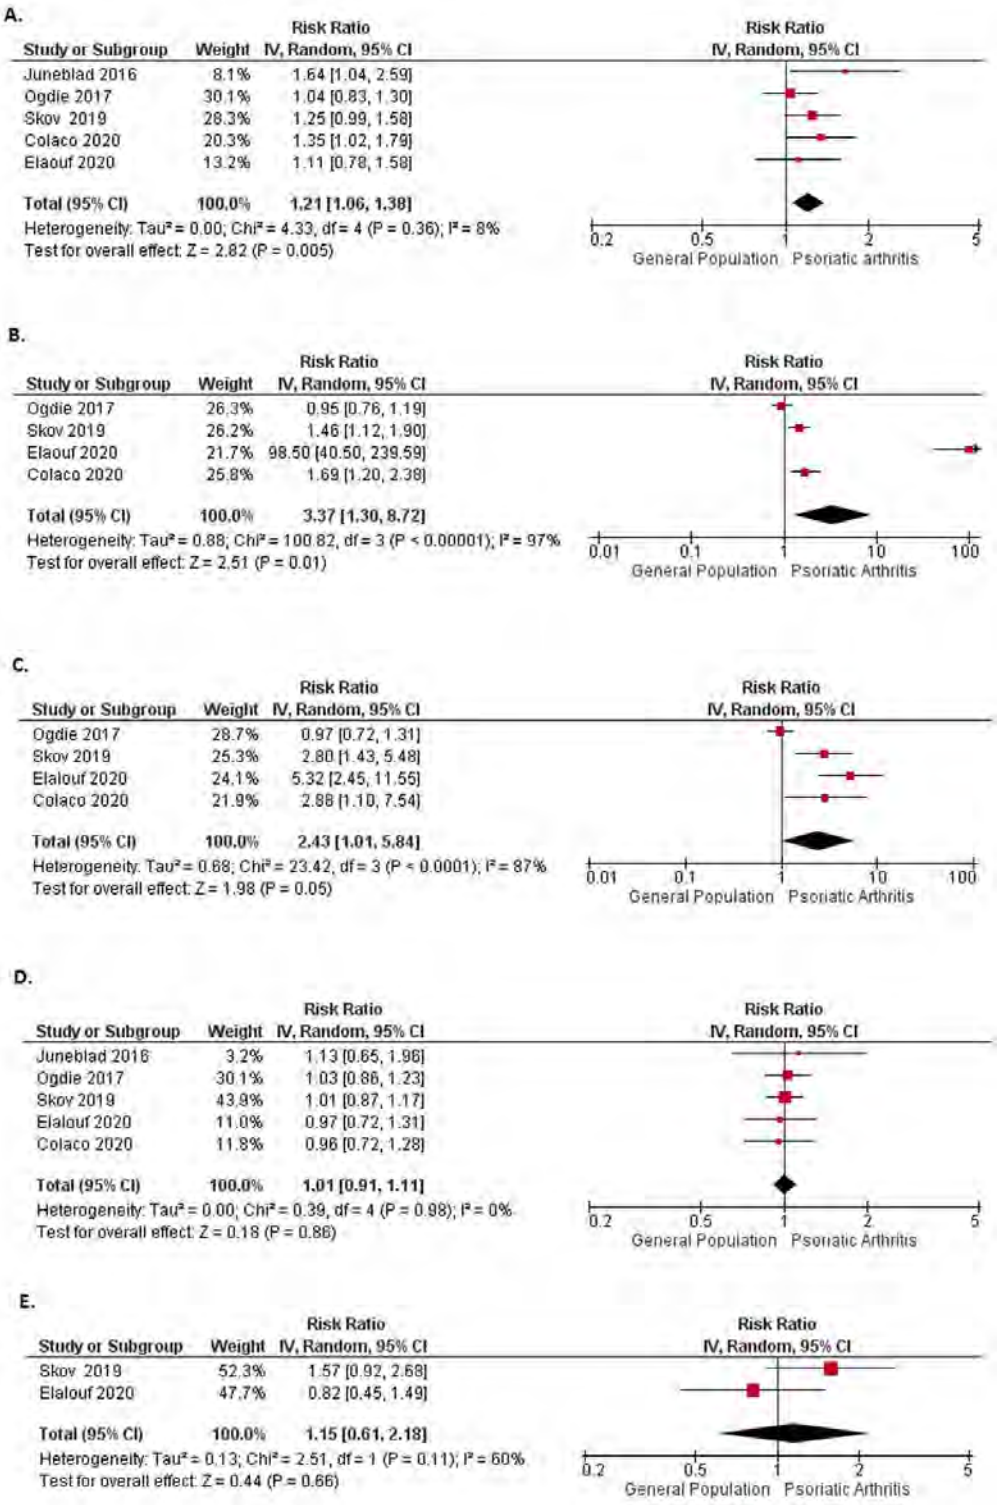

Figure 3. Forrest plot for cause-specific mortality in psoriatic arthritis A) cardiovascular B) respiratory C) infections D) malignancy E) Injury and poisoning

Results: We included 19 studies (eleven for PsA, seven for AS, one for both). In PsA studies, there was no increased mortality compared to the general population (RR: 1.12, 95% CI: 0.96-1.30, 10 studies). Cardiovascular, respiratory, and infection specific mortality risks were significantly higher for PsA patients (RR: 1.21, 95% CI: 1.06-1.38; RR: 3.37, 95% CI: 1.30-8.72; and 2.43, 95% CI: 1.01-5.84, respectively). Cancer related mortality in PsA was not higher

than the general population (RR: 1.01, 95% CI: 0.91-1.11). In AS, we found a higher risk of death from all causes (RR 1.64, 95% CI: 1.49-1.80, 6 studies) and cardiovascular causes compared to the general population (RR 1.35, 95% CI: 1.01-1.81, 3 studies).

Conclusion: This systematic review and meta-analysis showed a significantly increased risk of overall mortality in AS, but not PsA. Cardiovascular-specific mortality was higher for both PsA and AS, which emphasizes the importance of early screening and management of comorbidities to mitigate mortality risk.

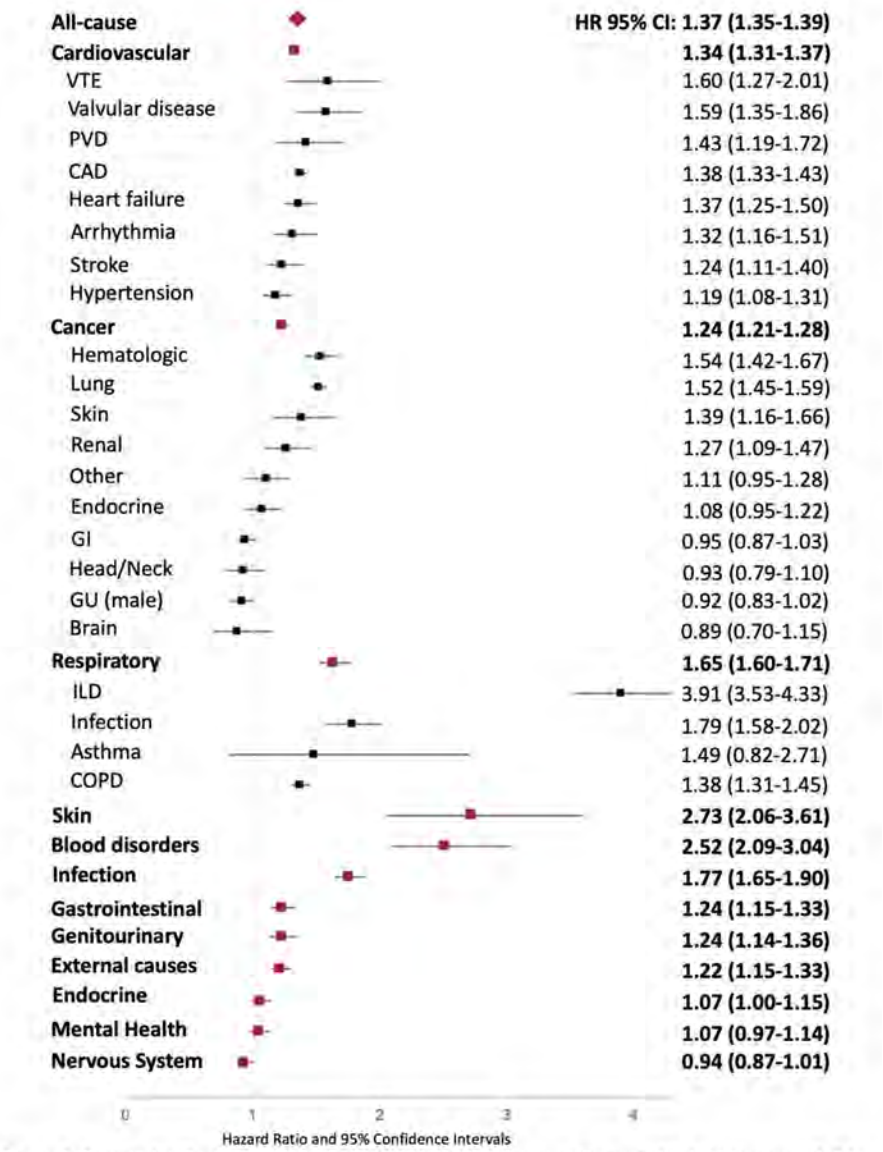

Figure 1. Forest plot illustrating the risk of all-cause and cause-specific mortality in Veterans with RA

Background/Purpose: Rheumatoid arthritis (RA) is recognized to increase the risk of premature death. The impact of RA on survival varies across causes of death, though few studies have precisely estimated mortality risk for specific causes. While all-cause mortality appears to be improving, perhaps due to advances in care, it remains unclear how these advances have impacted cause-specific mortality, particularly relative to the non-RA population. We examined risk and temporal trends in all-cause and cause-specific mortality in RA in the Veterans Health Administration (VHA), the largest integrated healthcare system in the U.S.

Methods: We conducted a retrospective, matched cohort study in the VHA from 1/1/2000-12/31/2017. RA patients (≥2 ICD codes for RA, rheumatologist diagnosis, and a positive autoantibody or DMARD fill) were matched up to 1:10 on age, sex, and year of VHA enrollment to non-RA patients. RA was considered incident if they received care in the VHA for ≥365 days without a RA diagnostic code or DMARD fill. Patients were followed from fulfillment of the RA algorithm (corresponding calendar date for non-RA) until death or end of study period. Vital status and cause of death

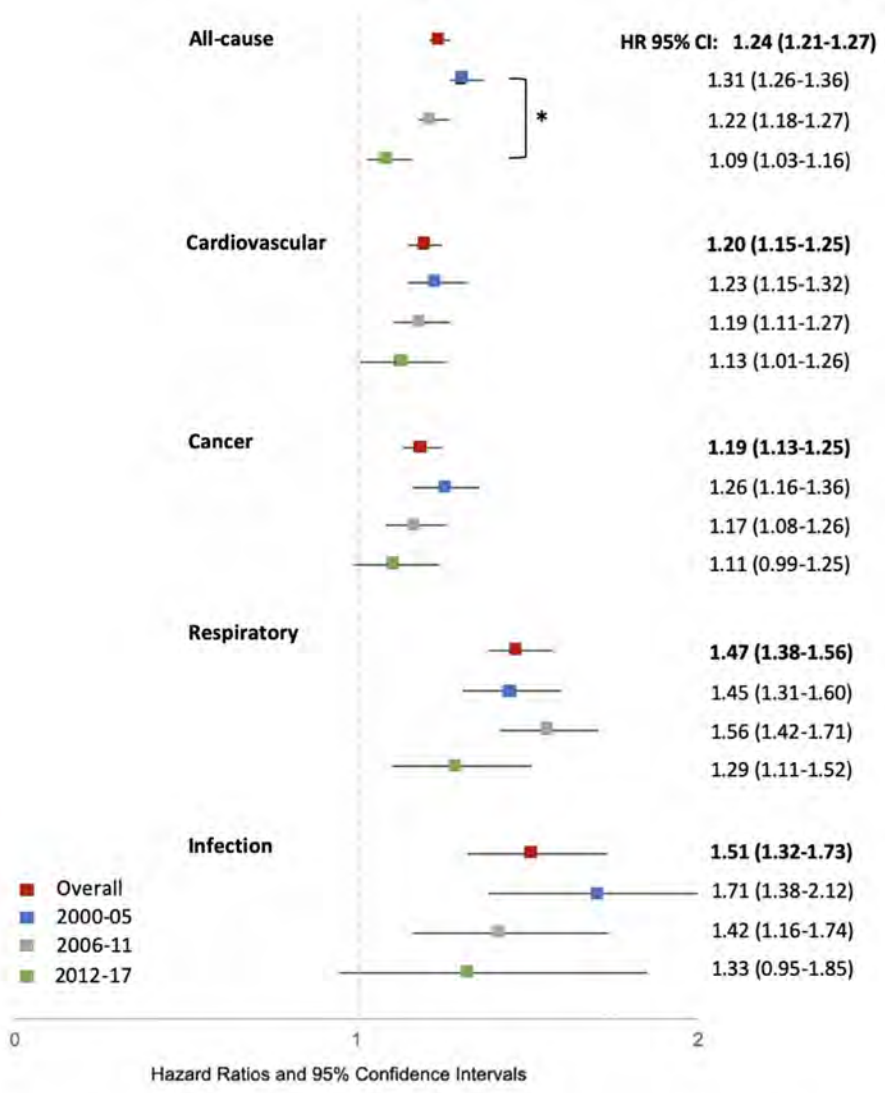

Figure 2. Forest plot illustrating overall risk and temporal trends of all-cause mortality and select causes of death in Veterans with incident RA.

*Interaction between RA status and 2012-17 vs 2000-05 time period, p = 0.02

Abbreviations: CI=confidence interval, HR=hazard ratio

Figure 2. Forest plot illustrating overall risk and temporal trends of all-cause mortality and select causes of death in Veterans with incident RA

were obtained from the National Death Index. Baseline covariates were obtained from national VHA databases and included demographics, smoking status, BMI, Rheumatic Disease Comorbidity Index, and health care utilization. Cox regression was used to examine the association of RA with all-cause and cause-specific mortality.

Results: We matched 69,433 RA patients (n=48,828 incident RA) to 612,230 non-RA patients. RA patients in this study were predominantly male (88.0%), had a mean age of 63 years, and were more frequently current smokers with greater comorbidity compared to non-RA. Crude incidence rates and causes of death are detailed in **Table 1**. After multivariable adjustment, RA patients were at increased risk of all-cause (HR 1.37 [95% CI 1.35-1.39]), cardiovascular (HR 1.34 [1.31-1.37]), cancer (HR 1.24 [1.21-1.28]), respiratory (HR 1.65 [1.60-1.71]), and infection-related mortality (HR 1.77, 1.65-1.90), as well as other less frequent causes **(Figure 1)**. Within these major causes of death, interstitial lung disease (ILD)-related deaths were most closely associated with RA (HR 3.91 [3.53-4.33]). Results were similar

in the incident RA cohort. In the incident cohort, all-cause mortality risk related to RA was significantly lower during 2012-2017 compared to 2000-2005 **(Figure 2)**, but still higher compared to non-RA. RA-associated risk for cardiovascular, cancer, respiratory, and infectious mortality were also numerically lowest in 2012-2017 but remained higher compared to non-RA.

Conclusion: In a national study of US veterans with and without RA from 2000-2017, we estimated a 37% increased risk of all-cause mortality in RA. Excess mortality was driven by cardiovascular, cancer, and respiratory causes, particularly ILD which was the most overrepresented cause of death in RA. Though our findings provide further support that RA-related mortality risk is improving over time, a mortality gap remains for all-cause and cause-specific mortality in RA suggesting continued efforts are needed to improve longevity.

SESSION INFORMATION

Session Date: Sunday, November 7, 2021

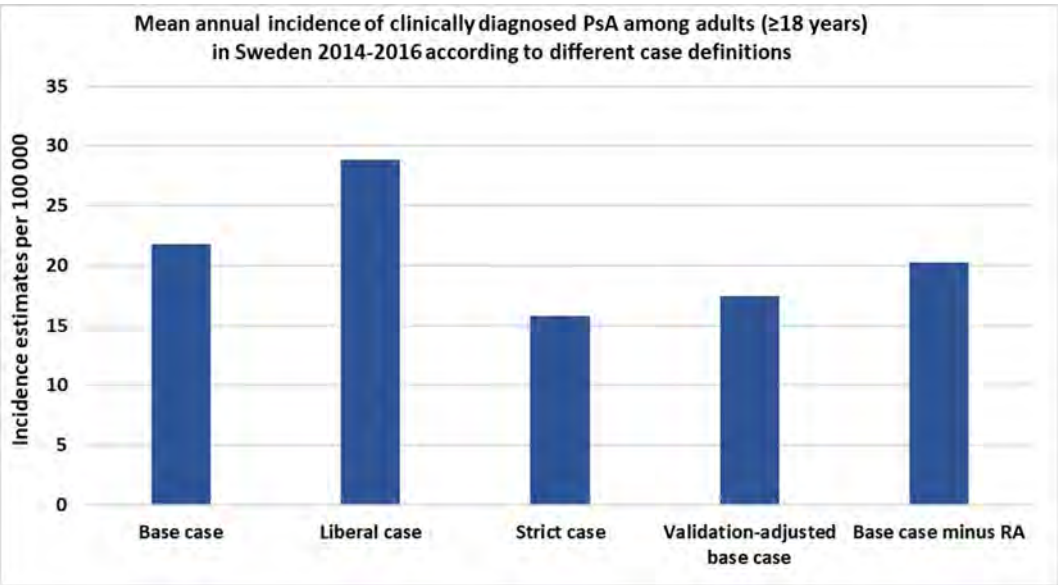
Session Title: Epidemiology & Public Health Poster II: Inflammatory Arthritis – RA, SpA, & Gout (0560–0593)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

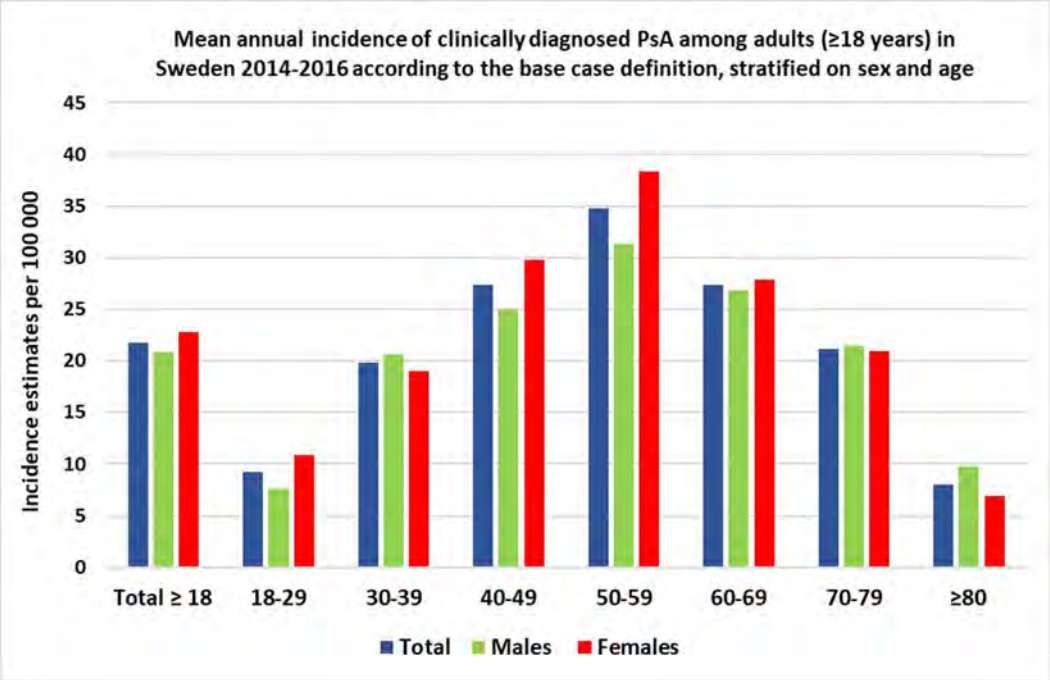
Background/Purpose: Psoriatic arthritis (PsA) incidence estimates vary considerably, and nationwide estimates are sparse. In Sweden, PsA is typically diagnosed in specialized care, although a limited subset with very mild disease may never be referred from primary care. The objectives of the current study were to estimate the mean annual incidence of PsA, diagnosed in specialized care, among adults in Sweden 2014-2016, overall and stratified by sex/age/education, and to describe the use of disease modifying anti-rheumatic drugs (DMARDs) among such cases.

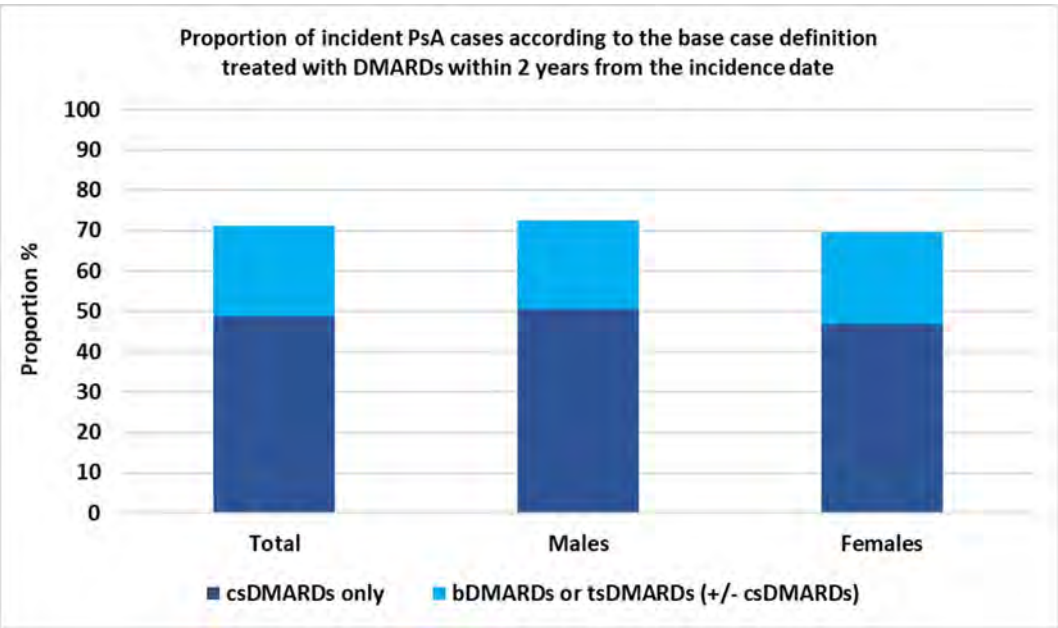
Methods: Incident PsA cases ≥18 years (y) 2014-2016 were identified from the Swedish National Patient Register (NPR) and/or the Swedish Rheumatology Quality register (SRQ), based on five different definitions; A) Base case (BC): ≥1 ICD-10 code for PsA (L40.5/M07.0-M07.3) as main diagnosis from rheumatology or internal medicine (IM) in NPR or PsA diagnosis registered in SRQ during the relevant year, and no prior such diagnoses; B) Liberal: ≥1 ICD code for PsA as main or secondary diagnosis from any department in NPR or PsA diagnosis in SRQ during the relevant year, and no prior such diagnoses; C) Strict: ≥1 ICD code for PsA as main diagnosis from rheumatology/IM during the relevant year and no prior such ICD registration or PsA diagnosis in SRQ, plus ≥1 additional PsA ICD code (main or secondary from any department) within 2 years of the first in NPR; D) As BC, but reducing the number of PsA cases in line with a prior validation study in which 80% of 200 incident cases fulfilled PsA classification criteria; E) As BC,



but excluding cases with ≥1 main diagnosis of rheumatoid arthritis from rheumatology/IM in NPR before or during 2 years after the incidence date. Irrespective of definition, cases < 18y at the incidence date or with a diagnosis of juvenile idiopathic arthritis (main/secondary) from any department in NPR or in SRQ ever, were excluded. Furthermore, DMARD use among cases within 2 years from the incidence date was assessed. The Swedish population the relevant years, demographics, education and treatments were retrieved from other national registers.

Results: The national, mean annual incidence of PsA, diagnosed in specialized care 2014-2016, in the population ≥18y was estimated at 21.8/100 000. Corresponding sensitivity analysis estimates ranged from 15.8 to 28.8/100 000 (Figure 1). The highest incidence was observed in the age-group 50-59y, followed by the age-groups 40-49 and 60-69y, regardless of sex (Figure 2). Irrespective of definition, the PsA incidence was numerically higher among females (Figure 2). Higher education was associated with lower age-/sex-standardized PsA incidence (>12y, 10-12y, ≤9y education: 21.1 vs 28.9 vs 25.1/100 000, respectively, in adults ≥30y by the BC definition). Among incident PsA cases





(BC definition), 22% received biologic or targeted synthetic DMARDs within two years of the incidence date, while an additional 49% received conventional synthetic DMARDs only (Figure 3).

Conclusion: The incidence of PsA, diagnosed in specialized care, in the adult Swedish population 2014-2016 was estimated at around 20/100 000. Almost 3/4 of cases received DMARD therapy within 2 years of the incidence date.

csDMARDs: Sulfasalazine, Leflunomide, Ciclosporine, Azathioprine, Methotrexate, Sodium aurothiomalate, Auranofin, Chloroquine, Hydroxychloroquine bDMARDs: Adalimumab, Certolizumab pegol, Etanercept, Golimumab, Infliximab, Abatacept, Ixekizumab, Secukinumab, Ustekinumab tsDMARDs: Apremilast, Tofacitinib

SESSION INFORMATION

Session Date: Sunday, November 7, 2021

Session Title: Epidemiology & Public Health Poster II: Inflammatory Arthritis – RA, SpA, & Gout (0560–0593)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Background/Purpose: Cardiovascular disease (CVD) is the leading cause of death in rheumatoid arthritis (RA). While chronic inflammation contributes to CVD pathogenesis, the role of specific circulating inflammatory mediators with CVD risk in RA is unclear. Because existing risk calculators underestimate CVD risk in RA patients, additional biomarkers to prognosticate CVD risk are needed. We evaluated the associations of serum cytokines and chemokines with incident major adverse cardiovascular events (MACE) and whether subclinical inflammation as assessed by these mediators predicts future CVD.

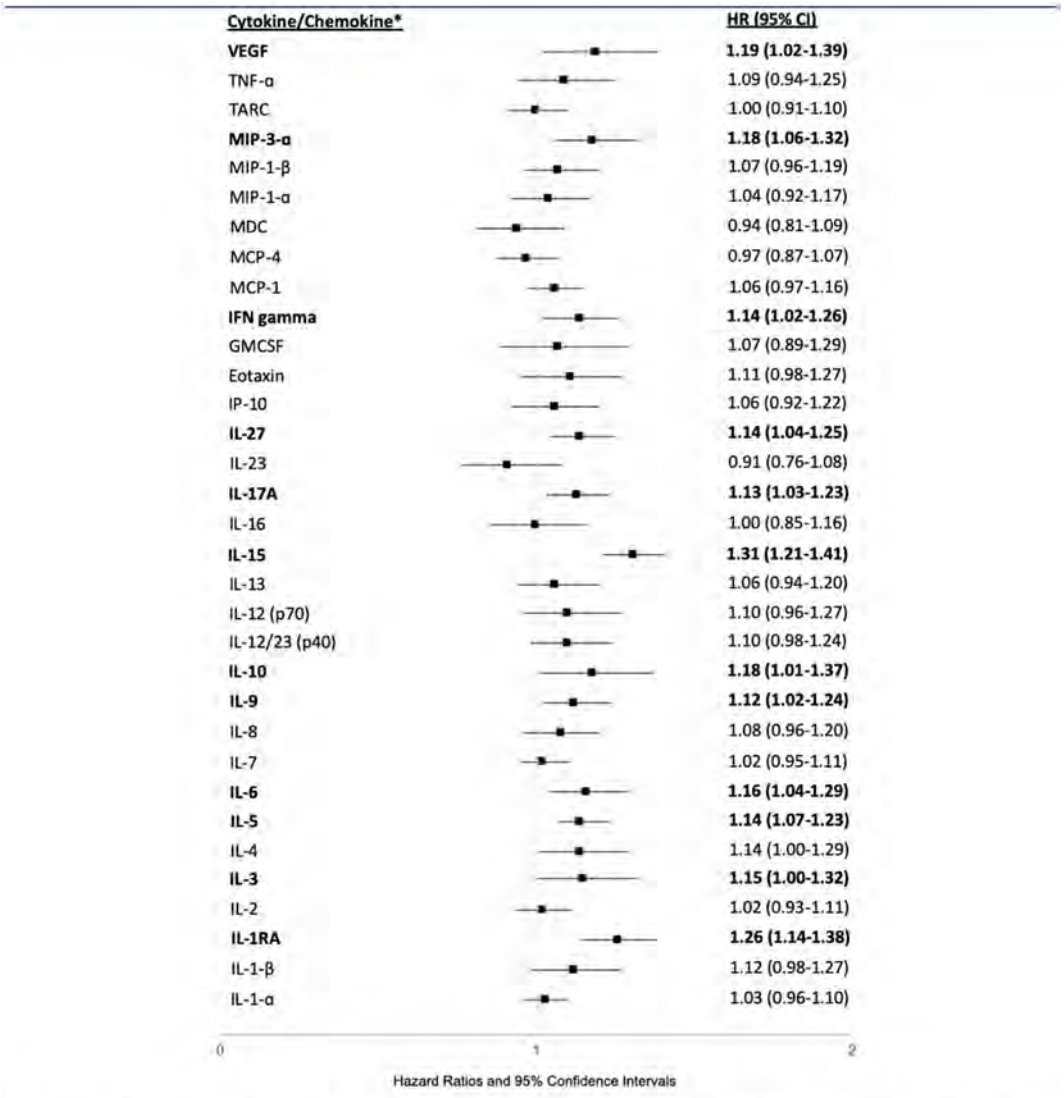

Figure 1. Association of circulating cytokine and chemokine concentrations with incident major adverse cardiovascular events in rheumatoid arthritis. Cytokines and chemokines each assessed in separate models adjusting for age, sex, BMI, current smoking, hypertension, diabetes, lung disease, prior MACE, medications (methotrexate, TNF biologic, prednisone), and DAS28. Values are hazard ratios per 1 SD change in analyte concentration.

*Analytes in bold indicate p<0.05

Abbreviations: CI=confidence interval, HF=hazard ratio, IL=interleukin, MDC=macrophage derived chemokine, MIP=macrophage inflammatory protein, TARC=thymus- and activation-regulated chemokine, TNF=tumor necrosis factor VEGF = vascular endothelial growth factor

Figure 1. Association of circulating cytokine and chemokine concentrations with incident major adverse cardiovascular events in rheumatoid arthritis

Methods: We included patients from a prospective, multicenter cohort of US Veterans with RA between 2003-2020 and followed them from enrollment to incident MACE, death, or end of follow-up. MACE was defined as a composite of myocardial infarction, coronary revascularization, stroke, or CVD-related death and identified with previously validated algorithms using ICD codes and the National Death Index. A multiplex assay was used to measure cytokines and chemokines (n=33) using serum banked at study enrollment. Values were log-transformed, standardized, and considered elevated if >2 SD above the mean. Covariates included demographics, smoking status, BMI, comorbidities (hypertension, diabetes, lung disease, prior MACE), LDL cholesterol, DAS28, and medications (methotrexate, TNFi, prednisone) at enrollment. Associations between individual analytes with incident MACE were estimated using multivariable Cox regression. In secondary analyses, we additionally adjusted for DAS28 and restricted the cohort to patients in remission or low disease activity (LDA).

Results: We studied 2,712 RA patients (mean age 72 years, 90% male, mean DAS28 of 3.7). We identified 406 MACE outcomes over 22,216 person-years of follow-up (19.3 events per 1,000 PY, mean time to event 4.9 years). After multivariable adjustment including traditional CVD risk factors, 12 of 33 analytes were significantly associated with an increased risk of MACE (HR per 1 SD range 1.11-1.22). Associations between cytokines / chemokines and incident MACE persisted after further adjusting for baseline DAS28 (Figure 1). Among 683 patients in remission/LDA at enrollment, 97 MACE outcomes occurred in follow-up. Five analytes (IL-6, IL-15, IL-17A, IFN-g, and macrophage inflammatory protein-3-α) remained associated with incident MACE (HR range 1.19-1.50) in these patients. The number of elevated cytokines was associated with an increased risk of MACE in the overall (HR 1.06 [95% CI 1.01-1.10]) and LDA / remission cohort (HR 1.11 [1.06-1.11]).

Conclusion: In a prospective, multicenter RA cohort, several circulating cytokines and chemokines were associated with a heighted risk of incident MACE, independent of traditional CVD risk factors and clinical RA disease activity. Elevated concentrations of these pro-inflammatory mediators similarly predicted MACE even in those in LDA or remission. Together, these findings suggest that measuring pro-inflammatory mediators in RA patients may aid in CVD risk stratification and prevention beyond existing traditional and RA-related CVD risk factors.

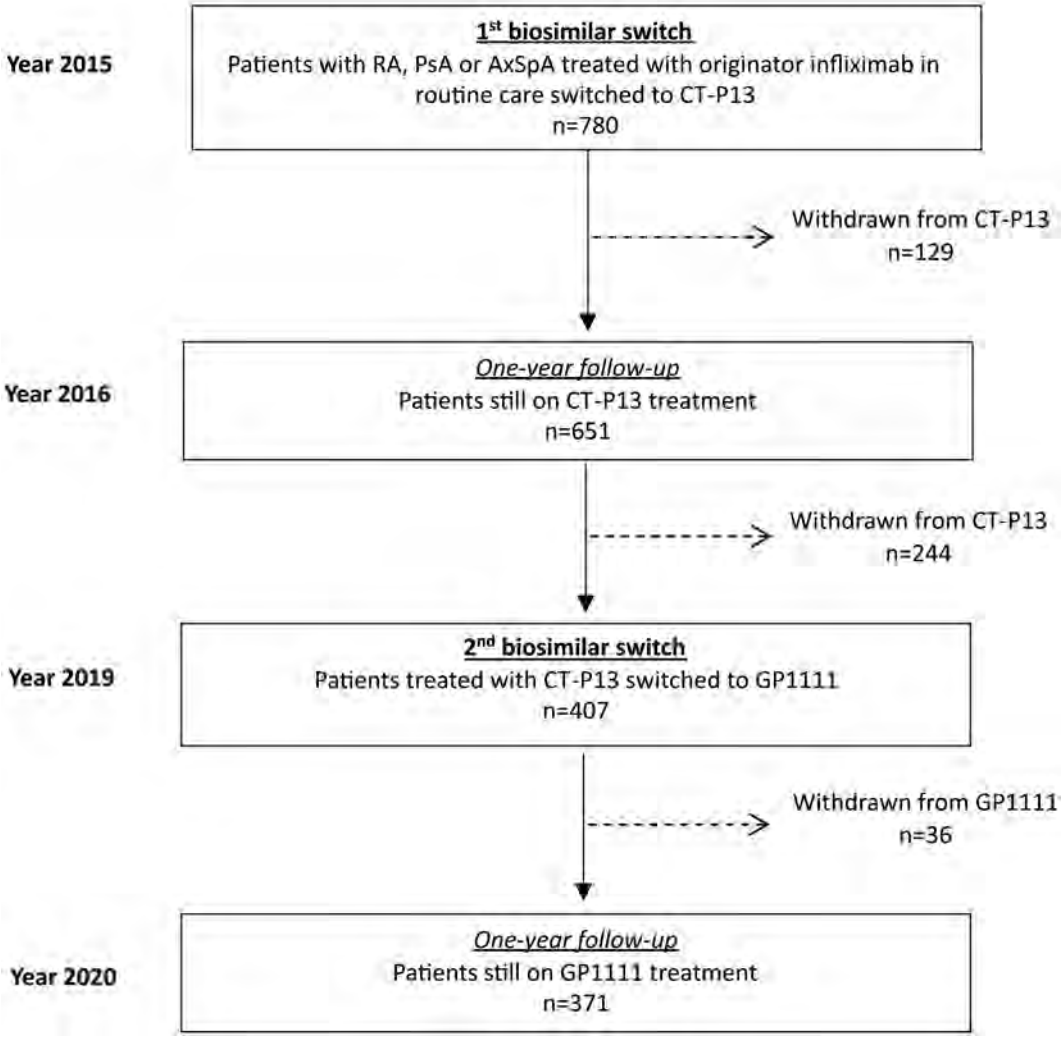
Figure Flowchart of patient inclusion and follow-up



Background/Purpose: In routine care, biosimilar to biosimilar infliximab switching may occur to save costs (=non-medical switching). Previous studies have investigated the efficacy and safety of a switch from originator infliximab to one of its biosimilars, whereas evidence regarding biosimilar to biosimilar switching is non-existing. Thus, robust, well-designed studies are needed to investigate the consequences of multiple switches on treatment effectiveness, drug safety and patient-reported outcomes.

In this real-life study, we aimed to explore baseline clinical characteristics and one-year treatment status in patients with inflammatory arthritis, who underwent mandatory multiple infliximab biosimilar switches (from originator infliximab to CT-P13 and subsequently to GP1111).

Methods: Observational cohort study based on DANBIO registry (clinical data) linked with national patient registries (prior comorbidities). For each switch, main outcomes were one-year treatment status (withdrawn yes/no), reasons for withdrawal, and baseline characteristics associated with withdrawal (Mann-Whitney, χ^2 test).

Results: In 2015, 780 patients switched from originator infliximab to biosimilar CT-P13 in accordance with a national guideline (366 RA/113 PsA/256 AxSpA; 51% women; median age 56 years; disease duration 14 years, infliximab treatment 7 years), **Table**. At baseline, 42% was in remission. At 1 year, 83% maintained CT-P13 treatment.

In 2019, 52% of the 780 patients were still receiving treatment with CT-P13 and performed a 2nd biosimilar switch to GP1111 due to change of guideline. After 1 year, 91% maintained GP1111, **Figure**.

For both rounds of switching, withdrawal during follow-up was associated with higher baseline patient-reported outcomes (PROs), higher HAQ and less frequent acceptable symptom state (PASS=yes) whereas objective markers (CRP, physician global) were similar.

Conclusion: Multiple biosimilar infliximab switches were well tolerated in patients who were long-term users of the originator. Risk of withdrawal was associated with higher baseline PROs, suggesting that outcomes were more affected by patient-related than drug-related factors.

Prevalence and Early Progression of Lung Diseases in Patients with Recently-Diagnosed Rheumatoid Arthritis: A Prospective Cohort Study

Tina Mahajan[1], Daniel Hershberger[1], Matt Devries[2], Punyasha Roul[1], Yangyuna Yang[1], Sherrie Edwards[1], Geoffrey Thiele[1], Ted Mikuls[1], James O'Dell[1] and Bryant England[1], [1]University of Nebraska Medical Center, Omaha, NE, [2]University of Nebraska Medical Center, Omaha

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Epidemiology & Public Health Poster II: Inflammatory Arthritis – RA, SpA, & Gout (0560–0593)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Several types of lung diseases complicate the rheumatoid arthritis (RA) disease course such as interstitial lung disease (ILD) and obstructive lung diseases. The prevalence of lung diseases varies substantially across studies, and there remains a poor understanding of the progression of lung diseases early in the RA disease course. We aimed to identify the prevalence and early progression of lung diseases in patients with recently diagnosed RA.

Methods: We performed a prospective cohort study of lung diseases in recently-diagnosed RA patients at an academic center from 2017-2021. Patients fulfilled the 2010 ACR criteria for RA and were diagnosed within the prior two years. At baseline and 1-year follow-up visits, patient-reported outcomes measures (e.g. Modified Research Council [MRC] dyspnea scale and Health Assessment Questionnaire), clinical assessments (e.g. DAS28-ESR), and complete

Table 1. Prevalence and Radiographic Severity of Lung Abnormalities on High-Resolution CT in Early RA Patients (n=37)

**individual severity scores listed

Prevalence and Radiographic Severity of Lung Abnormalities on High-Resolution CT

pulmonary function tests (PFTs) were collected. At the initial visit, a high-resolution computed tomography (HRCT) scan of the lungs was completed with thin (1.25 mm) slices with prone and supine imaging. HRCTs were scored semi-quantitatively in 6 lung regions by an expert chest radiologist blinded to clinical data.

Results: Among 37 recently-diagnosed RA patients, mean age was 57.2 (SD 11.9) years, and the majority were female (81.1%), white (81.1%), seropositive (83.8% RF, 86.5% anti-CCP), and MTX treated (81.1%). Cigarette smoking history was present in 59.5%, but a minority of patients had clinically-diagnosed lung disease (5.4% COPD, 10.8% asthma, 2.7% ILD). Despite 86.5% of subjects reporting no or only slight dyspnea (MRC grade 0 or 1), 29.7% had evidence of parenchymal disease, 59.5% had evidence of airway disease, and 62.2% had pulmonary nodules on HRCT (**Table 1)**. Semiquantitative HRCT scoring revealed most airway and parenchymal abnormalities to be mild in severity. Similarly, physiologic impairment on PFTs was infrequent with 16.2% demonstrating restrictive and 18.9% obstructive spirometry. Among patients who have completed 1-year of follow-up (n=27), there was no significant change in PFT parameters (FEV1, FVC, TLC, DLCO) or MRC score (**Table 2**). Stability in PFTs was present even among RA patients with detectable lung disease on HRCT. Baseline DAS28-ESR was negatively correlated with FVC (r = -0.42, p = 0.01) and positively correlated with MRC scores (r=0.57, p< 0.001), but not with other PFT parameters or with HRCT findings. Seropositivity for RF or anti-CCP antibody was not associated with an increase in airway or parenchymal abnormalities.

Conclusion: In this prospective cohort of patients with recently-diagnosed RA who underwent systematic evaluation for lung disease, airway and parenchymal abnormalities were commonly detected on HRCT but mild in severity. Pulmonary nodules were the most detected HRCT finding. Physiologic impairment was infrequent, and the stability of PFTs and dyspnea symptoms early after RA diagnosis is reassuring and may suggest that patients with asymptomatic imaging findings do not require treatment modifications, though longer follow-up periods are needed.

Table 2. Changes in PFT Parameters and MRC Dyspnea Scores over 1-Year of Follow-Up

	Baseline visit	1-Year Follow-Up Visit	P value*

World Mortality of Spondyloarthritis and Inflammatory Bowel Diseases in 2015 and Its Evolution Between 2001 and 2015

Olivier Fakih, Clement Prati, Daniel Wendling and Frank Verhoeven, Service de rhumatologie, CHU de Besançon, Besançon, France

SESSION INFORMATION

Session Date: Sunday, November 7, 2021
Session Title: Epidemiology & Public Health Poster II: Inflammatory Arthritis – RA, SpA, & Gout (0560–0593)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: There is little epidemiological data on mortality in spondyloarthritis (SpA). This study aimed to determine countries' mortality rates of ankylosing spondylitis (AS) and psoriatic arthritis (PsA), as well as chronic inflammatory bowel diseases (IBDs), which are related to SpA, and to describe their evolution between 2001 and 2015.

Methods: We used mortality data from the World Health Organisation (WHO), freely available on its website, which shows the number of deaths classified by age, sex, and cause of death coded by ICD-10. The code M45 was used for AS, L405 for PsA, K50 for Crohn's disease (CD), and K51 for ulcerative colitis (UC). Age-standardized mortality rates (ASMR) were constructed using the 2015 WHO reference population and are expressed as deaths per million inhabitants. Temporal trend analyses of ASMR were performed between 2001 and 2015, considering only countries with up to 3 years of missing data, using joinpoint regression.

Results: In 2015, the global ASMR of AS was 0.13 (0.11-0.14), ranging from 0.02 in Japan to 2.00 in Iceland (Figure 1A). The ASMR was 0.20 (0.18-0.23) for men and 0.07 (0.06-0.09) for women ($p < 0.0001$). The trend analysis did not show any significant variation between 2001 and 2015 (Figure 2A). The ASMR in Europe (0.17 (0.15-0.20)) was significantly higher than in North America (0.12 (0.09-0.14)) ($p=0.008$), South America (0.09 (0.06-0.12)) ($p=0.0001$) and Asia (0.08 (0.05-0.10)) ($p < 0.0001$).

For PsA, the global ASMR in 2015 was 0.04 (0.03-0.05), ranging from 0.01 in Mexico to 0.13 in Greece (Figure 1B). The ASMR was 0.06 (0.04-0.07) for men and 0.03 (0.02-0.04) for women ($p=0.01$). The trend analysis showed a signif-

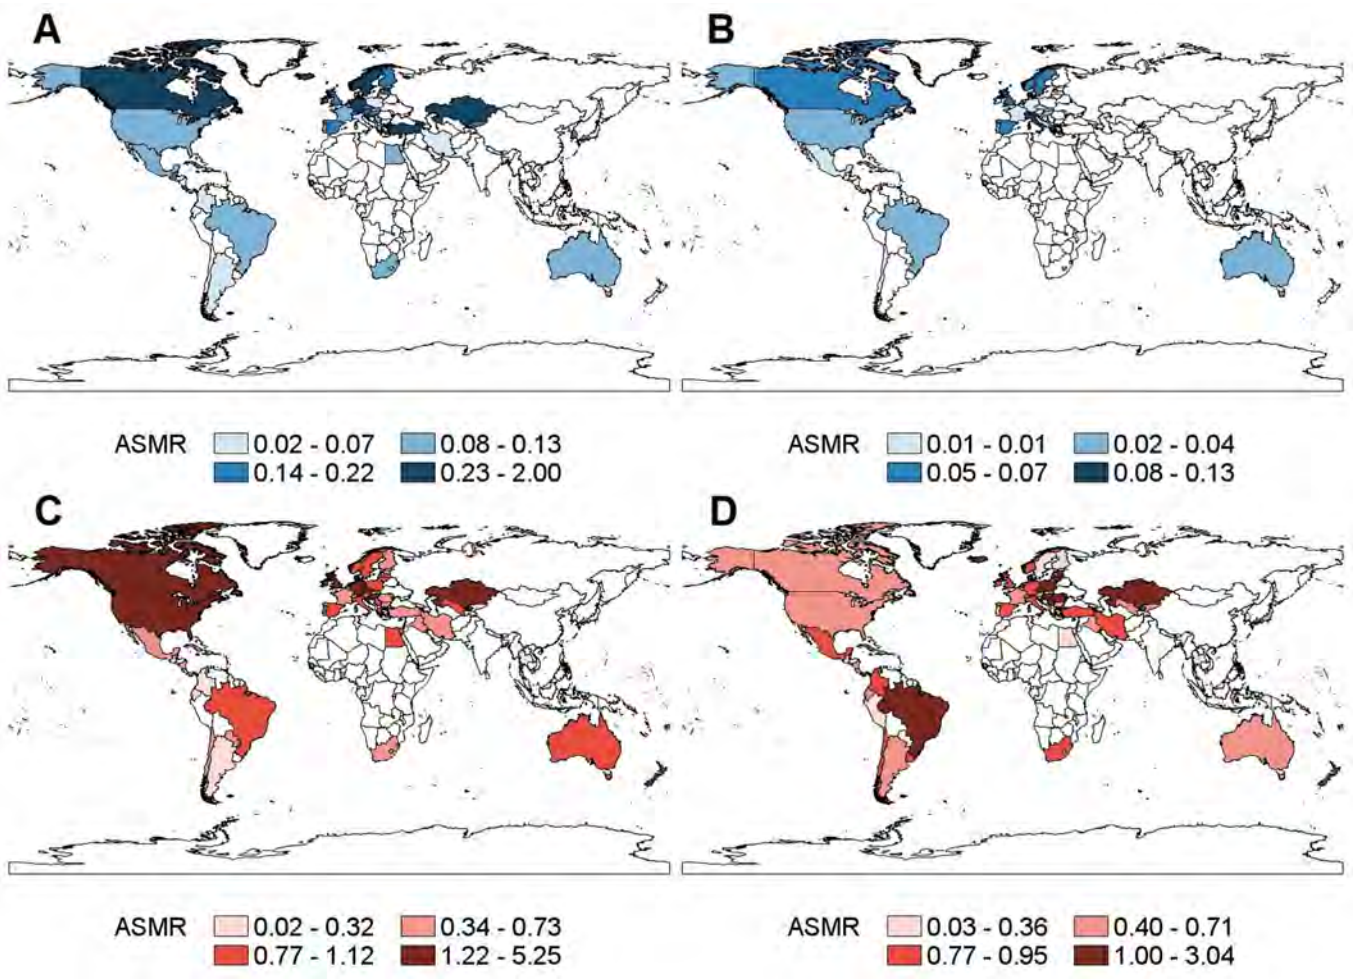

Figure 1. 2015 ASMR by country for ankylosing spondylitis (A), psoriatic arthritis (B), Crohn's disease (C) and ulcerative colitis (D).

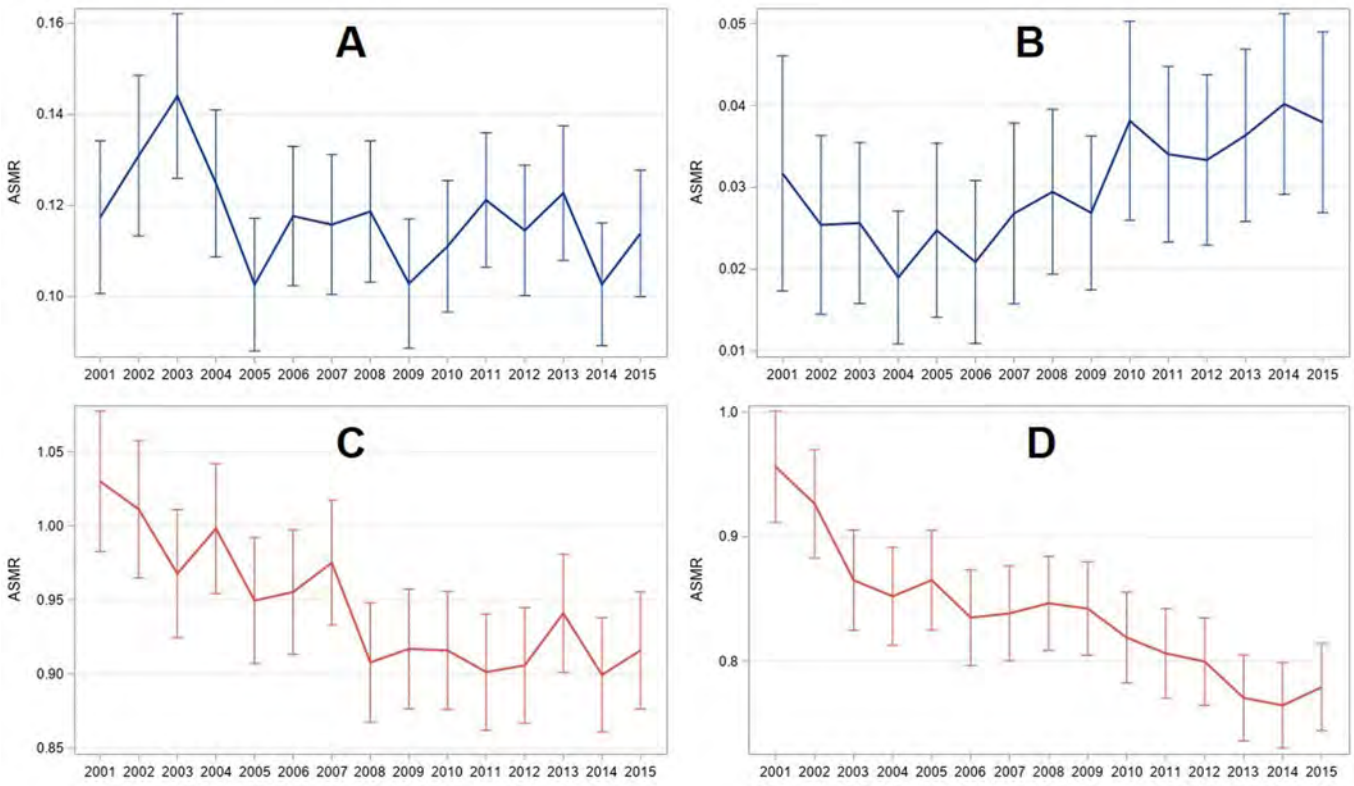

Figure 2. Evolution of the global ASMR with its 95% confidence interval from 2001 to 2015 for ankylosing spondylitis (A), psoriatic arthritis (B), Crohn's disease (C) and ulcerative colitis (D).

icant increase from 2004 to 2015 with a mean annual percent change (APC) of 5.94% (p=0.02) (Figure 2B). The ASMR in Europe (0.05 (0.03-0.06)) was significantly higher than in South America (0.02 (0.00-0.03)) (p=0.02).

For CD, the global ASMR in 2015 was 0.86 (0.82-0.89), ranging from 0.02 in Thailand to 5.25 in Luxembourg (Figure 1C). The ASMR was 0.41 (0.38-0.43) for men and 0.38 (0.36-0.41) for women (p=0.17). The trend analysis showed a significant decrease from 2001 to 2015 with a mean APC of -0.82% (p=0.048) (Figure 2C). The ASMR in Europe (1.12 (1.05-1.19)) was significantly lower than in North America (1.31 (1.21-1.41)) (p=0.001), but significantly higher than in South America (0.57 (0.51-0.64)) ($p < 0.0001$) and Asia (0.27 (0.23-0.32)) ($p < 0.0001$).

For UC, the global ASMR in 2015 was 0.76 (0.73-0.79), ranging from 0.03 in Thailand to 5.48 in Saint Lucia (Figure 1D). The ASMR was 0.37 (0.35-0.39) for men and 0.23 (0.21-0.24) for women ($p < 0.0001$). The trend analysis showed a significant decrease from 2001 to 2015 with a mean APC of -1.29% (p=0.01) (Figure 2D). The ASMR in Europe (1.00 (0.93-1.06)) was significantly higher than in North America (0.64 (0.57-0.71)) ($p < 0.0001$), Africa (0.57 (0.41-0.72)) ($p < 0.0001$), South America (0.84 (0.76-0.91)) (p=0.003)), Asia (0.47 (0.93-1.06)) and Oceania (0.58 (0.38-0.79)) (p=0.003).

Conclusion: ASMR for IBD are higher than those for SpA and are decreasing over time, in contrast to SpA where they remain essentially stable. There are geographical disparities which must be interpreted with caution due to the declarative nature of the data.

Associations of the *MUC5B* Promoter Variant with Timing of Articular Diagnosis and Interstitial Lung Disease in Rheumatoid Arthritis

Gregory McDermott[1], Ritu Gill[2], Staci Gagne[3], Suzanne Byrne[3], Weixing Huang[3], Jing Cui[4], Lauren Prisco[5], Alessandra Zaccardelli[3], Lily Martin[3], Nancy Shadick[6], Paul Dellaripa[3], Tracy Doyle[7] and Jeffrey Sparks[3], [1]Brigham and Women's Hospital, Brookline, MA, [2]Beth Israel Deaconess Medical Center, Boston, MA, [3]Brigham and Women's Hospital, Boston, MA, [4]Brigham Women's Hospital, Boston, MA, [5]Brigham and Women's Hospital, Pound Ridge, MA, [6]Brigham & Women's Hospital, Boston, MA, [7]Brigham and Women's Hospital, West Roxbury, MA

SESSION INFORMATION

Session Date: Sunday, November 7, 2021

Session Title: Epidemiology & Public Health Poster II: Inflammatory Arthritis – RA, SpA, & Gout (0560–0593)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Background/Purpose: The common promoter variant of *MUC5B* (G >T, rs35705950) is associated with increased mucin 5B production in lung parenchyma and is an established genetic risk factor for rheumatoid arthritis-associated interstitial lung disease (RA-ILD). The associations of this genetic polymorphism with features of the articular RA disease course and RA-ILD onset have not been previously studied. We investigated the association of the *MUC5B* promoter variant with age of RA onset and timing of RA-ILD within the RA disease course.

Methods: Patients with RA were identified from a large, multi-hospital biospecimen and clinical data collection study using a previously described algorithm and confirmed by medical record review. All patients with RA who had computed tomography (CT) imaging of the chest, lung biopsy, or autopsy were identified and screened for RA-ILD. RA-ILD was confirmed based on imaging findings, pulmonary function testing, and pathologic information using accepted criteria. We analyzed RA patients with available genotype information on

Table 1: Characteristics of patients with rheumatoid arthritis at enrollment (n=1,005).

rs35705950. Dates of RA and RA-ILD onset were determined by medical record review. Smoking and other covariate data were obtained by health questionnaire survey at enrollment and supplemented by electronic query and medical record review. We compared continuous variables using Wilcoxon rank sum tests and categorical variables using chi-squared tests. We examined the associations between *MUC5B* promoter variant status and features of RA including age of RA onset and RA-ILD onset relative to articular RA-onset using multivariable logistic regression.

Results: We identified 1,005 RA patients with available genotype data for rs35705950 (mean age 45 years; 79% women; 83% White). The *MUC5B* promoter variant was present in 155 RA patients (15.4%). A greater proportion of patients with the variant developed RA-ILD (12.9% vs. 3.8%, multivariable odds ratio (OR) 3.59 [95%CI 1.97-6.55]. Patients with the *MUC5B* promoter variant had increased odds of RA-ILD in the early RA period (prior to or within 5 years of articular RA diagnosis; OR 5.84, 95%CI 2.29-14.89). The *MUC5B* promoter variant was associated with older age of articular RA onset (50.1 vs 45.7 years, p=0.045) and increased odds of articular disease onset after age 55 (OR 1.58, 95%CI 1.10-2.27. The proportion with seropositive RA was similar by *MUC5B* status (54.8% vs. 61.2%, p=0.33).

Conclusion: We found that the *MUC5B* promoter variant may influence both older-onset RA and RA-ILD development in preclinical or early RA. *MUC5B* may impact RA-ILD risk early in the disease course of RA, particularly in those with older-onset RA, regardless of serostatus. These findings may lead to the identification of RA patients amenable to screening or prevention strategies for RA-ILD.

Abstract Number: 0577

Comorbidity Burden as Scored Using the Rheumatic Disease Comorbidity Index (RDCI) Is Associated with Varying Treatment Patterns in Patients with Inflammatory Arthritis – a Study Using the EHR-Derived Rheumatic and Arthritis Disease Information Registry (RADIR)

Diviya Rajesh, Deanna Jannat-Khah, Huong Do, Jonah Levine, Medha Barbhaiya, Lisa Mandl and Vivian Bykerk, Hospital for Special Surgery, New York, NY

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Epidemiology & Public Health Poster II: Inflammatory Arthritis – RA, SpA, & Gout (0560–0593)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Higher comorbidity burden (CB) has been associated with treatment choices in RA, but not assessed in populations including multiple forms of inflammatory arthritis (IA) in routine practice settings. The Rheumatic Disease Comorbidity Index (RDCI), scored 0-9, is a validated method of quantifying CB in RA patients, but is infrequently reported in USA-based electronic health record (EHR)-derived cohort studies. The objective of this study is to examine if a higher CB is associated with differential prescribing and reported use (Rx) of oral glucocorticoids (GC) and TNF inhibitors (TNFi), therapies both commonly used to treat many forms of IA, using data from a new EHR-derived 'Rheumatic and Arthritic Diseases Information Registry' (RADIR) of patients with systemic rheumatic diseases (SRDs).

Methods: We constructed RADIR to include adults aged ≥ 18 years seen at least twice by a rheumatologist from 3/1/2018-2/28/2021 at a tertiary academic center in New York City. Eligible patients had ≥ 2 ICD-10-CM codes entered ≥7 days apart for a SRD which can present with IA. Patient data included demographics, labs, medications, and comorbid conditions (reported by ≥ 2 ICD-10-CM codes) to score the RDCI. Of 12,216 patients entered into RADIR, we included patients with forms of IA commonly treated with TNFi. IA patients included in this retrospective cohort study had ≥ 2 ICD-10-CM codes for RA, PsA, AS, SpA, JRA, JIA, Auto Inflammatory Syndromes, Enteric or Reactive Arthritis, Sarcoidosis, or Behcet's Disease. Rx of GC and TNFi, demographics, and comorbidities were compared in IA patients with a low CB (RDCI ≤ 2) and high CB (RDCI > 2) by Pearson's chi-squared tests. Two multivariable logistic regression models were used to assess for independent associations (odds ratio (OR), 95% CI) between RDCI score and Rx of GC and TNFi in IA, using age, gender, race, ethnicity, obese BMI and smoking as covariates.

Results: Patients with 11 types of IA (n= 6,587) were mostly white (74%), female (72%), and without exposure to tobacco (67%) (Table 1). Most frequent forms of IA were RA (65%) and PSA (22%) (Table 1). Patients with a high CB (RDCI >2) were older and more often Black, Hispanic/Latinx, and with a BMI ≥ 30 (Table 2). Patients with a high CB had more Rx of GC and less Rx of TNFi (Table 2). Regression analyses revealed that for every 1 point increase in the RDCI, there was a 0.09 decrease in the odds of Rx of TNFi (OR 0.91, 95%CI [0.85, 0.98]) and a 0.26 increase in the odds (OR 1.26, 95%CI [1.19, 1.33]) of Rx of GC, while controlling for age, sex, race, ethnicity, obesity and smoking status (Table 3).

Table 1. Patient Characteristics	
	Total Cohort (N=6,574)
Age in years, mean (SD)	58.7 (16.3)
Male Sex	1824 (27.7%)
Race	
White	4874 (74.1%)
Black	513 (7.8%)
Other	953 (14.5%)
Ethnicity	
Hispanic/Latinx	709 (10.8%)
Smoking Status	
Never	4404 (67.0%)
Ever (Former, Current, Passive)	2161 (32.9%)
Obese (BMI≥30)	2055 (31.3%)
Rheumatic Diseases	
RA	4287 (65.2%)
PsA	1436 (21.8%)
Other	979 (14.9%)
Comorbidity	
Lung Disease	435 (6.6%)
Myocardial Infarction	20 (0.3%)
Other Cardiovascular Disease	347(5.3%)
Stroke	46 (0.7%)
Hypertension	751 (11.4%)
Fracture	380 (5.8%)
Depression	250 (3.8%)
Diabetes mellitus	242 (3.7%)
Cancer	206 (3.1%)
Ulcer/Other Stomach Problem	72 (1.1%)
Current Medication Use	
Oral Steroids	1497 (22.8%)
csDMARDs	1774 (27.0%)
TNFi bDMARDs	1623 (24.7%)
Note: All results are reported as n (%) unless otherwise noted. Comorbid conditions were used to calculate the RDCI and were determined using ICD-10 codes. Some pts had more than one IA diagnosis.	

Conclusion: This analysis of a large sample of IA patients cared for in practice included in a new EHR-derived registry of SRDs indicates more patients will be prescribed GCs and fewer prescribed TNFi as CB progressively increases, a relationship previously only described in RA. These data suggest that IA patients with a high CB may be receiving suboptimal treatment. These findings may have implications regarding safety, effectiveness and health disparities of Rx patterns that warrant further investigation.

Table 2. Comparison of Demographics, Comorbidities and Medication in IA Patients with High vs. Low Comorbidity Burden Estimated using the Rheumatic Disease Comorbidity Index (RDCI)

Variable	Low Comorbidity Burden (RDCI≤2)	High Comorbidity Burden (RDCI>2)	P-Value

Hyperinsulinemic Diet and Increased Risk of Female Gout: 2 Prospective Cohort Studies of US Women over 30 Years

Natalie McCormick[1], Chio Yokose[2], Na Lu[3], Amit Joshi[1] and Hyon K. Choi[4], [1]Massachusetts General Hospital, Boston, MA, [2]Massachusetts General Hospital, Waltham, MA, [3]Arthritis Research Canada, Vancouver, BC, Canada, [4]Massachusetts General Hospital, Lexington, MA

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Epidemiology & Public Health Poster II: Inflammatory Arthritis – RA, SpA, & Gout (0560–0593)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Gout and the metabolic (insulin resistance) syndrome frequently coexist. Intravenous insulin has been shown to raise serum urate (SU) levels in physiologic studies[1] and a Mendelian Randomization study[2] showed a causal role of fasting insulin on the risk of hyperuricemia and gout. However, it is unknown whether habitual hyperinsulinemic dietary intake confers gout risk, especially in women, a pertinent subgroup given the rising global burden of female gout,[3] and higher prevalence of obesity and type II diabetes in female gout patients compared to males. We prospectively examined the relation between two distinct insulin-related dietary indices and risk of incident gout in two large cohorts of US women over 30 years.

Methods: We studied 170,699 women from the Nurses Health Study I (1986-2016) & II (1989-2017) free of gout at baseline. Dietary intake and covariates were ascertained by validated questionnaires every 2-4 years, along with new cases of physician-diagnosed gout every 2 years. Insulinemic potential of diet was evaluated using: 1) a food-based

Table 1. Hazard Ratio (HR) of Incident Gout According to Quintiles of Insulin-Related Dietary Index

*Multivariable (MV) models adjusted for age (month), White race, smoking, menopause, hormone use, physical activity (MET h/week), history of hypertension, and diuretic use. **MV + BMI models additionally adjusted for body mass index (BMI), a likely causal intermediate.

empirical dietary index for hyperinsulinemia (EDIH) score that was pre-defined based on circulating C-peptide levels,[4] and reflects *insulin resistance*;[5] and 2) dietary insulin index (DII), which reflects *transient, postprandial insulin secretion*.[5] We assigned EDIH and DII scores for each woman, adjusted for total energy intake, and used Cox proportional hazard models to prospectively examine the relation between cumulative average scores and incident gout, adjusting for potential confounders.

Results: We ascertained 5,283 cases of incident gout over 4,317,270 person-years: 3,670 cases in the NHS and 1,613 in the NHS II. In pooled multivariable-adjusted (MV) analyses, women in highest EDIH quintile (i.e., higher insulin resistance) had 1.9-times (95% CI 1.7 to 2.1) greater gout risk, compared to the lowest (**Table 1**). This attenuated with further adjustment for BMI, a likely causal intermediate, but remained positive (MV HR 1.5, 95% CI 1.4 to 1.7). DII scores were inversely associated with gout risk (HR 0.74, 95% CI 0.68 to 0.80) (**Table 1)**.

Table 2. Hazard Ratio (HR) of Incident Gout According to Quintiles of Hyperinsulinemic Diet (EDIH) Score, by subgroups

Alcohol use						
No	1.00 (Ref)	1.20 (0.94 to 1.54)	1.10 (0.87 to 1.40)	1.47 (1.17 to 1.85)	1.95 (1.56 to 2.43)	0.34
Yes	1.00 (Ref)	1.07 (0.96 to 1.20)	1.35 (1.21 to 1.50)	1.54 (1.39 to 1.72)	1.84 (1.66 to 2.04)	

EDIH effects were similar across subgroups (**Table 2**) and cohorts, with HRs of 1.8 (1.7 to 2.1) in the NHS I (mean age of 50 years at baseline; 49% post-menopausal) and 2.1 (1.7 to 2.4) in the NHS II (mean age 36 years at baseline; 3.6% post-menopausal).

Conclusion: EDIH scores, reflecting chronic hyperinsulinemia (i.e., greater insulin resistance with reduced clearance), were positively associated with the risk of incident gout in these large prospective cohorts of US women, even beyond the pathway through adiposity. Conversely, higher DII scores, which reflect short-term, postprandial elevations in insulin levels (i.e., higher insulin sensitivity) conferred a lower risk. This corroborates human physiologic experiments[1] and Mendelian Randomization studies[2] showing insulin resistance can increase SU levels by decreasing renal excretion of urate and supports lowering insulinemic potential of diet as a strategy to reduce gout risk, especially in women.

Predicting Treatment Change in Rheumatoid Arthritis Patients Treated with TNF Inhibitors as First-Line Biologic Agent

Yinzhu Jin[1], Joan Landon[1], Whitney Krueger[2], Alexander Liede[2] and **Seoyoung Kim**[3], [1]Brigham and Women's Hospital and Harvard Medical School, Boston, MA, [2]AbbVie Global Epidemiology, Chicago, [3]Brigham and Women's Hospital, Boston, MA

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Epidemiology & Public Health Poster II: Inflammatory Arthritis – RA, SpA, & Gout (0560–0593)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Patient characteristics including serostatus, body mass index (BMI), and smoking are considered to be associated with their response to disease-modifying anti-rheumatic drugs (DMARD) treatment for rheumatoid arthritis (RA); however, previous real-world studies using claims data failed to identify factors strongly related to biologic DMARD treatment patterns. We utilized a linked database of claims and electronic health records (EHR) to explore how additional factors derived from the clinically rich EHR data may play a role in predicting

Methods: We used Optum Market Clarity database which linked pharmacy and medical claims with continuous, longitudinal EHR data from 01/01/2011 to 09/30/2019. We identified adults with RA who initiated a TNFi from prescription or procedure records. The first TNFi prescription date was defined as index date. Patients were required to have at least two RA diagnosis codes without any biologic or targeted synthetic (ts) DMARDs during 365-day pre-index baseline period. One-year continuous clinical activity were required before and after the index date. Outcomes were assessed during one-year post-index period. The primary outcome was any treatment change defined as having a different TNFi or switching to non-TNFi biologic or tsDMARDs. The secondary outcomes were the individual components of the primary outcome and non-persistence. Treatment non-persistence was defined as having no subsequent refill of the index TNFi or other biologics/tsDMARDs. Multivariable logistic regression with pre-defined variables and least absolute shrinkage and selection operator (LASSO) regression model were used as prediction models. C-statistics of each model and odds ratios (OR) with 95% confidence intervals of predictors were reported.

Results: We identified 24,871 RA cohort who initiated TNFi: 10,471 adalimumab, 1,166 certolizumab pegol, 9,391 etanercept, 1,037 golimumab, and 2,806 infliximab initiators. The mean age was 55.5 (±13.7) years and 77.2% were female. 83% were White, and 53.3% were covered by commercial insurances. 30.9% of the study patients were seropositive (**Table 1**). During the one-year after index TNFi initiation, 5,527 (22.2%) patients had either TNFi cycling or switching to non-TNFi/tsDMARDs. Specifically, 3,870 (15.6%) had TNFi cycling, 1,646 (6.6%) switched to non-TNFi biologics, and 780 (3.1%) switched to tsDMARDs. 5,157 (20.7%) were non-persistent users. In multivariable logistic regression models, index TNFi, gender, race, and insurance types were predictors of the treatment changes (**Table 2**). Model performance was similar between the regular and LASSO regression models. Adding EHR-specific factors, including BMI, smoking status, and serology tests improved the prediction models to some extent but the model performance was still suboptimal (c-statistics 0.64).

Conclusion: Predicting treatment change in RA patients with both claims and clinically rich EHR data still remains challenging. It could be due to unmeasured factors such as prescriber's preference or patient's belief in the medication which may play an important role in the treatment patterns.

Association Between Female Reproductive Factors and Gout: A Nationwide Population-based Cohort Study of 1 Million Postmenopausal Women

Yeonghee Eun[1], In Young Kim[2], Kyungdo Han[3], Kyu Na Lee[3], Dong-Yun Lee[1], Dong Wook Shin[1], Seonyoung Kang[1], Seulkee Lee[1], Hoon-Suk Cha[1], Eun-Mi Koh[1], Jaejoon Lee[1] and Hyungjin Kim[1], [1]Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, Republic of Korea, [2]National Police Hospital, Seoul, Republic of Korea, [3]Soongsil University, Seoul, Republic of Korea

SESSION INFORMATION

Session Date: Sunday, November 7, 2021

Session Title: Epidemiology & Public Health Poster II: Inflammatory Arthritis – RA, SpA, & Gout (0560–0593)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Background/Purpose: Previous studies have shown that the incidence and risk factors of gout differs according to sex. However, little research has been done on the association between reproductive factors and gout. We conducted an analysis of a large nationwide population-based cohort of postmenopausal women to determine whether there is an association between reproductive factors and the incidence of gout.

Methods: A total of 1,076,378 postmenopausal women aged 40–69 years who participated in national health screenings in 2009 were included in the study. The outcome was the occurrence of incident gout, which was defined using the ICD-10 code of gout (M10) in the claim database. Cox proportional hazard models were used for the analyses and stratified analyses according to body mass index (BMI) and the presence/absence of chronic kidney disease (CKD) were performed.

Results: The mean follow-up duration was 8.1 years, and incident cases of gout were 64,052 (incidence rate, 7.31 per 1,000 person-years). Later menarche, earlier menopause, and a shorter reproductive span were associated with a high risk of gout. No association between parity and gout incidence was observed. Use of oral contraceptives (OC) and hormone replacement therapy (HRT) were associated with an increased risk of gout. The association between reproductive factors and gout was not statistical significant in the high BMI group. The effects of OC and HRT usage on gout were not significant in the CKD group.

Conclusion: Shorter exposure to endogenous estrogen was associated with a high risk of gout. Conversely, exposure to exogenous estrogen such as OC and HRT was associated with an increased risk of gout.

Rheumatoid Arthritis Treatment Patterns in Massachusetts: Informative Findings from Insurance Claims Data

Mark Matza[1], D. Steven Fox[2], Kay Larholt[3], David Fritsche[3], Elizabeth Apgar[3], Mitesh Puthran[3], Gigi Hirsch[3] and Marcy Bolster[1], [1]Massachusetts General Hospital, Boston, MA, [2]University of Southern California, School of Pharmacy, Los Angeles, CA, [3]Massachusetts Institute of Technology (MIT) Center for Biomedical Innovation, Cambridge, MA

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Epidemiology & Public Health Poster II: Inflammatory Arthritis – RA, SpA, & Gout (0560–0593)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: A real-world current state of RA patients in Massachusetts (MA) is analyzed to provide a novel assessment of demographics, treatment patterns, and clinical settings of care, with particular focus on initial and subsequent prescribing patterns of DMARDs.

Methods: This was a retrospective cohort analysis of the MA Center for Health Information and Analysis all-payers claims database from 2013-2017, which aggregates claims data covering ~70% of the population, excluding traditional (fee-for-service) Medicare. The analytic cohort included all adults (18+ years) with ³2 RA-related claims on different dates. The treated cohort required ³1 claim for a conventional synthetic, biologic, or targeted synthetic DMARD (csDMARD, bDMARD, or tsDMARD, respectively). Further analysis included treatment patterns by year, demographics, medication, and specialization level (non-rheumatology (i.e. PCP and other specialty), general rheumatology, or a designated RA Center of Excellence).

Table 1 shows the baseline and demographic characteristics of the RA analysis cohort and treated RA cohort, including gender, age, index year, number of patients, insurance type, specialization level and duration data

Variable	RA Analysis Cohort N=70,613	Treated RA Cohort N=39,062

RA: Rheumatoid arthritis; PPO: Preferred provider organization; HMO: Health maintenance organization; COE: Center of excellence

[*]Values are the number (%) unless indicated otherwise. Results are based all patients in each cohort unless otherwise stated.

[1] Age category is summarized for patients who have been diagnosed with RA (i.e., index year and later) who are "Present" (have at least one claim) in data set for year of observation. Table presents aggregate of age observations across 2013-2017, therefore patients contribute for each year of observation. Patient count reflects sum of years of observation (with non-missing age) for RA population.

[2] RA Patients "Present" by year summarizes the size of the RA cohort by year. To be counted, patients must have been diagnosed with RA (i.e., index year and later) and have at least one claim in data set for year of observation.

[3] Table includes all observed insurance types; therefore, categories will add to more than 100%.

[4] Specialization level was the most specialized care setting at which a patient had at least 2 encounters according to the hierarchy: rheumatology at center of excellence, general rheumatology, non- rheumatology.

[5] Duration data is a claims-based proxy for patient-level observation time and is calculated as the duration between a patient's first (earliest date) medical or pharmacy claim and last (latest date) medical or pharmacy claim.

Results: The analytic cohort comprised 70,613 patients. The majority were female (74.7%), age ³45 years (86.6%), index date in 2013 (54.6%), the latter suggesting established RA diagnoses. (Table 1) The treated cohort included 39,062 patients (55.3%), of which 13,149 (33.7%) received only a single csDMARD, predominately HCQ (46.4%) or MTX (44.9%). HCQ as a single agent was more common in female patients of childbearing age, with HCQ use falling

Table 2 shows RA treatment groups and patterns by DMARD type

Treatment Groups 2013-2017	Treated RA Cohort N=39,062	
Any csDMARD	***18,670 (47.8)***

COE: center of excellence, b/tsDMARD: biologic disease modifying anti-rheumatic drug/targeted synthetic disease modifying anti-rheumatic drug

*Values are the number (%).
**Individual cell counts <11 and cell counts from which individual cell counts <11 could be calculated are suppressed.
[1] Excludes cells of <11 patients, therefore categories will not add up to 100%.
[2] Other includes Anakinra and Sarilumab

adalimumab (ADA) were the most common initial agents (66.3%). Of those, 998 patients (28.6%) had claims for a second bDMARD or tsDMARD. Of 998, a TNF-inhibitor (TNFi) was the first agent in 818 (82.0%), and the second agent for the majority was another TNFi (70.3%), followed by other bDMARD (20.5%) and tsDMARD (9.2%). (Table 3)

Specialization level was rheumatology for 40.7% of the analysis cohort, 50.6% of the treated cohort, and 77.7% of those initiating a bDMARD or tsDMARD. (Table 1). Drug selection varied by specialization level. Among the 8,390 (21.5%) patients receiving a single TNFi agent (+/- csDMARD), more patients received ETN and ADA in rheumatology settings and infliximab in non-rheumatology settings.

Conclusion: Overall, DMARD prescribing was low, and there was a high level of HCQ monotherapy and TNFi use. An unexpectedly high number of RA patients in MA were treated in non-rheumatology settings. This first state-wide current state analysis of RA in MA elucidates treatment patterns for RA in the United States, highlighting opportunities for practice improvement and helping to direct treatments in a timely and patient-centered fashion.

Altered Risk of Gout According to Change of Metabolic Parameters in Young Adults

Yeonghee Eun[1], In Young Kim[2], Kyungdo Han[3], Seonyoung Kang[1], Seulkee Lee[1], Hoon-Suk Cha[1], Eun-Mi Koh[1], Hyungjin Kim[1] and Jaejoon Lee[1], [1]Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, Republic of Korea, [2]National Police Hospital, Seoul, Republic of Korea, [3]Soongsil University, Seoul, Republic of Korea

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Epidemiology & Public Health Poster II: Inflammatory Arthritis – RA, SpA, & Gout (0560–0593)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Previous studies have shown a link between gout and metabolic syndrome (MetS). It is well known that lifestyle modifications such as weight reduction and abstinence from alcohol are effective in the treatment of gout, but data are lacking on how exactly the change of metabolic parameters affects gout. The purpose of this study was to investigate the relationship between gout risk and metabolic parameters in a nationwide population based young adult cohort, and to determine whether changes in metabolic parameters affect gout risk changes.

Methods: Among adults aged 20-39 years who participated in the national health checkup program from 2009 to 2012, 2,598,905 subjects who participated in the health checkup again two years later were included in the analysis to evaluate the effect of changes in metabolic parameters on the occurrence of gout. Outcome was defined as the occurrence of gout, where the ICD-10 code M10 was registered twice in the claim database. Cox proportional hazard model and Kaplan Meier curve were used for analysis.

Results: The mean age of the study population was 32.7 years, and 62.4% were male. The mean follow-up duration was 5.71 years, and 71,245 subjects were newly diagnosed with gout (incidence rate 4.80 per 1,000 person-years). Compared to those who did not have MetS at two health screenings, the risk of gout was 2.5 times higher in those who had MetS consistently (adjusted HR 2.54; 95% CI 2.48, 2.60). The adjusted HR of gout of those who did not have MetS at the first checkup but developed MetS at the second checkup was 1.88, and the adjusted HR of gout of those who had MetS at the first checkup but did not have MetS at the second checkup was 1.76. Each component of MetS was also associated with an increase in the risk of gout, and hypertriglyceridemia and abdominal obesity showed the greatest association.

Conclusion: In young adults, the risk of gout was highest in those with persistent MetS compared to those who did not. Among the components of MetS, hypertriglyceridemia and abdominal obesity had the greatest association with the risk of gout. Management of MetS in young adults is helpful in reducing the risk of gout.

HR, hazard ratio; CI, confidence interval; ref, reference category; WC, waist circumference; NS-SEC, national statistic socio-economic classification. Fully adjusted model for obesity/central obesity: adjusted for gender, age, ethnicity, alcohol, smoking, education, occupation, wealth and index of multiple deprivation. Fully adjusted model for socioeconomic indicators: adjusted for age, gender, alcohol, smoking, BMI and WC. There was no indication of moderation between obesity and SEP indicators and incident OA/RA. Overall p-values for interaction OA: obesity*education=0.691, obesity*occupation=0.890, obesity*wealth = 0.882, obesity*IMD=0.252. Overall p-values for interaction RA: obesity*education=0.409, obesity*occupation=0.138, obesity*wealth=0.759, obesity*IMD=0.422.

Background/Purpose: Obesity is a known risk factor for OA and hypothesised as a risk factor for RA, although due to different underlying mechanisms. Lower socioeconomic position (SEP) has also been associated with both OA and RA. Given the well-established links between SEP and obesity, there may be interactions between these two risk factors in the development of OA and RA. This study investigated obesity and SEP in relation to incident OA and RA including potential interactions between obesity and SEP.

Methods: The English Longitudinal Study of Ageing (ELSA) is a nationally representative panel study of adults aged ≥50 years, with biannual waves of data collection (2002–2019). Participants with at least one nurse visit measuring height, weight and waist circumference (WC) and one follow-up assessment were included in this study. BMI of ≥30kg/m^2 and WC ≥102 cm for men and ≥88 cm for women defined total and central obesity, respectively. Level of education, occupation (current or last occupation if retired), wealth quintiles and index of multiple deprivation (IMD) quintiles were used as SEP indicators. Outcomes were self-reported incident OA and RA during follow-up. Prevalent OA and RA cases at baseline were excluded for the two different samples; however, people with OA could be included in the RA analyses and vice versa. Weighted Cox proportional hazards models were used to investigate the associations of obesity and SEP indicators with incident OA and RA separately, controlling for baseline covariates. Effect modification of each SEP indicator and obesity was tested by including interaction terms between them. Multiple imputation using chained equations was used to impute missing data on predictors and covariates.

Results: The OA and RA analyses included 9,281 (51.3% female; mean age 63.6 (SD 9.6); mean follow-up 7.8 (SD 4.2) years; and 2,369 incident cases of OA) and 10,931 (54.1% female; mean age 64.0 (standard deviation (SD) 9.6); mean follow-up 8.8 (SD 4.2) years; and 1,216 incident cases of RA) participants, respectively. In both samples, more women than men had total and central obesity. Total and central obesity were both associated with incident OA and RA and these associations were maintained after adjustment for covariates, including SEP indicators (Table 1). Those with the lowest education, who are/were employed in manual/routine occupations, who have lower wealth status and were from the most deprived areas were more likely to develop OA and RA; this is seen in basic models and maintained after adjustments for covariates including BMI and WC (Table 1). There was no evidence of effect modification/interactions between obesity and SEP indicators.

Conclusion: Obesity and SEP are both associated with incident OA and RA among adults aged 50 years and older in England and there was no evidence of an interaction between obesity and SEP indicators for incident OA and RA. Although obesity is a known risk factor for OA, the results show that SEP is independently associated with incident OA. Educating rheumatologists and public health experts about the importance of both of these factors, may result in better prevention strategies. To understand underlying mechanisms, further research should investigate the mediators of these associations.

SESSION INFORMATION

Session Date: Sunday, November 7, 2021

Session Title: Epidemiology & Public Health Poster II: Inflammatory Arthritis – RA, SpA, & Gout (0560–0593)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Background/Purpose: Older people are often underrepresented in trials because the generally high number of comorbid conditions (1). The objective of this abstract is to document the baseline status and frequency of comorbid conditions and concomitant medications in the GLORIA study population which consists of older rheumatoid arthritis (RA) patients.

Methods: This double-blind, randomized, placebo-controlled, multicenter trial (2) was open for patients with RA according to the 1987 or 2010 criteria, age ≥65 years, and disease activity score of 28 joints (DAS28) of ≥2.6. Its pragmatic design featured minimal exclusion criteria tailored to seniors. Patients were recruited from rheumatology clinics in 7 European countries. Eligible patients were randomized to two years of treatment with daily 5 mg prednisolone or matching placebo. All other medication was allowed, except for glucocorticoids.

Results: The population consists of 451 patients with mean disease duration 10.6 (Q1-Q3: 3-15) years. The majority (70%) is female, mean age is 72.5 (Q1-Q3: 68-76, range: 65-88) years, 66% were positive for rheumatoid factor and 56% for ACPA. Patients had a median of 6 comorbidities besides RA (4 active) and therefore used multiple medications (median 7, max 19 for all indications) (Table 1). The most common comorbidities in this older population are, by system organ class: cardiac and vascular disorders (17%), musculoskeletal and connective tissue disorders excl. RA (16%), and metabolism and nutrition disorders (9%). At baseline, patients were most frequently on medication for gastroprotection or hypertension (both 51%). Most patients also have an extensive history of anti-rheumatic treatment. At the start of the trial most patients (79%) were on cDMARD treatment; 14% were on bDMARDs/tsDMARDs. Almost half of the patients previously had been treated with glucocorticoids, with a mean duration of 3.4 years and a mean last dose of 4.6 mg/day.

Conclusion: Our data show the medical reality of a study population aged 65+ when minimal eligibility criteria are applied. These patients with multiple comorbidities next to RA and concomitant treatment are similar to patients seen

Table 1. Reported comorbidities and concomitant medications at baseline in the safety population of the GLORIA trial (n=449; total number of comorbidities: 2752).

Comorbidities, (median, range per patient)	**6**	**0-26**

Predictors of Health-Related Quality of Life in Rheumatoid Arthritis Patients

Nejat Hassen[1], Yufei Zheng[2], Hui Xie[2], Karim Khan[3], Jacek Kopec[4] and Diane Lacaille[2], [1]University of British Columbia, Arthritis Research Canada, Richmond, BC, Canada, [2]Arthritis Research Canada, Richmond, BC, Canada, [3]University of British Columbia, Vancouver, BC, Canada, [4]University of British Columbia, Richmond, BC, Canada

SESSION INFORMATION

Session Date: Sunday, November 7, 2021

Session Title: Epidemiology & Public Health Poster II: Inflammatory Arthritis – RA, SpA, & Gout (0560–0593)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Background/Purpose: Health-related quality of life (HRQoL) is lower in rheumatoid arthritis (RA) patients compared to the general population, yet a comprehensive study evaluating predictors and the relative contribution of sociodemographic, RA-related, comorbidities, and lifestyle factors is lacking. Our study's objectives were to identify factors that predict 1) HRQoL one year after baseline assessment; and 2) change in HRQoL over 12 months.

Methods: Survey data from a longitudinal quality of care study of RA patients recruited from a population-based cohort identified using administrative data were analysed. Participants who completed a questionnaire in 2015 and 2016 assessing sociodemographic, health status (RA-related and comorbidities), and lifestyle variables were included. The dependent variable HRQoL was measured using EQ5D-VAS. Three model selection procedures for multivariable linear regression models – stepwise selection (p-entry< 0.05;p-exit≥0.15), all-possible selection, and LASSO method – were used to select important HRQoL predictors. Models were compared using cross-validation (CV) and the model with smallest CV error was selected. Model selections without and with 2015 EQ5D-VAS, in separate analyses, were conducted to determine best models for absolute value-, and change in HRQoL, respectively. We used R^2 to assess the variance explained by each model and to determine the relative contributions of sociodemographic, RA-related, comorbidities, and lifestyle factors (sum of R^2 values for each domain). Data analyses were conducted using RStudio 1.3.1093.

Results: Our sample included 168 individuals with RA (72% women, mean age 70.7 ± 10.6 years, mean disease duration 24.3 ± 11.9 years). EQ5D-VAS in 2016 was 67.5/100 ± 19.4. Significant predictors and variance explained

Table 1. Model excluding 2015 HRQoL

Variable	Coefficient (95%CI)	p-value	R^2
Age >65yo (yes vs. no)	7.37 (1.94, 12.80)	<0.01	0.025
Alcohol consumption (yes vs. no)	7.75 (2.20, 13.31)	<0.01	0.061
Depression score (0-27)	-1.44 (-2.01, -0.86)	<0.01	0.143
HAQII (0-3)	-8.04 (-12.23, -3.86)	<0.01	0.100
Smoking (yes vs. no)	9.80 (0.42, 19.18)	0.041	0.008
Total model AIC=1416.93, R^2=0.34			

*Variables evaluated for inclusion in the multivariable model included Sociodemographic factors (age, sex, ethnicity, marital status, rural vs. urban residence, education, employment, income), health status factors (RA-related measures [physical function (HAQII), disease activity (RADAI), pain, fatigue], and comorbidities, including depression (PHQ9), obesity), and lifestyle factors (physical activity, smoking, alcohol consumption).

Table 2. Model including 2015 HRQoL			
Variable	**Coefficient (95%CI)**	**p-value**	**R^2**
Age >65yo (yes vs. no)	5.61 (0.42, 10.81)	0.034	0.019
Alcohol consumption (yes vs. no)	7.14 (1.88, 12.39)	<0.01	0.052
Depression score (0-27)	-0.71 (-1.35, -0.07)	0.030	0.086
RADAI (0-10)	-0.06 (-0.12, 0.00)	0.058	0.073
Sex (male)	4.74 (-0.64, 10.12)	0.084	0.010
2015 HRQoL (0-100)	0.39 (0.23, 0.55)	<0.01	0.162
Total model AIC=1401.85, R^2=0.40			
*Variables evaluated for inclusion in the multivariable model included Sociodemographic factors (age, sex, ethnicity, marital status, rural vs. urban residence, education, employment, income), health status factors (RA-related measures [physical function (HAQII), disease activity (RADAI), pain, fatigue), and comorbidities, including depression (PHQ9), obesity), and lifestyle factors (physical activity, smoking, alcohol consumption).			

by models without, and with, 2015 HRQoL are presented in Tables 1 and 2, respectively. The model controlling for baseline 2015 HRQoL had a lower AIC and better predictive ability (R^2 value) for 2016 HRQoL. HRQoL in the previous year contributed most to predicting HRQoL. Of the RA-related factors, only disease activity and physical function (in models with, and without, 2015-HRQoL) were significant predictors. Both variables were highly correlated (r=0.69) and likely capture similar disease effects. Of the comorbidities evaluated, only depression predicted HRQoL, and it had a greater contribution to HRQoL than RA-related factors. Lifestyle and sociodemographic factors evaluated in our study contributed little to HRQoL.

Our study limitations include potential respondent bias and a predominantly White and older sample with longstanding disease. Our findings may not be generalizable to samples with different characteristics.

Conclusion: HRQoL in our RA sample was multifactorial. Predictors from different domains contributed to HRQoL. HRQoL in the previous year contributed most to predicting future HRQoL. Depression was the second most important predictor. Early identification and management of depression may improve overall HRQoL in RA patients.

Recommended Fiber Intake, but Not Overall Dietary Quality, Is Associated with Reduced Risk of Rheumatoid Arthritis – Results from a Nested Case-control Study

Rebecka Bäcklund[1], Isabel Drake[1], Emily Sonestedt[2], Jan-Åke Nilsson[1], Ulf Bergström[1] and **Carl Turesson**[3], [1]Lund University, Malmö, Sweden, [2]Lund University, Lund, Sweden, [3]Lund University, Malm, Sweden

SESSION INFORMATION

Session Date: Sunday, November 7, 2021

Session Title: Epidemiology & Public Health Poster II: Inflammatory Arthritis – RA, SpA, & Gout (0560–0593)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Table 1.

Table 1. Cut-off values for dietary components included in the Diet Quality Index (DQI).

DQI components	Recommendation
Fibre (g/MJ)	≥2.4
Vegetables and fruits (g/day)	≥400
Fish (g/week)	≥300
Sucrose (E%)	<10
Saturated fatty acid (E%)	≤14
Polyunsaturated fatty acid (E%)	5–10

Background/Purpose: Diet has received attention as a factor possibly contributing to development of rheumatoid arthritis (RA). The aim of this study was to investigate the relation between overall diet quality, diet components, and the risk of RA.

Methods: Participants in a population-based cohort established in 1991-1996 who were subsequently diagnosed with RA were identified through register linkage and validated in a structured process. Four controls for each case, matched for sex, year of birth, and year of inclusion, were selected from the study cohort. The controls were alive

Table 2.

Table 2. Odds ratios (ORs) describing the relation between Diet Quality Index (DQI) and its components and the risk of developing rheumatoid arthritis. Conditional logistic regression analysis.

Standard deviation (SD), Percent of total energy intake (E%), Confidence interval (CI), Reference (Ref)
* All energy misreporters excluded

and RA-free when the index person was diagnosed with RA. At inclusion, diet was assessed using a seven-day food diary, a diet history questionnaire, and a complementary diet interview.

The validated Diet Quality Index (DQI) has been developed for distinguishing high-quality and low-quality diets by assessing adherence to the Swedish nutrition recommendations from 2005 and the Swedish dietary guidelines. The DQI score ranges from 0 to 6. A score of 1 is assigned to each component where the individual is compliant with the recommendation, i.e. fiber, fruit and vegetables, fish and shellfish, saturated fat, polyunsaturated fat, and sucrose (Table 1).

We applied conditional logistic regression analysis to study the relation between DQI, its components, and RA. The DQI was divided into categories, defined as low (0–1) (reference), moderate (2–4) and high (5–6), the category "low" was set as the reference. All models were adjusted for reported total energy intake, and potential misreporters of total energy intake were excluded.

We designed multivariable models in which we included covariates that have been associated with diet and RA (smoking, alcohol and leisure time physical activity). Interrelationships between dietary variables were assessed using Spearman's correlation test.

Results: In the study population, 172 RA cases were identified. Greater fiber intake was associated with decreased risk of RA both as dichotomous (i.e. compliant with recommendation or not) and continuous variables, with adjusted odds ratios (ORs) 0.48 (95% CI 0.28–0.82) and 0.71 per SD (95% CI 0.53–0.94), respectively. Furthermore, intake of vegetables and fruit >400 g/day was associated with decreased risk of RA, OR 0.52 (95% CI 0.31–0.88). The DQI was not associated with RA in these models (Table 2).

In multivariable models, associations for fiber and vegetables and fruits remained significant. There were strong correlations between intakes of vegetables and fruits and fiber (r=0.67 for continuous variables and r=0.50 for dichotomous variables). In the final multivariable model, compliance with the recommendation for intake of fibre was associated with lower risk of RA (OR 0.51; 95% CI 0.29–0.90).

Conclusion: In conclusion, fiber intake was independently associated with decreased risk of RA. Fiber intake was highly correlated with intake of vegetables and fruits, which was also associated with decreased risk of RA in multivariable models. No statistically significant associations were seen for DQI with the development of RA. Our results indicate that individual foods, rather than overall diet quality, associate with RA.

DMARD Use in Medicare Patients with Rheumatoid Arthritis and Risk of Long-Term Opioid Use

Akhil Sood[1], Yong-Fang Kuo[2], Jordan Westra[2] and Mukaila Raji[2], [1]University of Texas Medical Branch, League City, TX, [2]University of Texas Medical Branch, Galveston, TX

Table 1. Risk of Long-Term Opioid Use Based on DMARD Regimen

	DMARD Regimen	Adjusted OR (95% CI)
Drug Group	No DMARD	1.00 (Reference)
	Single DMARD*	0.91 (0.85, 0.97)
	DMARD Combination*	0.86 (0.78, 0.94)
	Non-TNF Biologic‡ without Methotrexate	0.88 (0.79, 0.97)
	Non-TNF Biologic‡ + Methotrexate	0.87 (0.77, 0.98)
	TNF without Methotrexate	0.88 (0.79, 0.97)
	TNF + Methotrexate	0.83 (0.75, 0.91)

* Includes Methotrexate, Leflunomide, Sulfasalazine, Hydroxychloroquine
‡ Includes Rituximab, Abatacept, IL-6 inhibitors, and JAK Inhibitors

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Epidemiology & Public Health Poster II: Inflammatory Arthritis – RA, SpA, & Gout (0560–0593)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Patients with rheumatoid arthritis (RA) are at increased risk for opioid use. Disease-modifying antirheumatic drugs (DMARDs) have led to better control of disease activity. Whether this has led to decreased opioid use in RA patients for pain control is unclear. We thus conducted a cross-sectional study examining different types of DMARD use in patients with rheumatoid arthritis (RA) and its association with long-term opioid use using national Medicare database.

Methods: We identified a cohort of RA patients enlisted in Medicare database for the year 2017-18 who were receiving at least 30-day prescription of opioids. We evaluated the long-term opioid use in this cohort. Long-term opioid use was defined as receiving opioid prescription for at least 90 consecutive days. The risk of long-term opioid use was compared between DMARD users and non-DMARD users. Patients on DMARDs were further subclassified into regimens set forth by American College of Rheumatology (ACR) for treatment of RA. Demographics and risk factors including depression, anxiety, drug use, and opioid use disorder were also obtained.

Results: The study was composed of 27, 028 RA patients receiving opioid prescription for at least 30 days. The mean age was 69.7 years, 80% were female, 76.8% were Caucasian, and 11.7% were African American. Seventy percent of patients were on DMARDs. Long-term opioid use was lower among DMARD users compared to non-DMARD users (37.4% vs 43.3%). Risk factors for long-term opioid use were common in both groups but higher in non-DMARD users (anxiety 42.8% vs 31.9%, depression 43.6% vs 36.6%, previous drug abuse 18.6% vs 12.2%, and previous opioid use disorder 17.0% vs 11.0%). After adjusting for these factors, the odds of long-term opioid use was significantly lower among DMARD users compared to non-DMARD users (OR 0.89, 95% CI 0.84-0.93). The odds remained low irrespective of DMARD regimen (Table 1).

Conclusion: DMARD use in RA patients was associated with decreased risk of long-term opioid use. These agents represent a possible opportunity to lower the risk of long-term opioid use in an especially vulnerable population. Appropriate use of DMARDs in RA patients may result in decreased dependence on opioids for chronic pain.

Abstract Number: 0588

Effectiveness of TNFi versus Non-TNFi Biologics on Disease Activity in Obese Patients with Rheumatoid Arthritis: Data from the ACR's RISE Registry

Milena Gianfrancesco[1], Jing Li[1], Clairissa Ja[2], Andrea Seet[1], Gabriela Schmajuk[1] and Jinoos Yazdany[1], [1]University of California San Francisco, San Francisco, CA, [2]UC Davis, San Francisco

SESSION INFORMATION

Session Date: Sunday, November 7, 2021

Session Title: Epidemiology & Public Health Poster II: Inflammatory Arthritis – RA, SpA, & Gout (0560–0593)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Background/Purpose: Our understanding of how medications such as biologic disease modifying anti-rheumatic drugs and targeted small molecules (b/tsDMARDs) influence disease activity in RA is based largely on randomized controlled trials (RCTs). However, most U.S. trials in RA are limited by small sample sizes and have often excluded patients who are older, male, racial/ethnic minorities and across the spectrum of body mass index (BMI). Whether effectiveness of b/tsDMARDs varies in real-world populations has largely been unexplored. We aimed to examine differences in longitudinal RA disease activity by demographic and clinical characteristics using the RISE registry. We simulated various treatment assignments of b/tsDMARDs that have been examined in RCTs: namely, TNF-inhibitors (TNFi) and non-TNFi.

Methods: We included 16,448 individuals from the ACR's RISE registry with > 2 RA diagnoses (ICD-9: 714.0, ICD-10: M06.9) > 30 days apart, who had at least 2 recorded clinical disease activity index (CDAI) scores and no historical b/tsDMARD use documented in RISE. b/tsDMARD use and CDAI scores were assessed at each quarter; covariates included sex, race (white, Black, Asian, other), ethnicity (Hispanic/non-Hispanic), age, smoking, obesity (BMI > 30 mg/kg2), area deprivation index, other DMARD use, RF status, anti-CCP status, and practice type. Longitudinal targeted maximum likelihood estimation estimated the average treatment effect (ATE) of cumulative TNFi vs. non-TNFi use over a 12-month period on CDAI score among the entire population and across various subgroups based on demographic and clinical characteristics, accounting for censoring.

Results: Approximately 75% of patients were female with a mean age of 65.1 (+/- 13.7) years. Sixty percent of patients were white, 8% black, 2% Asian, and 30% other/mixed or unknown race; 6% were Hispanic, and 42% obese.

Table 1. Average treatment effect (ATE) of cumulative TNFi vs. non-TNFi use at 12-months on CDAI score in obese patients with RA

	TNFi vs. Non-TNFi ATE (95% CI)	TNFi vs. Abatacept ATE (95% CI)	TNFi vs. Rituximab ATE (95% CI)	TNFi vs. Tocilizumab ATE (95% CI)	TNFi vs. Tofacitinib ATE (95% CI)
Overall (n=16,448)	0.85 (-0.26, 1.96)	2.37 (1.38, 3.35)*	2.12 (1.21, 3.02)*	2.71 (1.79, 3.64)*	0.44 (-0.45, 1.34)
Obese					
Yes (n=6,832)	0.63 (-1.08, 2.34)	3.29 (1.96, 4.61)*	-1.06 (-2.36, 0.23)	0.68 (-0.55, 1.92)	1.08 (-0.07, 2.23)
No (n=9,616)	0.64 (-0.71, 1.99	0.63 (-0.56, 1.81)	1.84 (0.83, 2.84)	4.00 (2.97, 5.03)*	-0.60 (-1.74, 0.54)

*$P<0.05$

Disclaimer:
This data was supported by the ACR's RISE Registry. However, the views expressed represent those of the authors, not necessarily those of the ACR.

The mean CDAI score at baseline was 11.3 (+/- 10.7). For the overall population, there was no significant difference in disease activity between TNFi and non-TNFi at 12 months (ATE= 0.85, 95% CI -0.26, 1.96; Table 1). Similarly, there was no significant difference in disease activity between TNFi and non-TNFi in obese and non-obese individuals. However, analyses by specific non-TNFi medications demonstrated higher disease activity associated with TNFi use compared to abatacept in obese patients (ATE=3.29, 95% CI 1.96, 4.61), but not non-obese patients. Contrastingly, TNFi use was associated with higher disease activity compared to tocilizumab in non-obese patients (ATE=4.00, 95% CI 2.97, 5.03), but not obese patients. In analyses comparing TNFi use and rituximab, and TNFi and tofacitinib, there were no differences in disease activity scores at 12 months for obese and non-obese patients.

Conclusion: Results from this RCT simulation study suggest that specific non-TNFi may have differential effects for obese and non-obese individuals with rheumatic disease, even though some medications are adjusted for weight. These novel findings fill gaps where RCTs have not been conducted, highlight the need for inclusion of diverse populations in future trials, and have the potential to lead to a more personalized approach to rheumatologic care.

Circulating Adipokines and Risk of Rheumatoid Arthritis in Women

Zhe Fang[1], Jing Cui[2], Jeffrey Sparks[1], Susan Malspeis[2], Kazuki Yoshida[1], Karen Costenbader[3], Elizabeth Karlson[1] and **Bing Lu**[4], [1]Brigham and Women's Hospital, Boston, MA, [2]Brigham Women's Hospital, Boston, MA, [3]Brigham and Women's Hospital, Belmont, MA, [4]Brigham and Women's Hospital and Harvard Medical School, Newton, MA

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Epidemiology & Public Health Poster II: Inflammatory Arthritis – RA, SpA, & Gout (0560–0593)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Adipokines secreted by adipose tissues thought to be involved in RA pathogenesis by stimulating systematic inflammation. We examined the association between circulating adipokines (leptin, visfatin and resistin) and risk of developing RA in women.

Methods: We conducted a nested case-control study within the Nurses' Health Study and Nurses' Health Study II among 202 incident RA cases with a preclinical blood sample and 399 controls (~1:2) who were free of RA at the time of diagnosis of index case, and matched on age, ethnicity, fasting status, time of day of blood draw, and menopausal status /hormone use. All covariates were measured before blood draw. Adipokine biomarkers were log-transformed to improve normality. Multivariable linear regression models adjusted for matching factors and other potential confounders were used to examine the differences in adjusted means of circulating leptin, visfatin, and resistin between pre-clinical RA cases and controls. We examined strata defined by age at RA diagnosis, BMI, time between blood draw and RA (0-3.9, 4-< 7.9 and >8 years), and RA seropositivity (rheumatoid factor and/or anti-cyclic citrullinated peptide).

Results: Characteristics of the pre-RA cases and controls are shown in Table 1. After adjusting for matching factors and other risk factors, pre-clinical RA cases had a significantly higher level of leptin compared with controls (p=0.002) (Table 2). No significant differences were observed in levels of visfatin and resistin between all pre-clinical RA cases and controls. In stratified analyses for leptin, significant associations were found among women aged 55 years or

less, women who had BMI < 25 kg/m^2 at the date of blood draw, and those who underwent blood draw 4-7.9 years before RA diagnosis or matched controls. Similarly, seropositive cases but not seronegative cases, had a higher level of leptin compared to controls. A significant difference in resistin level was also observed among women with BMI< 25 kg/m^2 and who underwent blood draw < 4 years before diagnosis vs. controls. In exploratory analyses, among both cases and controls, a higher level of leptin was significantly associated with higher levels of inflammatory markers [*monocyte chemoattractant protein-1 (*MCP-1), IL6, and tumor necrosis factor receptor *2 (*TNFR2)] (Table 3).

Conclusion: Circulating level of leptin was higher in women with preclinical RA than in controls. These results indicated that adipokines secreted by adipose tissues may be involved in RA pathogenesis. The screening for leptin could be used to identify high risk groups to prevent RA.

SESSION INFORMATION

Session Date: Sunday, November 7, 2021

Session Title: Epidemiology & Public Health Poster II: Inflammatory Arthritis – RA, SpA, & Gout (0560–0593)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Background/Purpose: Lipid mediators are endogenously derived from the metabolism of omega-3 and omega-6 polyunsaturated fatty acids (PUFAs) and have important roles in promoting and resolving inflammation. As such PUFAs have been implicated in the pathogenesis of systemic inflammatory and autoimmune diseases including rheumatoid arthritis (RA). As lipid mediators share common pathways and enzymes, individual lipid mediators do not act in isolation and therefore must be analyzed in combination as a profile. The goal of this study was to determine the association of polyunsaturated fatty acid (PUFA)-derived lipid mediator profiles with progression from pre-diagnosis RA-related autoimmunity to clinically apparent inflammatory arthritis (IA).

Methods: Using the Studies of the Etiologies of Rheumatoid Arthritis (SERA), we examined a prospective cohort that includes first-degree relatives (FDRs) of individuals with RA (FDR cohort) and individuals who screened positive for RA-related autoantibodies at health fairs (screened cohort). We followed 133 anti-CCP3.1 positive participants, of which 29 participants subsequently developed IA during follow-up (mean time to IA development = 1.15 years). Exposures

Table 1. Characteristics of the ACPA-positive study participants (n = 133) at baseline visit. Except where indicated otherwise, values are the number (%); IA = inflammatory arthritis

Characteristic	IA Control (n = 104)	IA Case (n=29)	p-value
Age, mean (SD)	54.3 (13.5)	49.9 (14.7)	0.152
Gender, Female	73 (70.2%)	18 (62.1%)	0.544
Race, non-Hispanic White	87 (83.7%)	21 (72.4%)	0.271
Education, high school or higher	82 (78.8%)	25 (86.2%)	0.536
Shared epitope (SE), present	47 (45.2%)	20 (69.0%)	0.040
Smoker†, non-smoker	61 (58.7%)	18 (62.1%)	0.836
Recruitment Group, FDR	69 (66.3%)	11 (37.9%)	0.0108

Except where indicated otherwise, values are the number (%); IA = inflammatory arthritis.
† Data were missing for 1 participant.

Average of 3.74 years of follow-up

Table 2. PC Factor Loadings. Factor loadings are shown for each lipid mediator for the 5 profiles of interest. Lipid mediators with large impact loadings are highlighted either red (negative loading) or green (positive loading). Negative loadings means the individual lipid mediator is negatively correlated with the PC, while positive loadings means the individual lipid mediator is positively correlated. The precursor fatty acid and omega fatty acid type (either omega3 or omega6) are shown for each lipid mediator

Table 3. Cox proportional hazard results for the outcome of Inflammatory Arthritis (IA) for each lipid mediator profile (PC). All models were adjusted for age at baseline and recruitment type (FDR or health fair). For total population models, SE status was adjusted for as well

Lipid Mediator Profile	Population	Hazard Ratio	95% Confidence Interval	p-value
PC1	Total	0.97	(0.83, 1.13)	0.675
PC2	**Total**	**0.79**	**(0.66, 0.96)**	**0.018**
PC3	Total	1.01	(0.75, 1.36)	0.938
PC4*	SE Negative	0.99	(0.56, 1.77)	0.981
PC4*	**SE Positive**	**0.53**	**(0.32, 0.87)**	**0.012**
PC5	Total	0.86	(0.64, 1.17)	0.340

*PC4 had a significant interaction effect with SE (p-value = 0.048) and therefore reporting the stratified results for this profile.

included concentrations (pg/ml) of lipid mediators quantified from baseline plasma samples via liquid chromatography tandem mass spectrometry with profiles identified via principal component analysis (PCA). Multivariable Cox proportional hazard models were then developed for each lipid mediator profile, either stratified by or adjusted for HLA-DRB1 shared epitope status (dependent on presence of effect modification between lipid mediator profile and shared epitope).

Results: Baseline characteristics of the study population is shown in Table 1. The top 5 PCA components (PC) explained >50% of all variance among the lipid mediators, with the factor loadings of each lipid mediator shown in Table 2. Of these lipid mediator profiles, PC2 had a significant protective effect on IA risk (HR 0.79, 95% CI: 0.66-0.96, p-value = 0.018) in the total study population (Table 3). For profile PC2, the important lipid mediators had a mix of positive and negative loadings for lipid mediators in the cytochrome P450 soluble epoxide hydrolase (CYP sEH) and 15-lipoxygenase (15-LOX) enzymatic pathways. PC4 also demonstrated a significant protective effect on IA risk, but only within the shared epitope positive study population (HR 0.53, 95% CI: 0.32-0.87, p-value = 0.012). For profile PC4, the vast majority of important lipid mediators had negative loading factors and are downstream products from omega-3 parent fatty acids. Other lipid profiles identified showed no association with the risk of IA.

Conclusion: Our study revealed two lipid mediator profiles to be significantly associated with incident IA in a high-risk pre-diagnosis cohort characterized by ACPA positivity. These findings suggest specific PUFA metabolite profiles impact on the early evolution of RA and ultimately the development of IA, some working solely within the SE positive population.

Abstract Number: 0591

The Temporal Association Between Hospital Admissions, Disease-modifying Anti-rheumatic Drugs Usage and Direct Health Care Costs in Rheumatoid Arthritis Patients

Khalid Almutairi[1], Johannes Nossent[1], David Preen[1], Helen Keen[2] and Charles Inderjeeth[3], [1]University of Western Australia, Perth, Australia, [2]University of Western Australia, Daglish, Australia, [3]University of Western Australia, Nedlands, Perth, Australia

SESSION INFORMATION

Session Date: Sunday, November 7, 2021
Session Title: Epidemiology & Public Health Poster II: Inflammatory Arthritis – RA, SpA, & Gout (0560–0593)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Rheumatoid arthritis (RA) carries a substantial burden for patients and society in terms of morbidity, disability, and medical expenses. The Australian Pharmaceutical Benefits Scheme (PBS) subsidised biological disease-modifying anti-rheumatic drugs (bDMARD) since 2003. We investigated the association between subsidised bDMARD therapy for RA in 2003 hospitalisation rates and health care costs.

Methods: Hospital admissions for RA patients between 1995 and 2014 were identified in the Western Australia (WA) Hospital Morbidity Data Collection (ICD codes 714 and M05.00–M06.99). State-specific dispensing data for conventional

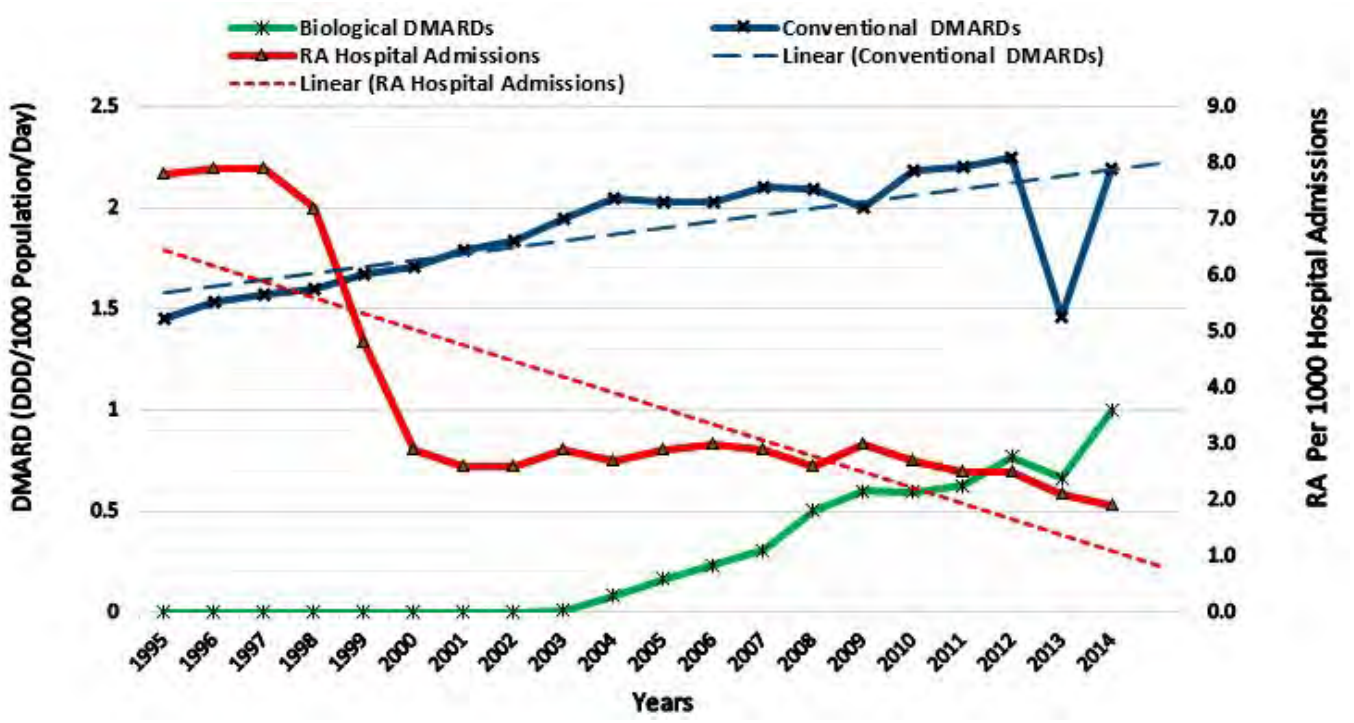

Figure 1. Conventional and biological DMARD trends and hospital admission for rheumatoid arthritis, 1995–2014, Western Australia. DDD, defined daily doses; DMARD, disease-modifying anti-rheumatic drugs; RA, Rheumatoid Arthritis.

DMARD (cDMARD) and bDMARD for RA was obtained from Statistics Australia and expressed as defined daily doses /1000 population/day (DDD) using the WA population census. Principal component analysis (PCA) was applied to determine the relationship between DMARD use and hospital admission rates. Total expenditure for DMARD and RA hospital admissions were obtained from the PBS domain and Australia's health care expenditure report.

Results: A total of 17,125 patients had 50,353 admissions with a diagnostic code for RA. Between 1995 and 2002, the number of RA admissions fell from 7.9 to 2.6/1,000 admissions, while cDMARD use rose from 1.45 to 1.84 DDD. Between 2003–2014, RA admissions decreased further to 1.9/1,000 hospital admissions, while cDMARD use increased to 2.19 DDD and bDMARDs from 0.01 to 1.0 DDD. In PCA analysis, cDMARD (methotrexate and leflunomide) and bDMARD use had an inverse relationship with hospital admission rates. The annual costs of bDMARD utilisation was 22.5 million in 2003–2014, while annual cost savings of RA hospital admissions was 9.2 million.

Conclusion: The increased use of cDMARD use for RA has coincided with a significant decline in hospital admissions for RA patients in WA, while a more modest further decline followed bDMARD introduction. BDMARD therapy was not as cost-effective as cDMARD in relation to RA hospital admissions costs.

Abstract Number: 0592

Gender Modifies the Effect of Rheumatoid Arthritis on All-Cause Mortality

Srikanta Banerjee[1] and Stephanie Falls[2], [1]Walden University, Leola, [2]PA Department of Health, Leola

SESSION INFORMATION

Session Date: Sunday, November 7, 2021
Session Title: Epidemiology & Public Health Poster II: Inflammatory Arthritis – RA, SpA, & Gout (0560–0593)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Rheumatoid arthritis (RA) is a chronic and systemic autoimmune disease which predominantly affects joints with varying severity. While RA has been found to be more prevalent in women, there is conflicting information about gender-specific mortality rate as it relates to RA. In this study, we explored the relationship between RA and all-cause mortality and if gender modifies this effect.

Methods: The study was conducted on participants aged 20 years or older in the United States living. We assessed RA status by using the arthritis screening in the NHANES survey for the years 1999 to 2010 with mortality follow-up through December 31, 2015. Prospective analysis was performed using complex samples Cox Regression with adjustment for known confounders to determine the relationship of RA and mortality, especially as it pertains to gender.

Results: Prevalence of RA in this population (N=27,371) was 1.9% among males and 2.8% among females. The mean follow-up was 11.1 years. For all-cause mortality, the overall unadjusted hazard ratio (HR) of rheumatoid arthritis to no rheumatoid arthritis was 2.89 (95% confidence interval [CI], 2.48-3.37, $p < 0.001$). Adjusted HR was elevated, 1.34 (CI 1.04-1.73, $p < 0.05$), among female participants with RA but closer to 1.0 (1.02 CI 0.83-1.25, $p > 0.05$) among male participants with RA, after controlling for medical (obesity, diabetes, CKD, and CVD) and demographic risk factors (age, education, and food insecurity).

Table 1. Multivariable Cox Hazard Model for Rheumatoid Arthritis and all-cause mortality after controlling for demographic and medical risk factors stratified by gender

	Male All Cause-Mortality (n=15,878)			Female All Cause-Mortality (n=8,173)

Diabetes	1.56	1.28-1.90	<0.001	1.55	1.23-1.96	<0.001
Chronic Kidney Disease[b]	1.56	1.35-1.79	<0.001	1.63	1.34-1.98	<0.001
Education						
Some High School	1.69	1.41-2.04	<0.001	1.37	1.11-1.67	0.003
High School Grad	1.47	1.28-1.69	<0.001	1.14	0.92-1.42	0.22
Some College	Reference	Reference	Reference	Reference	Reference	Reference
Age	1.08	1.07-1.08	<0.001	1.08	1.08-1.09	<0.001
Ethnicity						
Non-Hispanic White	Reference	Reference	Reference	Reference	Reference	Reference
Non-Hispanic Black	1.26	1.01-1.59	<0.001	1.19	0.97-1.47	0.09
Hispanic	0.98	0.78-1.23	0.68	1.07	0.78-1.45	0.68
Other	0.75	0.44-1.28	0.29	1.24	0.80-1.90	0.33

[a]Cardiovascular disease was defined by self-reported positive response to congestive heart failure, stroke, angina, coronary heart disease, or heart attack.
[b]Chronic Kidney Disease was ascertained through the classification of Glomerular Filtration Rate determined by the Cockcroft-Gault equation.

Conclusion: RA was found to cause three times higher mortality rate than the general population, which is higher than previous estimates. The findings also show that RA disproportionately affects females and also leads to worse outcome than in males. Risk scoring and social policy, when addressing RA, should address gender disparities related to outcomes.

Abstract Number: 0593

Labour Force Participation Among Individuals with Osteoarthritis, Rheumatoid Arthritis/Other Arthritis Types, or with Joint Symptoms but Without a Diagnosis: An Age-Stratified Population-Based Study

Shatabdy Zahid, Elizabeth Badley and **Anthony Perruccio**, Schroeder Arthritis Institute, University Health Network, Toronto, ON, Canada

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Epidemiology & Public Health Poster II: Inflammatory Arthritis – RA, SpA, & Gout (0560–0593)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Having arthritis is known to affect labour force participation. Most research has focused on individuals with doctor-diagnosed rheumatoid arthritis (RA) and, to a lesser extent, doctor-diagnosed osteoarthritis (OA). However, for younger working-age adults in particular, OA is often underdiagnosed and underreported. Using a national population-based sample and with a focus on age-specific associations, we compared labour force participation among individuals with doctor diagnosed OA, RA or other arthritis types, and those with joint symptoms but no diagnosis.

Methods: Data are from the Canadian Longitudinal Study on Aging (Cycle 1), a national study with sociodemographic, economic and health data from Canadians aged 45-85. All data were self-reported and include questions on labour force participation, and if respondents had doctor-diagnosed RA/other type of arthritis, or OA (hands, hips or knees). Respondents also reported on joint symptoms in these joints. Five mutually exclusive groups were derived:

Table 1. Characteristics of the Canadian Longitudinal Study on Aging sample.

	Overall (n = 24, 813)	45-54 years of age (n = 7,595)	55-65 years of age (n = 9,856)	65-74 years of age (n = 7,362)
		%		
Controls (no arthritis/no joint symptoms)	43.6	55.3	41.4	34.6
RA or other arthritis type	12.4	9.8	12.6	14.7
Osteoarthritis	19.9	10.2	21.3	28.1
1 joint site symptom (no arthritis diagnosis)	18.6	19.6	19.2	16.8
2-3 joint site symptom (no arthritis diagnosis)	5.5	5.1	5.5	5.9
Female	51.2	51.7	51.6	50.1
Has dependents ≤18 years old at home	18.5	45.9	9.0	2.9
< Post secondary education	13.0	9.4	12.6	17.3
Comorbid conditions 0-1	28.8	42.3	28.1	15.8
2-3	43.6	43.2	44.6	42.8
4+	27.6	14.6	27.3	41.4
Out of the labour force	39.3	9.9	37.1	72.7

Table 2. Results from age-stratified log-binomial regression analyses assessing associations (reported as prevalence ratios) between arthritis groups and labour force participation (out vs. in labour force), Canadian Longitudinal Study on Aging.

	Age stratified models* Prevalence Ratio ((95% CI))		
	45-54	55-64	65-74
RA or other arthritis type	**1.30 (1.06, 1.60)**	**1.09 (1.01, 1.19)**	0.99 (0.95, 1.03)
Osteoarthritis	**1.31 (1.08, 1.60)**	**1.12 (1.05, 1.20)**	1.02 (0.98, 1.05)
1 joint site symptom (no arthritis)	1.04 (0.87, 1.25)	1.05 (0.98, 1.13)	0.99 (0.95, 1.03)
2-3 joint site symptom (no arthritis)	**1.33 (1.04, 1.70)**	1.02 (0.91, 1.15)	1.02 (0.97, 1.08)

Bolded estimates indicate statistical significance at p<0.05

*adjusted for sex, education, if respondent had a dependent (≤18 years of age) living at home, and comorbidities

controls (no arthritis/no joint symptoms), RA/other, OA, and for those with no arthritis diagnosis but with symptoms, single joint site and 2-3 joint site symptoms.

Age-stratified (45-54/55-64/64-74) log-binomial regressions were used to examine the association (reported as prevalence ratios) between labour force participation and group membership. Analyses were adjusted for sex, education, dependent (≤18 years of age) living at home and comorbidities.

Results: From a sample of 24,813, 20% had OA, 12% RA/other types of arthritis, and 19% and 6% had 1 joint site symptoms and 2-3 joint site symptoms, respectively, without an arthritis diagnosis (Table 1).

In the youngest age group (45-54) individuals with OA, RA/other, and those with 2-3 joint symptoms but without a diagnosis were equally likely to be out of the labour force (Table 2). Among those aged 54-64, those with OA and RA/other types were equally likely to have an increased likelihood of being out of the labour force. No differences in labour force participation were found between the groups in the older age group.

Conclusion: OA and RA/other arthritis types were similarly associated with being out of the labour force for working age adults. Importantly, among individuals in the youngest age group, individuals with symptoms at 2-3 joint sites but without a diagnosis were as likely to be out of the labour force as those with OA and RA/other arthritis types. Younger individuals may be less likely to make a physician visit for joint symptoms or to receive an arthritis diagnosis. An exclusive focus on diagnosed arthritis may miss an important segment of the population to target with interventions to positively impact labour force participation.

The Burden of Systemic Lupus in Five Distinct Racial and Ethnic Groups in Israel: A Population-based Study

Titilola Falasinnu[1], Nada Rizk[1], Becca Feldman[2], Devy Zisman[3], Michael Leshchinsky[2], Gabriella Lawrence[2], Yashaar Chaichian[4] and Julia Simard[1], [1]Stanford School of Medicine, Stanford, CA, [2]Clalit Research Institute, Clalit Health Services, Ramat Gan, Israel, [3]Carmel Medical Center, Haifa, Israel, [4]Stanford University, Los Gatos, CA

SESSION INFORMATION

Session Date: Sunday, November 7, 2021
Session Title: Healthcare Disparities in Rheumatology Poster (0594–0622)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Misclassification of race and ethnicity in data can impact how disparities in prevalence, incidence, severity, and complications of systemic lupus erythematosus (SLE) are interpreted. Categorizing and labeling individuals' race/ethnicity is often limited to preset options. Consequently, in many regions, people of Middle Eastern descent are asked to choose between "White" and "Other." Our objective was to use population-based data from Israel to characterize the burden of SLE in the population by infrequently examined race/ethnic groups (i.e. Sephardi, Ashkenazi, Ethiopian, Arab/Bedouin, and Mixed ancestry).

Methods: A cohort of patients with SLE was identified using electronic health record data between 2010 and 2017 from Clalit Health Services (CHS), the largest healthcare provider in Israel comprising 53% of the adult population (4.7 million patients). SLE prevalence was estimated on January 1, 2017 and annual incidence was examined over time for several SLE definitions by sex, age, and ethnicity. Ethnicity (Sephardi, Ashkenazi, Ethiopian, Arab/Bedouin, Mixed

	SLE Case Definitions
Most Sensitive	*Definition 1*. At least one visit with the relevant ICD9 code (710.0 or other based on findings from the Clalit database and accompanying free text) for SLE. Defined as present with the first of these codes (N=6,267).
	Definition 2. At least one visit with the relevant ICD9 code (710.0 or other based on findings from the Clalit database) and accompanying free text for SLE, and at least one ANA positive test result (N=3,493).
	Definition 3. At least one visit with the relevant ICD9 code (710.0 or other based on findings from the Clalit database) for SLE in inpatient setting, or at least two visits coded for SLE in outpatient setting (N=3,637).
	Definition 4. At least two visits with the relevant ICD9 code (inpatient or outpatient setting) plus at least one positive ANA test result (N=2,418).
	Definition 5. At least two visits with the relevant ICD9 code for SLE in inpatient or outpatient setting (or both), with at least one SLE-coded visit from a specialist (including nephrology, rheumatology, immunology, dermatology or internal medicine) (N=2,243).
Most Specific	*Definition 6*. At least two visits with the relevant ICD9 code for SLE in inpatient or outpatient setting (or both), with at least one SLE-coded visit from a specialist (nephrology, rheumatology, immunology, dermatology or internal medicine), plus at least one related lab finding, including positive ANA, positive anti-dsDNA, low C3, low C4 (N=1,967).

*Prevalence estimates as of January 1, 2017

Figure 1. SLE Case Definition Classifications from most sensitive to most specific. *

shown as % yes unless otherwise specified

Jews, Unknown) was defined using data on four grandparents; and categorized those with more than one noted ethnicity among grandparents as "mixed", while those missing 2 or more grandparents was "unknown". We used SLE definitions from the existing literature and added serologic testing to generate six definitions varying in sensitivity and specificity (Fig 1). These definitions incorporated ICD9 coded inpatient and outpatient visits, provider type/specialty, number of SLE-coded visits, and serologic testing (including antinuclear antibody positivity, anti-double stranded DNA antibodies, and low C3 and C4).

Results: In total, our study population included up to 6,267 potential SLE cases and 404,838 comparators from the CHS membership. The distribution of sociodemographic factors varied little between case Definitions 2 and 5 (Table 1). The prevalent cases, regardless of definition, were older and more likely to be female, have hypertension, diabetes, and kidney disease than the general CHS comparator group. Overall prevalence on January 1, 2017 ranged from 155 cases per 100,000 to 49 cases per 100,000 depending on the sensitivity vs specificity of the definition. Women comprised the majority of prevalent and incident cases across all age groups, and prevalence increased with age. Among

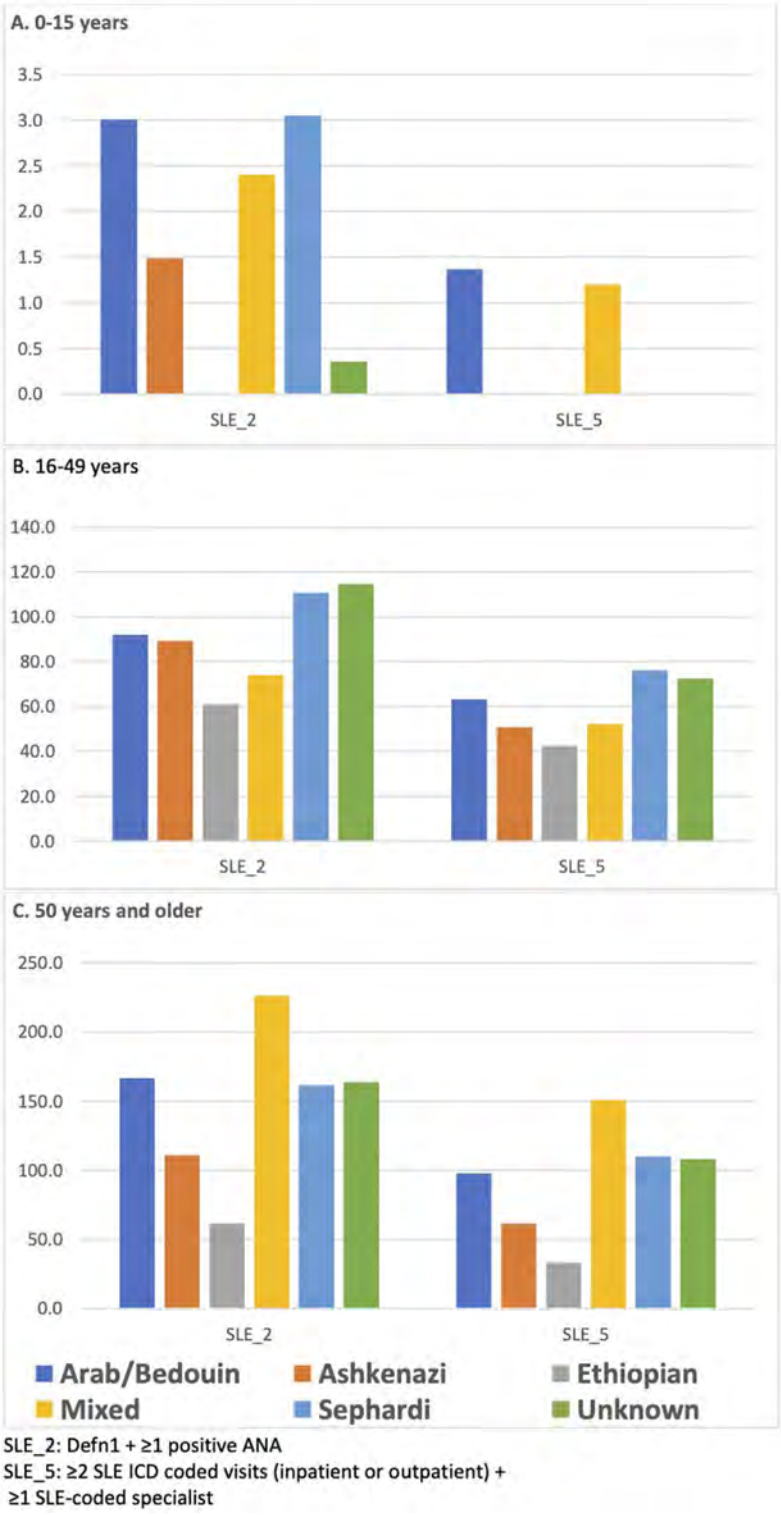

Figure 2. SLE Prevalence (per 100,000) by age and race/ethnicity in Clalit Health Services, Jan 1, 2017

children (0-15y) prevalence was highest among Arab/Bedouin and Sephardic groups (Figure 2). Among 16-49 year-olds, prevalence was highest among Sephardi and those of unknown ethnicity. Among those 50+ years, prevalence was highest among those of mixed ancestry. Individuals with Ethiopian ancestry had the lowest prevalence in all age groups. Overall incidence was highest in Sephardi and Arab/Bedouin groups (data not shown).

Conclusion: In our retrospective study, the burden of SLE in Israel appeared to vary by race/ethnicity and age. Notably, differences in SLE prevalence and incidence became apparent when groups that are typically misclassified as "White" or "Other" were further stratified into their racial and ethnic groups.

Abstract Number: 0595

Lupus Nephritis Disparities Amongst Hospitalizations in the United States: A National Inpatient Sample Study

Sonia Gupta, Koree Willer, Amir Begovic, Mitch Waters, Laura Tarantino, Olufunmilayo Badejo, Ryan Walters and Theresa Townley, Creighton University School of Medicine, Omaha, NE

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Healthcare Disparities in Rheumatology Poster (0594–0622)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Black, Hispanic, and Native American populations in the US experience increased morbidity and mortality from systemic lupus erythematosus (SLE), with higher rates and worse outcomes for lupus nephritis (LN). The purpose of our study was to identify socio-demographic indicators and outcomes of lupus nephritis on a national level in order to identify disparities and potential areas for intervention.

Methods: Our study utilizes the National Inpatient Sample (NIS), which is an all-payer national database. We used the NIS to identify inpatient hospitalizations between October 2015 and December 2017 with an ICD-10 diagnosis of SLE stratified by the additional diagnosis of lupus nephritis (LN) in patients 18 or older. We calculated the rate of lupus nephritis during hospitalizations, organized by patient and facility demographics. In addition, we examined dialysis, death, and cost of care for SLE and LN hospitalizations.

Results: We identified 333,020 hospitalizations with SLE, of which 8,575 (2.6%) included an LN diagnosis. The median age was lower LN group compare to SLE patients without LN (37 vs 55 years, $p < .001$) (Table 1). SLE disproportionately affects females, however, the lupus nephritis rate was higher in males than females (3.8 vs. 2.4). Hospitalizations with SLE were disproportionately higher in the White population, Black cohort (28.1%) and relatively lower in the Hispanic cohort (11.6%) Rates of LN were higher for Blacks (4.6%), Hispanics (4.0%) and Other races (3.7%) compared to Whites (1.1%, all $p < .001$). The lowest income quartile had the highest rate of LN (3.0%) and the upper quartile the lowest (2.1%, $p < .001$). Discharge with dialysis- dependence occurred in 29% of hospitalizations with LN diagnoses (Table 2). Cost of hospitalization was significantly higher with LN than without LN ($11,200 vs. $9,109, $p < .001$) (Table 3).

Table 1. Patient demographic characteristics stratified by lupus nephritis

	SLE without LN (n = 324,445)	SLE with LN (n = 8,575)	Rate of Lupus Nephritis (%)	p
Age at admission	54.6 [41.5- 66.0]	36.6 [24.2- 50.4]		<.001
Age				<.001
18-24	3.3	14.3	10.4	
25-34	10.7	29.9	6.8	
35-44	15.0	20.8	3.5	
45-54	19.8	15.5	2.0	
55-64	22.4	11.8	1.4	
65-74	17.6	5.3	0.8	
75+	11.2	2.3	0.6	
Sex				
Male	10.5	15.9	3.8	<.001
Female	89.5	84.1	2.4	
Race				
White	55.1	22.7	1.1	<.001
Black	28.1	51.4	4.6	
Hispanic	11.6	18.3	4.0	
Other	5.2	7.6	3.7	
Income Quartile				
0 to 25th	34.7	40.3	3.0	<.001
26th to 50th	24.8	24.1	2.5	
51st to 75th	22.4	20.8	2.4	
76th to 100th	18.1	14.8	2.1	

Conclusion: From the NIS hospitalizations, the presence of LN among hospitalizations with SLE is disproportionately associated with younger populations, Black and Hispanic populations and lowest income quartile. These hospitalizations primarily occur at urban teaching hospitals. There was a significant increase in cost associated with these hospitalizations. The rate of LN and dialysis is particularly concerning given the younger age of these hospitalizations. Further investigation is essential for identifying the structural causes that leads to these disparities and informing equitable care for patients with SLE and LN.

Table 2. Clinical characteristics stratified by lupus nephritis

	SLE without LN (n = 324,445)	SLE with LN (n = 8,575)	Rate of Lupus Nephritis (%)
Dependence on Dialysis	5.7	29.2	11.9

Table 3. In-hospital outcomes stratified by lupus nephritis

	SLE without LN (*n* = 324,445)	SLE with LN (*n* = 8,575)	*P value*
Hospital Cost, 2017 $	9,109 (9,012-9,207)	11,200 (10,721-11,742)	<.001

Racial Disparities in US Adults with Systemic Lupus Erythematosus: Prevalence, Quality of Life, Comorbidities and Healthcare Costs

Shannon Grabich[1], Cullen Seal[2], Robert Ortmann[3] and Sandra Sze-jung Wu[4], [1]Xcenda, Durham, NC, [2]Xcenda, Carrollton, TX, [3]AstraZeneca, Greenwood, IN, [4]AstraZeneca, Wilmington, DE

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Healthcare Disparities in Rheumatology Poster (0594–0622)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: SLE is a chronic, multisystem autoimmune disease characterized by reoccurring flares and remissions. It is more common among Asian, Black, and Hispanic populations. Racial disparity in SLE disease burden, including socioeconomic status (SES), and quality of life (QOL), is not well described in SLE patients. Our study sought to characterize the prevalence of SLE, demographic characteristics, SES, QOL, and health care resource utilization between Black vs. White adults in the US.

Methods: We analyzed 2016 - 2018 Medical Expenditure Panel Surveys (MEPS). MEPS is an annual survey designed to represent the US civilian non-institutionalized population. MEPS oversamples specific racial minority groups to

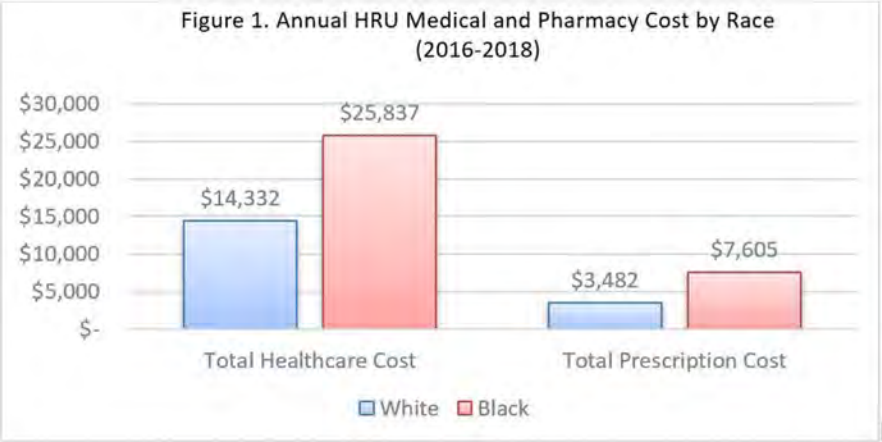

Table 1. Key SLE Respondent Characteristics by Race in MEPS (2016-2018)	White	Black

Not depressed in the last 2 weeks	**59%**	34%
Limitation in physical functioning[a]	39%	**61%**
A lot of difficulties or unable to…..		
Lift 10 lbs	27%	**44%**
Walk up 10 steps	23%	**64%**
Walk 3 blocks	52%	**81%**
Walk a mile	65%	**89%**
Using fingers to grasp	8%	**21%**

[a]All adults who responded "Yes" to "Limitation in physical functioning were asked the subsequent questions

employed (39% vs. 53%), and less likely be privately insured (37% vs. 67%) (Table 1). Black SLE respondents had a significantly higher prevalence of select comorbidities including arthritis (86% vs. 54%), diabetes (30% vs. 6%) , stroke (17% vs. 5%). MI (10% vs. 1%),and heart disease (27% vs. 19%). Black adults reported poorer overall health and health-limited activity, including the ability to work (Table 2). 52% Black adults (vs. 14% White) reported "completely unable to do activities." White SLE respondents were 2–3 times less likely to report difficulty with physical limitations—including standing, walking, bending, and reaching. More Black respondents reported using antimalarial medication than White (80% vs. 57%), with no other differences in SLE-related medications. Overall, Black SLE respondents had higher annual healthcare expenses ($25,837 (95% CI 16,318 - $34,972) vs $14,332 (95% CI 9,551 - $19,112)) which were driven by higher costs within office visits and emergency room events. Prescription costs were also higher in Black compared to White respondents, although not statistically different.

Conclusion: In this survey population, when compared with White SLE adults, Black SLE adults were younger, presented with more comorbidities, reported more physical limitations, and higher expenses in emergency room visits and overall healthcare spending. These differences may adversely affect long-term outcomes, suggesting there is a continuing need to further assess racial disparities in SLE to improve outcomes for this population.

Abstract Number: 0597

Sex Differences in Multimorbidity Between Patients with Systemic Lupus Erythematosus and Comparators in a Large Nationwide US Study

Ali Duarte-Garcia[1], Herbert Heien[1], Nilay Shah[1] and Cynthia Crowson[2], [1]Mayo Clinic, Rochester, MN, [2]Mayo Clinic, Eyota, MN

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Healthcare Disparities in Rheumatology Poster (0594–0622)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Patients with systemic lupus erythematosus (SLE) have an increased burden of multimorbidity. Although many comorbidities may vary by sex and men with lupus may have more severe disease than women, sex differences in multimorbidity among SLE patients have not been examined.

Table. Comparison of multimorbidity prevalence between females and males among patients without SLE and patients with SLE.

	Multimorbidity (2+ conditions) Odds ratio*	Multimorbidity (5+ conditions) odds ratio*
Non SLE		
Women	Ref.	Ref.
Men	0.91 (0.83-0.99)	0.93 (0.80-1.08)
SLE		
Women	Ref.	Ref.
Men	1.09 (1.01-1.18)	1.15(1.05-1.25)
*Adjusted for age, race/ethnicity, and region		

Methods: We used the OptumLabs Data Warehouse (OLDW), a longitudinal, real-world data asset with de-identified administrative claims for commercial and Medicare Advantage enrollees, to identify cases of SLE and matched comparators. Cases were defined as patients with ≥3 diagnoses of SLE between January 2006 and September 2015. Controls were persons without SLE matched 1:1 to SLE cases on age, sex, race/ethnicity, and enrollment date. Race was classified as non-Hispanic White (White), non-Hispanic Black (Black), Asian, Hispanic, based on self-report or derived rule sets. Multimorbidity (2 or more comorbidities) was defined using 172 chronic comorbidities from the chronic condition indicator of the clinical classification software (healthcare cost and utilization project). SLE, cutaneous lupus, and rheumatoid arthritis ICD-9 codes were excluded from the analysis. Two or more ICD-9 codes at least 30 days apart were used to define a comorbidity. A secondary analysis was performed including those with 5 or more comorbidities. Logistic regression models were used to estimate odds ratios (OR) with 95% confidence intervals (CI) adjusted for age, race/ethnicity, and region.

Results: The study included 34,752 cases with SLE and 34,752 matched non-SLE comparators. The mean age was 48 years (SD 14.2), and 90.6% were female for both cohorts in both cohorts, women were slightly younger (mean age 48 vs. 50 years). In both cohorts, women were more racially/ethnically diverse than men, with 66.2% of women (69.4% men) being White, 11.8% (12.3%) Hispanic, 18.7% (14.8%) Black, 3.4% (3.5%) Asian.

Patients with SLE had more multimorbidity than non-SLE subjects (58.1% vs 26.3%). Observed rates of multimorbidity were higher in men than women with SLE (57.8% women vs 60.9% men, p=0.0006), but similar non-SLE patients, (26.3% women vs 26.1% men, p=0.74). Following adjustment for age, race/ethnicity, and geographic region, multimorbidity among SLE patients remained higher in men (OR: 1.09; 95% CI: 1.01-1.18) compared to women and but lower for non-SLE men than women (OR: 0.91; 95% CI: 0.83-0.99). Secondary analysis in those with 5 or more comorbidities also demonstrated higher multimorbidity in men with SLE compared to women (OR: 1.15; 95%CI: 1.05-1.25), but similar in those without SLE (OR:0.93, 95% CI: 0.93 (0.8-1.08) (Table).

Conclusion: This large, nationwide claims study showed increased occurrence of multimorbidity in men with SLE compared to women with SLE, but similar to men and women without SLE. These differences may reflect the long-term effects of more severe disease in men with SLE than women.

Baseline CLASI Activity Score, Median (IQR)	4.5 (2.0-9.0)	5.0 (2.0-10.0)	0.912[c]
Baseline CLASI Damage Score, Median (IQR)	10.0 (6.0-14.5)	6.0 (3.0-10.0)	**<0.001[c]**

[a] Non-Black patients consisted of 45 Caucasians, 18 Hispanics, 5 Asians, 2 Mixed patients and 1 Middle Eastern patient with DLE.
[b] Smoking status is missing for 8 patients.
[c] P-values were calculated with Mann Whitney U test.
[d] P-values were calculated with Chi-Square test.
Abbreviations: CLASI – Cutaneous Lupus Erythematosus Disease Activity and Severity Index, DLE – Discoid Lupus Erythematosus, IQR – Interquartile Range, Yr - Year

DLE patients are not well understood. The objective of this retrospective cohort study was to examine the differences in DLE lesion distribution and characteristics of Black individuals compared to non-Black individuals.

Methods: Patients were recruited from the University of Texas Southwestern cutaneous lupus erythematosus (CLE) registry from January 2009 to June 2020. Adult DLE patients with a reported race/ethnicity and Cutaneous Lupus Erythematosus Disease Area and Severity Index (CLASI) scores were included in this study. Patients were excluded if they had an additional CLE subtype, or if they were < 18 years old. DLE lesion locations and characteristics based on CLASI scores were the primary outcome variables. The primary predictor variable was race, which was categorized into Blacks and non-Blacks. Additional predictor variables included age at initial visit, gender, disease duration at initial visit, follow up duration, smoking status and presence or absence of SLE. SKINDEX-29+3 qualify of life scores were secondary outcome measures. Univariate analyses were performed to determine demographic differences and to compare lesion location, lesion characteristics, and quality of life scores between Black and non-Black patients. Multivariable logistic regression was performed to determine significant predictors of DLE lesion location.

Results: 183 DLE patients (112 Black and 71 non-Black) were included in this study. Black DLE patients had worse baseline CLASI damage scores compared to non-Black DLE patients (median: 10.0 (IQR: 6.0-14.5) vs. 6.0 (3.0-10.0), p< 0.001) (**Table 1**) and were more likely to have. In univariate analysis, Black patients were more likely to have scalp involvement [OR (95% CI): 2.54 (1.12-5.79), p=0.013] (**Table 2**). In multivariable analysis, Black patients had 2.54 (1.20-5.37) greater odds of having scalp involvement (p=0.015) and 1.97 (1.06-3.68) greater odds of having ear

Table 2. Univariate analyses of DLE lesion distribution based on CLASI scores in 112 Black and 71 non-Black patients

Anatomical Location	Black (N, %)	Non-Black (N, %)	OR (95% CI)	P-Value[a]
Scalp	97 (87%)	51 (72%)	2.54 (1.12-5.79)	**0.013**
Ears	66 (59%)	32 (45%)	0.92 (0.92-3.33)	0.067
Nose/Malar Area	60 (59%)	40 (56%)	0.89 (0.47-1.70)	0.714
Rest of Face	63 (56%)	37 (53%)	1.18 (0.62-2.24)	0.584
V-Area of Neck (Front)	22 (20%)	19 (27%)	0.67 (0.31-1.44)	0.260
Posterior Neck/Shoulders	22 (20%)	20 (28%)	0.62 (0.29-1.33)	0.181
Chest	20 (18%)	18 (25%)	0.64 (0.29-1.41)	0.223
Abdomen	10 (9%)	1 (1%)	N/A[b]	0.053[c]
Back and Buttocks	27 (24%)	18 (25%)	0.94 (0.44-1.99)	0.849
Arms	40 (36%)	25 (35%)	1.02 (0.53-2.00)	0.945
Hands	19 (17%)	9 (13%)	1.41 (0.56-3.77)	0.432
Legs	23 (21%)	18 (25%)	0.76 (0.36-1.65)	0.446
Feet	20 (18%)	8 (11%)	1.71 (0.67-4.77)	0.228
Mucous Membrane	15 (13%)	9 (13%)	1.07 (0.41-2.94)	0.889

[a] P-values were calculated with Chi-square test unless otherwise specified.
[b] OR not calculated due to low numbers of patients with abdomen involvement in the non-Black patient group.
[c] P-values were calculated with Fisher's exact test.
Abbreviations: CLASI - Cutaneous Lupus Erythematosus Disease Area and Severity Index, DLE – Discoid lupus erythematous

Table 3. Univariate analyses of DLE lesion characteristics based on CLASI scores in 112 Black and 71 Non-Black patients

Anatomical Location and Lesion Characteristics	Black (N, %)	Non-Black (N, %)	P-Value[a]
Erythema in Any Location	99 (88%)	63 (89%)	0.944
Scale in Any Location	78 (69%)	53 (75%)	0.464
Dyspigmentation in Any Location	111 (99%)	56 (79%)	**<0.001**
Scarring in Any Location	100 (89%)	55 (77%)	0.030
Scalp			
Erythema	75 (59%)	42 (67%)	0.284
Scale/Hypertrophy	58 (52%)	34 (48%)	0.607
Dyspigmentation	92 (82%)	32 (48%)	**<0.001**
Scarring Alopecia	89 (79%)	40 (56%)	**0.001**
Non-Scarring Alopecia	49 (44%)	29 (41%)	0.699
Ears			
Erythema	36 (32%)	20 (28%)	0.570
Scale/Hypertrophy	34 (30%)	22 (31%)	0.928
Dyspigmentation	63 (56%)	25 (35%)	**0.006**
Scarring	31 (28%)	14 (20%)	0.223

[a] P-Values were calculated with Chi-Square test.
Abbreviations: CLASI - Cutaneous Lupus Erythematosus Disease Area and Severity Index, DLE – Discoid lupus erythematous

involvement (p=0.032) compared to non-Blacks. Black patients were more likely to have dyspigmentation (99% vs. 79%, p< 0.001) in any anatomical location), scalp (82% vs. 48%, p< 0.001), and ear (56% vs. 35%, p=0.006). They were also more likely to have scarring alopecia (79% vs. 56%, p=0.001) than non-Blacks (**Table 3**). No significant differences in SKINDEX-29+3 scores were seen between Black and non-Black patients with DLE.

Conclusion: Black DLE patients have important lesion location and characteristic differences compared to non-Black DLE patients. Signs of disease damage, particularly ear dyspigmentation, scalp dyspigmentation and scarring alopecia, can more frequently affect Black DLE patients and can help assist diagnosis and treatment plans. Our findings will help clinicians better understand racial differences in DLE presentation, which may lead to proper diagnosis and treatment initiation.

Abstract Number: 0599

Effectiveness of a Provider Led Intervention on Medication Adherence in an Urban Lupus Clinic

Nancyanne Schmidt[1], Yevgeniya Gartshteyn[2], Teja Kapoor[3], Laura Geraldino[4], Leila Khalili[5] and Anca Askanase[6], [1]New York Presbyterian/Columbia University Medical center, New York, NY, [2]Columbia University Medical Center, Glen Rock, NJ, [3]Columbia University Irving Medical Center, Leonia, NJ, [4]New York Presbyterian Hospital - Columbia Campus, New York, NY, [5]Columbia University Medical Center, New Haven, NY, [6]Columbia University Medical Center, New York, NY

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Healthcare Disparities in Rheumatology Poster (0594–0622)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Medication adherence is a difficult charge in SLE. Up to 75% of lupus patients are non-adherent with hydroxychloroquine (HCQ). Pharmacy refill data measured by percent days covered (PDC) and HCQ levels are the main adherence measures used in SLE. Health literacy is an important culprit in non-adherence. Social cognitive behavior theories have been applied to understand the link between medication adherence and health literacy. Health literacy universal precautions refers to the steps that providers should take assuming all patients have difficulty comprehending health information. This study aimed to evaluate the effect of a provider led universal precautions intervention on medication adherence using indirect (PDC) and direct (HCQ blood level) measures of medication adherence and disease activity measures in a predominantly Hispanic, low SES, low health literacy, SLE population.

Methods: Data collected during a 6-month prospective intervention was compared with data from the 6-month pre-intervention period. Interventions based on the Agency for Healthcare Research and Quality universal health literacy precautions kit included 1) encouraging questions, 2) teach-back communication, and 3) brown-bag medication review. Analysis was performed using paired t-tests, comparing PDC (for HCQ, corticosteroids, immunosuppres-

**Biologics: Rituximab, subcutaneous Belimumab

patients were prescribed corticosteroids, 11% biologics, and 43% immunosuppressants. During the intervention period, physicians completed 56 patient visits, 2 visits/patient, 113 ± 72 days apart. Median toolkit administration time was < 5 minutes. HCQ PDC decreased from 0.61 pre- to 0.53 post- intervention (p=NS); non-adherent < 0.80. HCQ blood levels were >1000 ng/mL both pre- and post-intervention, therapeutic HCQ > 500ng/ml. On an individual level, PDCs and blood levels were discordant. Two patients had high post intervention PDC (>0.8) and sub-therapeutic blood levels. Prednisone adherence based on PDC increased from 0.6 to 0.67 (p=NS). Immunosuppressants PDC remained the same, 0.57. Biologics PDC was >0.8. SLEDAI decreased from 4.02 ± 4.31 to 2.88 ± 2.67 ($p < 0.05$).

Conclusion: In a population of predominantly Hispanic patients with SLE, low health literacy, and low SES, non-adherence was high across all medications except for biologics. The application of health literacy interventions provided conflicting results. This discordance could be due to differences in the recall periods; the recall period for PDC is 6 months, while HCQ levels only reflect weeks of adherence. The reasons for this discordance and non-adherence need to be further investigated and improved interventions to increase adherence should be sought.

A Cohort Study of Retention in Ambulatory Lupus Care Among Medicare Patients with SLE-related Hospitalizations

Maria Schletzbaum[1], Carlos Torres[2], Amy Kind[2], Andrea Gilmore Bykovskyi[3], Ann Sheehy[2] and Christie Bartels[2], [1]University of Wisconsin School of Medicine and Public Health, Middleton, WI, [2]University of Wisconsin School of Medicine and Public Health, Madison, WI, [3]University of Wisconsin - Madison School of Nursing, Madison, WI

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Healthcare Disparities in Rheumatology Poster (0594–0622)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: In other conditions that require chronic management, poor retention in ambulatory care is associated with adverse outcomes. We previously identified that living in the most disadvantaged neighborhoods was the greatest predictor of poor care retention among lupus patients in one urban cohort. Given high hospitalization and rehospitalization rates among lupus patients, this study aims to measure rates and predictors of retention in lupus care prior to hospitalization. Results will inform efforts to improve care retention, health disparities, and outcomes for patients with lupus.

Methods: This retrospective cohort study used a 20% random Medicare sample of adult hospitalizations with an SLE diagnosis code from 2013-2014. Inclusion required at least one year of continuous Medicare AB coverage before hospitalization.

Retention in lupus care was measured in the 12 months prior to hospitalization. Visit-based retention in care used an established threshold of at least two ambulatory rheumatologist visits >= 90 days apart. Rates of visit-defined care retention were calculated by sociodemographic and comorbidity groups. Generalized logistic regression, clustered by patient, was performed to identify predictors of care retention.

Table 1. Care retention status by baseline characteristics of Medicare admissions with SLE

30-Day Readmission (n [column %])		2,601 (24.0)	891 [21.5]	1,710 [23.9]	0.001

**p values calculated using ANOVA for numeric variables and chi-square for categorical comparisons.*
Abbreviations: RUCA = rural urban commuting area, ADI = area deprivation index, HCC= Hierarchical Classification Code, CHF = congestive heart failure.

Results: Among 11,296 SLE-related hospitalizations, the overall observed rate of visit-defined care retention in the year prior to hospitalization was just 36.7%. White, Black, and Hispanic patients had lower rates of retention when compared to Asian/Pacific Islander patients (37.7%, 34.7%, 36.0% vs. 43.4% p=0.02, Table 1). Retention rates for rural-residing patients were significantly lower than suburban (29.5% vs 38.8%, $p < 0.001$). Hospitalizations associated with the most disadvantaged neighborhood ADI quintile had lower rates of patient retention (32.7% vs 38.5%, $p < 0.001$). Thirty-day rehospitalization rates were 21.5% among those with baseline retention compared to 23.9% without.

Multivariable analysis showed that women were more often retained (aOR 1.41, 95% CI 1.15-1.73) (Table 2). Rural residents had 26% lower odds of being retained in care when compared to urban residents (0.74, 0.59-0.94). History

Table 2. Odds Ratios for Predictors of Visit-Defined Care Retention

		Adjusted Odds Ratio	Adjusted 95% CI

	Suburban	1.03	0.83-1.28
	Large Rural	0.99	0.80-1.22
	Small town/ Rural	**0.74**	**0.59-0.94**
HCC score		1.03	0.99-1.08
Comorbidities	Anxiety	**0.83**	**0.73-0.95**
	Alcohol use disorder	**0.54**	**0.35-0.84**
	Diabetes mellitus	**0.84**	**0.73-0.97**
	Fluid & electrolyte disorders	**0.79**	**0.70-0.90**
	Obesity	**1.23**	**1.05-1.44**
	Peripheral vascular disease	**0.83**	**0.70-0.99**
	Renal failure	**0.64**	**0.56-0.75**
	Tobacco use disorder	**0.75**	**0.64-0.88**

The model also adjusted for additional comorbidities (chronic lung disease, coagulopathy, congestive heart failure, depression, liver disease, neoplasms, neurological disease, opioid or drug use disorder, pulmonary circulatory disease, valvular disease, weight loss) which were not significant predictors.

of Medicaid enrollment, a proxy of low SES, was significantly associated with decreased odds of retention in care (0.73, 0.63-0.85). Similarly, alcohol use (0.54, 0.35-0.84), tobacco use disorders (0.75, 0.64-0.88), and renal failure (0.64, 0.56-0.75) were associated with lower odds of retention in care. Obesity predicted 23% greater odds of retention (1.23, 1.05-1.44). Race/ethnicity and ADI quintile were not significant in the full model. Limitations include potential misclassification of NP/PA visits.

Conclusion: Rural residence and lower SES, indicated by Medicaid eligibility, predicted lower likelihood of retention in ambulatory lupus care prior to hospitalization. Several comorbid conditions, including renal failure, also predicted lower retention. Those retained in care had lower rates of 30-day readmission. Findings highlight the importance of addressing ambulatory access and outreach to retain and re-engage lupus patients in rheumatology care. Results can aid patient-provider communication on the importance of continuity of lupus care.

Racial Differences in Medication Beliefs Among SLE Patients

D Ryan Anderson[1], Amanda Eudy[2], Megan Clowse[3], Rebecca Sadun[2], Jennifer Rogers[2], Lisa Criscione-Schreiber[4], Jayanth Doss[2], Corrine Volis[5], Theresa Coles[2] and Kai Sun[2], [1]Duke University Hospital, Durham, NC, [2]Duke University, Durham, NC, [3]Duke University, Chapel Hill, NC, [4]Duke University School of Medicine, Durham, NC, [5]University of Wisconsin School of Medicine and Public Health, Madison, WI

SESSION INFORMATION

Session Date: Sunday, November 7, 2021

Session Title: Healthcare Disparities in Rheumatology Poster (0594–0622)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Background/Purpose: Medication adherence is essential to establishing and maintaining disease remission among SLE patients. Patients' beliefs about treatment influence engagement and adherence to therapy. We previously found racial disparities in medication adherence between White and non-White SLE patients, but racial differences in beliefs about medications have not been well explored. In this study, we investigated differences in medication beliefs and their association with medication adherence between White and non-White SLE patients.

Methods: Patients meeting ACR or SLICC SLE criteria completed the 18-item Beliefs about Medicines Questionnaire (BMQ), which measures four belief domains: disease-specific medication necessity, disease-specific medication concern, general medication overuse, and general medication harm. Adherence was measured using the Domains of Subjective Extent of Nonadherence (DOSE- nonadherence) questionnaire. Due to small numbers of patients who identified as Asian and Hispanic, they were grouped with Black patients and analyzed as non-White. We compared median BMQ scores between White and non-White patients, and explored differences in BMQ scores between adherent and non-adherent patients by race.

Results: This analysis included 102 patients (48 White, 48 Black, 5 Asian, 1 Hispanic, mean age 50, 96% female, 33% < college education, 54% private insurance). For the 18 individual questions, 11 produced answers that were statistically different between the White and non-White patients. Compared to Whites, non-White patients had more general beliefs that medications are harmful (8.5 [interquartile range (IQR) 7-10] vs 7 [IQR 5-9], p=0.005) and overused (11 [IQR 9-12] vs 8.5 [IQR 8-10], p=0.003).

Table 1. comparing BMQ domains between adherent and non-adherent patients by race

	White			Non-white		
	Adherent (n=32)	Nonadherent (n=15)	p-value	Adherent (n=24)	Nonadherent (n=29)	p-value
BMQ specific necessity[1]	20[18-23.5]	19[17-22]	0.5	20[17.5-21.5]	17[15-20]	0.06
BMQ specific concern[1]	**11[7-13]**	**13.5[12-19]**	**0.03**	12[10-16]	15.5[13-17]	0.1
BMQ general overuse[2]	8[7-10]	9[8-10]	0.3	**9.5[8-12]**	**11[10-13]**	**0.04**
BMQ general harm[2]	7[5-8]	8[5-9]	0.4	**8[6-10]**	**9.5[8-11]**	**0.008**

[1] score range 5-25, [2] score range 4-20; BMQ = Beliefs in Medicines Questionnaire

While 71% of White patients reported adherence, only 44% of non-White patients reported adherence. Among White patients, those who were nonadherent reported more SLE-specific medication concerns. In contrast, among non-White patients, those who were non-adherent reported more general beliefs that medications are harmful and overused (Table 1).

Conclusion: We found significant differences in medication beliefs between White and non-White SLE patients with the greatest difference in general beliefs about medications. These racial differences in medication beliefs were also present in adherence data, with non-adherence in the White group being driven by specific concerns about SLE medications while non-adherence in the non-White group was driven by general concerns about medications. These results suggest adherence interventions tailored to race may be more effective, with a focus on building trust in the non-White community. Future studies should investigate the relationship between medication beliefs and SLE outcomes. The extent to which racial differences in medication beliefs may be driven by mistrust in the medical system and systemic racism also deserves further study.

Use of a Popular Opinion Leader Model to Disseminate Information Virtually About Clinical Trial Enrollment to People of Color with Lupus

Kreager Taber[1], Holly Milaeger[2], Jessica Williams[1], Daniel Erickson[3], Elmer Freeman[4], Patricia Canessa[5], Rosalind Ramsey-Goldman[6] and Candace Feldman[1], [1]Brigham and Women's Hospital, Boston, MA, [2]Northwestern University, Feinberg School of Medicine, Chicago, IL, [3]Northwestern University, Feinbergy School of Medicine, Chicago, IL, [4]CCHERS, Inc., Boston, MA, [5]State of Illinois Board of Health, Chicago, IL, [6]Northwestern University, Chicago, IL

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Healthcare Disparities in Rheumatology Poster (0594–0622)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Despite a disproportionate burden of systemic lupus erythematosus (SLE) and disparities in adverse outcomes among Black compared to white individuals, people of color are underrepresented in SLE clinical trials. Our aims were: 1) to leverage a community-academic partnership in Boston and Chicago to develop clinical trial education modules for individuals who self-identify as Black with SLE and 2) to recruit and train trusted Popular Opinion Leaders (POLs) with robust social networks to disseminate this information in their communities. Due to COVID-19, we adapted the traditional, in-person, community-based POL model to a virtual platform and assessed the feasibility of this approach.

Methods: Rheumatologists and public health experts from two academic institutions developed training modules in partnership with community leaders and SLE advocates in Boston and Chicago. POLs age ≥18 years old with and without SLE were recruited through community- and hospital-based networks from Boston and Chicago neighborhoods with high proportions of Black individuals. To train the POLs, five presentations were delivered using an interactive, virtual platform. Modules included: 1) Description of the POL Model, 2-3) Introduction to Clinical Trials, I/II, 4) History of Racism and Clinical Trials, and 5) Clinical Trials: Barriers, Facilitators, and Mediators. POLs completed

Table. Characteristics of Popular Opinion Leaders (POLs) in Boston and Chicago			
Site		Boston	Chicago
Number of POLs		19	17
Mean (SD) Age		55.6 (11.4)	52.8 (18.2)
Sex – N (%)	Female	18 (95)	14 (82)
	Male	1 (5)	3 (18)
Self-identified Race/Ethnicity- N (%)	Black/African American	13 (68)	16 (94)
	White	3 (16)	0
	Other	2 (11)	0
	Hispanic	1 (5)	1 (6)
Educational Attainment* – N (%)	High School	6 (32)	1 (6)
	Technical School/GED	3 (16)	2 (13)
	Bachelor's Degree	4 (21)	6 (38)
	Master's Degree	6 (32)	3 (19)
Mean Years of Work Experience (SD)		28.8 (13)	27.4 (10)
Marital Status- N (%)	Single	11 (58)	7 (41)
	Married	4 (21)	6 (35)
	Divorced	3 (16)	2 (12)
	Widowed	1 (5)	2 (12)
Housing – N (%)	Live with spouse, blood relatives and family	10 (53)	10 (59)
	Live alone	9 (47)	7 (41)
Self-Reported Health Conditions – N (%)	Diagnosed with lupus	12 (63)	13 (77)
	Diabetes	1 (5)	0
	Hypertension	7 (37)	9 (53)
	Arthritis	12 (63)	12 (71)
	Obesity	9 (47)	4 (24)
Relative with Lupus – N (%)		8 (42)	11 (65)
Previous Community Experience- N (%)	Previous training as a health promoter	8 (42)	3 (18)
	Participated in previous lupus educational training	13 (68)	13 (77)
	Hosted presentations or community-based events	11 (58)	9 (53)
	Gave testimony	10 (53)	5 (56)
	Presented at health fairs	8 (42)	8 (89)
	Distributed educational materials	10 (53)	8 (89)
	Contacted stakeholders	6 (32)	3 (33)
	Participated in patient advocacy	9 (47)	4 (44)
	Collected information from community members (surveys or other)	6 (32)	3 (33)
	Patient navigation	5 (26)	3 (33)
Social Network- N (%)	Member of a gym/sports club	7 (37)	8 (47)
	Member of a faith-based organization such as a church or ministry	11 (58)	13 (77)
	Have meeting places with social network members	10 (53)	8 (47)
Abbreviations: POL, Popular Opinion Leader; GED, General Educational Development; *5 not reported in Chicago cohort			

pre and post tests for the modules, which were compared using paired t-tests. POLs were also taught to use virtual platforms to share information learned with their social networks. POLs reported their dissemination data.

Results: Nineteen POLs were recruited in Boston and 17 in Chicago (**Table)**. In Boston, 18 (95%) were female, 13 (68%) self-identified as Black, and mean age was 55.6 years. In Chicago, 14 (82%) were female, 16 (94%) self-identified as Black, and mean age was 52.8 years. Retention of POLs throughout the training was 82% both in Boston and Chicago. For the two-part clinical trials module, POLs' knowledge of clinical trials improved significantly overall (mean difference of 3.92 points, 95% CI 3.35-5.89), and separately in Boston (mean difference of 2.80 points, 95% CI 3.33-7.18,) and Chicago (mean difference of 5.45 points, 95% CI 2.42-6.10). As of May 2021, 7 POLs documented 36 encounters and reached 1,023 total individuals; dissemination is ongoing. Boston POLs reached 233 people, including 122 individuals through a sorority newsletter, 104 through Zoom, 6 through phone calls, and 1 in person. Chicago POLs personally reached 240 individuals, including 163 people in a social media group for SLE patients and families, as well as 550 individuals through email interactions.

Conclusion: The POL model was effectively adapted to a virtual program in the context of the COVID-19 pandemic. Modules developed jointly by academic and community partners were implemented and successfully improved knowledge regarding clinical trials. POL retention was high, possibly due to the convenience of virtual trainings and the sense of community developed through the training sessions. POLs successfully disseminated information virtually about clinical trials. Further studies are needed to determine impact on the diversity of SLE trial enrollment.

SESSION INFORMATION

Session Date: Sunday, November 7, 2021

Session Title: Healthcare Disparities in Rheumatology Poster (0594–0622)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Background/Purpose: Older people remain underrepresented in clinical trials, and evidence generated in younger populations cannot always be generalized to older patients.

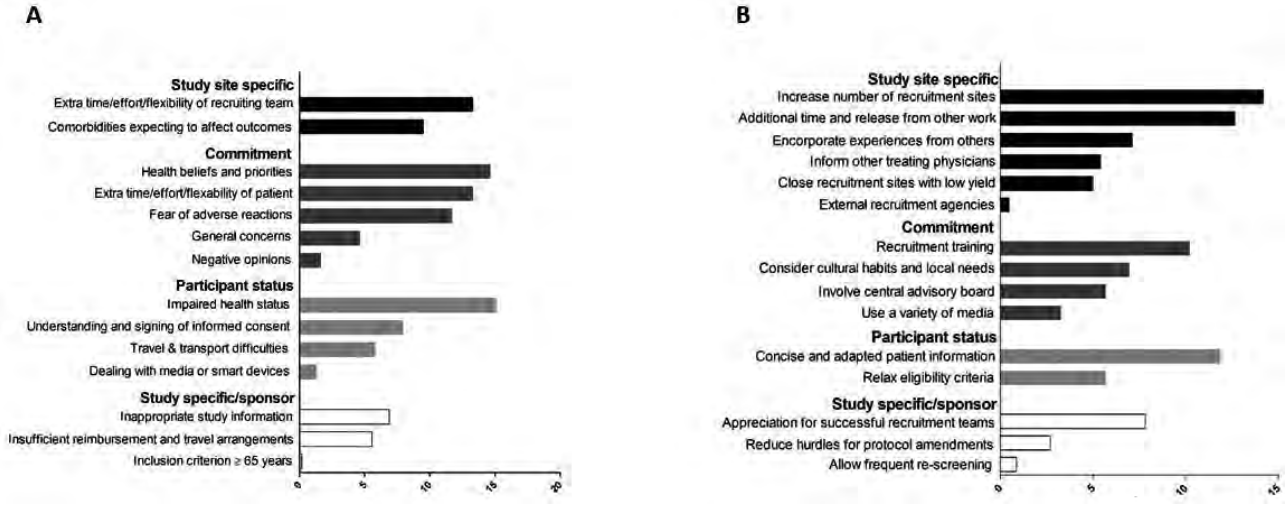
We aimed to identify key barriers and to discuss solutions to specific issues affecting recruitment and retention of older participants in clinical trials based on experience gained from six current European randomized controlled trials (RCTs) focusing on older People (Table 1).

Methods: A multidisciplinary group of experts including representatives of the six RCTs held two networking conferences and compiled lists of potential barriers and solutions. Every item was subsequently allocated points by each study team according to how important it was perceived to be for their RCTs.

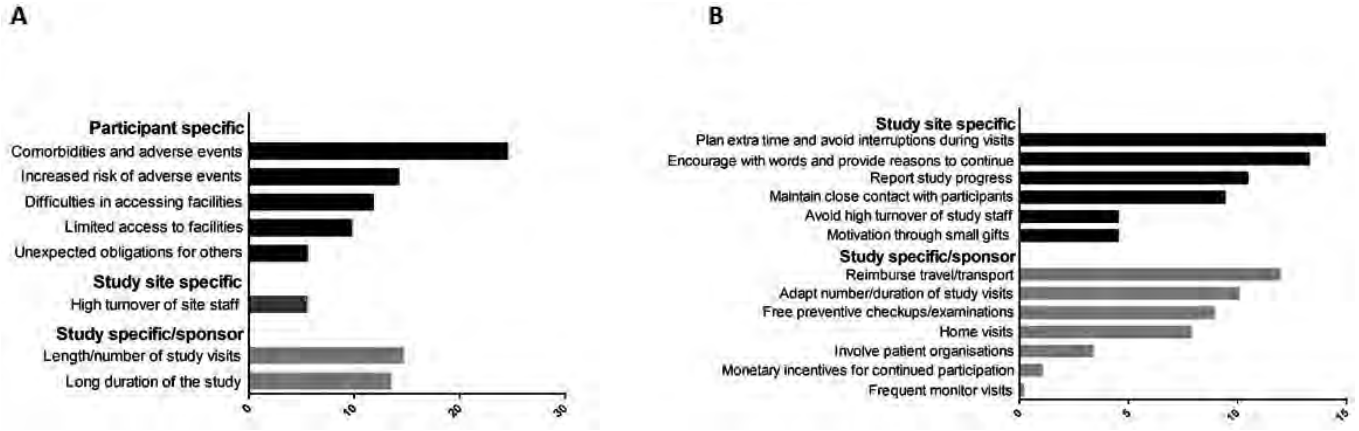
Results: The six RCTs enrolled 7612 older patients (Table 1). Key barriers to recruitment were impaired health status, comorbidities and diverse health beliefs including priorities within different cultural Systems (Figure 1A). All trials had to increase the number of recruitment sites. Other measures felt to be effective included the provision of extra time, communication training for the study staff and a re-design of patient Information (Figure 1B). Key barriers for retention included the presence of severe comorbidities and the occurrence of adverse events. Long study duration, frequent study visits and difficulties accessing the study site were also mentioned (Figure 2A). Solutions felt to be effective included spending more time maintaining close contact with the participants, appropriate measures to show appreciation and reimbursement of travel Arrangements (Figure 2B).

Six international multi-center randomized controlled trials (RCTs), designed for patients aged ≥ 65 years and supported by the European Commission Horizon 2020 research and innovation programme

Trial Acronym	Participants enrolled	Countries	Short description
GLORIA	451	Portugal, Germany, Italy, Slovakia, Hungary, Romania, The Netherlands,	Comparing the cost-effectiveness and safety of additional low-dose glucocorticoid in treatment strategies for elderly patients with rheumatoid arthritis
SECURE	2499	Spain, Italy, Germany, France, Poland, Hungary, Czech Republic	Secondary prevention of cardiovascular disease in the elderly
SITLESS	1369	Spain, France, United Kingdom, Germany, Denmark	Exercise referral schemes enhanced by self-management strategies to battle sedentary behaviour in the elderly
OPERAM	2008	Switzerland, Belgium, The Netherlands, Ireland	Optimising therapy to prevent avoidable hospital admissions in the multimorbid elderly
EU-CaRE	179 (RCT part)	Denmark, Spain, The Netherlands, France, Switzerland	The European study on effectiveness and sustainability of current cardiac rehabilitation programmes in the elderly RCT: effectiveness of tele-rehabilitation in patients not (willing to) taking part in regular rehabilitation
PRECIOUS	Currently 1106	United Kingdom, Norway, Italy, Hungary, The Netherlands, Poland, Estonia, Germany, Greece	Prevention of complications to Improve outcome in elderly patients with acute Stroke



A: Challenges in retention. Mean number of points awarded per item (standard error range: 1,92 – 4,84). The more points an item got, the more relevant it was perceived to be for the respective trial. B: Solutions in retention. Mean number of points awarded per item (standard error range: 0,21 – 4,47). The more points an item got, the more relevant it was perceived to be for the respective trial.



A: Challenges in retention. Mean number of points awarded per item (standard error range: 1,92 – 4,84). The more points an item got, the more relevant it was perceived to be for the respective trial. B: Solutions in retention. Mean number of points awarded per item (standard error range: 0,21 – 4,47). The more points an item got, the more relevant it was perceived to be for the respective trial.

Conclusion: Recruitment and retention of older patients in trials requires special recognition and a targeted approach. Our results provide scientifically-based practical recommendations for optimizing future studies in this population.

Disparities in Burden of Disease in Patients with RA Across Racial and Ethnic Groups

Jacqueline O'Brien[1], Sang Hee Park[2], Taylor Blachley[1], Maya Marchese[1], Nicole Middaugh[1], Xue Han[2], Keith Wittstock[2] and Leslie Harrold[1], [1]CorEvitas, LLC, Waltham, MA, [2]Bristol Myers Squibb, Princeton, NJ

SESSION INFORMATION

Session Date: Sunday, November 7, 2021
Session Title: Healthcare Disparities in Rheumatology Poster (0594–0622)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Prior research has shown that differences exist in disease activity and clinical outcomes for RA across racial and ethnic groups in the US.[1] This study provides an updated analysis examining differences in disease burden and change in clinical outcomes over time across racial and ethnic groups.

Methods: This study used data from CorEvitas' RA Registry, which consists of over 56,000 RA patients across 42 US states. We included patients with a visit during two time periods (visit 1: 2013–2015; visit 2: 2018–2020) and selected the first visit in the first time period and the last visit in the second time period for each patient. Patients self-reported race and ethnicity at enrollment; Clinical Disease Activity Index (CDAI) score was obtained at both visits.

Table 1. Demographic and clinical characteristics of study population by race/ethnicity

Asian	61.2	(41.6 to 77.8)	0.498	
Achievement of remission (%)[b]				
White	19.2	(16.3 to 22.5)	Reference	0.905
Black	17.9	(12.7 to 24.6)	0.662	
Hispanic	19.2	(14.0 to 25.8)	0.994	
Asian	21.9	(13.5 to 33.6)	0.560	
Change in HAQ-DI score from visit 1 to visit 2				
White	0.07	(0.04 to 0.09)	Reference	0.145
Black	0.08	(0.02 to 0.14)	0.660	
Hispanic	0.10	(0.04 to 0.16)	0.218	
Asian	−0.03	(−0.13 to 0.07)	0.063	

[a]Pairwise *P* is used to determine if there is a difference between means in patients in a specific race/ethnicity group compared with White patients; overall *P* is used to assess the differences in means across all race/ethnicity groups; [b]Only performed for those not in the disease state at visit 1 (patients not in LDA at visit 1: White, n = 2871; Black, n = 231; Hispanic, n = 235; Asian, n = 48; patients not in remission at visit 1: White, n = 5698; Black, n = 401; Hispanic, n = 409; Asian, n = 102).
CDAI, Clinical Disease Activity Index; CI, confidence interval; HAQ-DI, HAQ-disability index; LDA, low disease activity.

Patient characteristics at visits 1 and 2 by race/ethnicity (white [non-Hispanic], Black [non-Hispanic], Hispanic, or Asian) are summarized. The primary outcome was CDAI at visits 1 and 2. Secondary outcomes included the proportion of patients in low disease activity (LDA; CDAI ≤ 10) or remission (CDAI ≤ 2.8), and HAQ-disability index (DI) at each visit. We evaluated mean change in CDAI and HAQ-DI from visit 1 to 2 and probability of achieving LDA and remission at visit 2.

Linear regression models were adjusted for demographics, clinical characteristics, and site as a random effect variable. From these models, marginal means or mean change for each outcome were computed; overall and pairwise tests were used to detect differences in outcomes between races.

Results: Of 9363 eligible patients (8142 White, 527 Black, 545 Hispanic, 149 Asian), a majority (76–85%) were female. Mean age at visit 1 ranged from 55.1 to 60.7 years, and mean disease duration ranged from 9.8 to 11.8 years (**Table 1**). Many patients had history of serious infections (50–61%) and hypertension (22–41%).

In adjusted analyses, we estimated higher CDAI scores for Hispanic vs White patients at both visits 1 and 2 (**Table 2**). Proportions of patients in LDA and remission were similar across groups at visit 1; at visit 2, a significantly lower proportion of Hispanic patients were in LDA and remission compared with White patients.

Functional status declined over time for all groups, indicated by greater mean HAQ-DI scores at visit 2 vs visit 1. Compared with White patients, Hispanic patients had significantly higher mean HAQ-DI scores at visit 1, and both Black and Hispanic patients had significantly higher mean HAQ-DI scores at visit 2 (**Table 2**).

Longitudinally, CDAI scores improved for all groups from visit 1 to 2, though Hispanic patients improved significantly less than White patients (**Table 3**). There were no statistically significant differences in achievement of LDA or remission or change in HAQ-DI over time across groups.

Conclusion: Disease activity improved over the 7-year time period across all racial and ethnic groups. However, disparities between racial and ethnic groups in disease activity and functional status did persist over time, suggesting that further effort is needed to understand the drivers of these discrepancies and close this racial gap.

Abstract Number: 0605

Impact of Area of Residence on Perceptions of Health and Disease Activity in Ethnic Minorities with Rheumatoid Arthritis in an Urban Setting

Mohamed Jalloh[1], Sharon Dowell[2], Richard Ogunti[1] and Gail Kerr[3], [1]Howard University Internal Medicine Residency, Washington, DC, [2]Howard University College of Medicine, Washington, DC, [3]Washington D.C., Veterans Affairs Medical Center (VAMC)/Georgetown and Howard Universities, Washington, DC

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Healthcare Disparities in Rheumatology Poster (0594–0622)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Health care disparities in hypertension and other chronic disease are well established. Ethnic minority residents of Washington DC, particularly Wards 7 and 8, have higher rates of chronic disease and shortened lifespans, but little is known about the impact on rheumatoid arthritis (RA) in these areas. The Ethnic Minority Rheumatoid Arthritis Consortium (Howard University Hospital –[HUH]) comprised of 9 sites nationwide, reported more severe RA disease, worse outcomes, and less use of biologic therapy. Further, socioeconomic factors were linked to delayed diagnosis, worse prognosticators/seropositivity and functional outcomes. Patient assessment of overall health and disease activity have been shown to correlate positively with RA outcomes, but may be influenced by non-RA factors such as comorbidities. HUH serves a primarily DC residential African American population. We evaluated the association of area of residence on perceptions of health and RA disease status.

Methods: EMRAC participants seen at HUH and with at least one follow-up visit were evaluated. The associations of sociodemographic factors and RA disease status with Wards/Area of residence, perception of health (poor, fair, good, excellent) and physical activity (seldom, monthly, weekly) were evaluated. Logistic regression models were used to estimate associations of patients' perception of health and RA disease activity (RAPID3) within non-DC and DC regions, adjusting for gender, age, race, physical activity and comorbidities.

Results: An enrollment cohort of 96 EMRAC subjects (females 83%, mean age 55 years (SD 15.5) was available for analysis (Table 1.). Wards 4-8 corresponded to the NE, SE areas of DC and comprised of younger patients with more frequent seropositivity and higher disease activity compared to Wards 1-3 (NW, SW DC). Sixty-four percent (56/87)

had moderate to high disease activity; of whom, 66% of whom were from Wards 4-8. More non-DC patients were in remission/low disease activity at baseline and at 18 months – 13/23 (56.5%) and 11/13 (84.6%) respectively. Of 69 DC residents, 46 patients reported good to excellent perception of health (7 NW, 13 NE, and 10 SE). Of the remaining 23 DC residents (who reported fair to poor health), 70% resided in NE, SE areas. Non-DC residents (84%) were more likely to have a good to excellent perception of health compared to DC residents. Insurance data were available for 86 patients, 5 (6%) had non-DC Medicare/Medicaid, 38 (44%) had DC Medicare/Medicaid, and 43 (50%) were privately insured. Weekly physical activity was positively associated with perception of good health, regardless of area of residence (p-value: 0.02). Logistic regression (Table 2), controlling for demographic factors, found low disease activity and a non-DC domicile was significant (p-value: 0.05).

Table 2: Linear Regression Model for dependent variable Moderate to high disease activity

Observations: 48
Dependent Variable: Moderate to high disease activity on follow-up
Type: Generalized linear model
MODEL FIT:
$X^2(11) = 16.19$, $p = 0.13$
Standard errors: MLE

	exp (Est.)	2.5%	97.5%	z val.	p

SE DC Region	1.16	0.26	5.13	0.20	0.84
Age	1.01	0.96	1.05	0.32	0.75
Male Gender	0.80	0.13	5.11	-0.23	0.81
Latino	0.31	0.04	2.13	-1.19	0.23
Poor to Fair Perception of Health	2.38	0.57	9.91	1.19	0.24
RF & CCP Positive	0.32	0.03	4.00	-0.88	0.38
RF & CCP Negative	4.25	0.12	148.82	0.80	0.42
RF positive	0.39	0.03	5.14	-0.72	0.47
Comorbidities present	1.45	0.31	6.86	0.47	0.64

Conclusion: RA patients in an urban region served by a single institution demonstrated differences in disease activity and perceptions of health based on area of residence. While physical activity may play a role in the perception of health it may not be solely explained by RA disease activity. Evaluation of the role of insurance coverage and physical activity in improving RA outcomes is a priority in this vulnerable population

Abstract Number: 0606

How Might We Care for Rheumatoid Arthritis (RA) Patients Unable to See a Rheumatologist And/or Use Certain of Our Medications? Proposed Preliminary Recommendations for RA Patients Who Don't Meet Our Established Guidelines

Nicole Zagelbaum Ward[1], Abhimanyu Amarnani[1], Baljeet Rai[2], Corinne Feldman[1], Brett Feldman[1] and Richard Panush[1], [1]LAC+USC Medical Center, Los Angeles, CA, [2]LAC USC, Los Angeles, CA

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Healthcare Disparities in Rheumatology Poster (0594–0622)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Physicians share responsibilities to promote social justice and assure equitable healthcare for all. Street medicine (SM) is a field dedicated to address the need of homeless patients, often by visiting them in the street or anywhere they reside to deliver care. We, rheumatologists and SM providers, have been interested in identifying and improving the management and outcomes of our homeless RA patients. They do not fit available

Table 1. Key Principles, Key Terms, and Drug Categories for the Proposed Rheumatoid Arthritis Guidelines

Key Principles	
1. Focus on common barriers to access to medical care including homelessness. 2. Cost, distance, transportation and access to medications are important priorities. 3. Disease activity measurement using an ACR-recommended measure should be performed if possible but may not be feasible and providers must use best clinical judgement. 4. Functional status assessment should be performed when possible and services including PT, OT and assistance devices are important tools. 5. Patients with low RA disease activity or is in clinical remission should generally be maintained and treatment changes should be made when disease activity is moderate to high. 6. Treatment recommendations of one medication over another means does not imply that the non-favored medication is contraindicated, and use may be considered per provider preference. 7. In making treatment decisions, priority should be made on maximizing functionality and minimizing suffering. Lab work, subspecialty appointments, and monitoring may be obtained as possible.	
Key Term	**Definition**
Homeless RA Patient	Adults, >18 years, meeting the ACR RA classification criteria and experiencing housing insecurity
Disease activity	Low, moderate, or high as per validated scales, ideally CDAI or RAPID-3 given minimal reliance on labs
Optimal dosing of RA treatments	1) Medication dosing to achieve benefit given consideration of patient priorities 2) ideally taken at least 3 months before therapy escalation or switching
Drug category	**Description**
Disease Modifying Anti-rheumatic Drugs (DMARDs)	Leflunomide (10 mg PO uptitrate to 20 mg daily), sulfasalazine (500 mg PO BID uptitrate to 1,000 mg BID), hydroxychloroquine (5 mg/kg PO), methotrexate (10 mg PO or SQ), uptitrate to 20-25 mg weekly), tofacitinib (5 mg PO BID), minocycline (100 mg PO BID), auranofin (6 mg PO daily)
Glucocorticoids	Low dose <10 mg daily, high dose >10 mg daily, short term <3 months
TNFα inhibitor (TNFi)	Adalimumab (40 mg SQ every other week), certolizumab pegol (400 mg SQ week 0, 2, 4 then 200 mg every other week), etanercept (50 mg SQ weekly), golimumab (2 mg/kg SQ week 0, 4, then every 8 weeks), infliximab (3 mg/kg SQ week 0, 2, 6 then every 8 weeks)
Rituximab	1,000 mg IV day 1, day 15
Other biologics	Those that could be administered SQ (i.e., abatacept, tocilizumab, anakinra) may be considered

treatment guidelines or recommendations. Nor do many patients worldwide who, for challenges including distance, transportation, disabilities, income, and insurance, have limited access to care and medications. Therefore, with the encouragement of the SM Institute, we propose guidelines for rheumatologists and non-rheumatologists seeing these patients.

Methods: We adapted procedures for guidelines development from the ACR. A leadership team, of senior rheumatology faculty with extensive experience, including with guidelines, in RA (RSP) and SM (CF, BF), examined the available evidence. A research team critically reviewed the pertinent literature, synthesized the discussion, and formulated

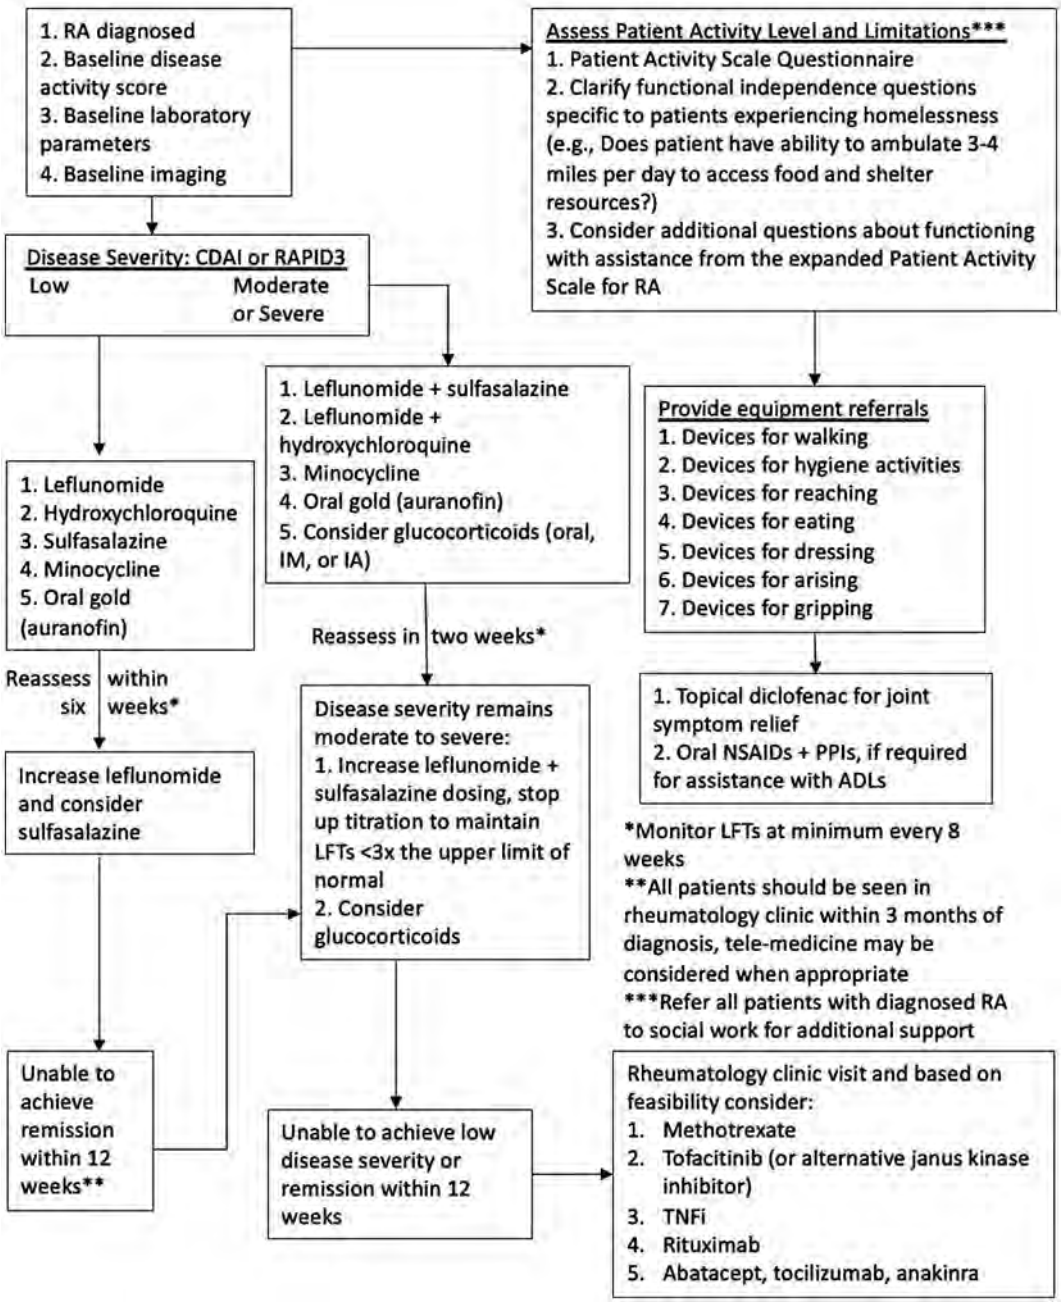

Figure 1. Proposed Rheumatoid Arthritis Treatment Algorithm.

guiding principles and PICO (population, intervention, comparator, and outcome) for possible regimens (NZW, AA, BR, SH). For each PICO question, the panel reviewed evidence and provided recommendations. Also assessed were data about therapies' efficacy, potential toxicities, ease of administration and monitoring, cost, and likely availability. The authors communicated through a series of questions focused on describing their approaches to affected patients.

Results: The Table summarizes key principles, terms, descriptions, and drug categories. We developed the principles outlined in Figure 1, which are based on patients' inability to consistently access rheumatologists; obtain, take, and store medications reliably; or get routine laboratory (or other) studies. Initial treatment regimens include leflunomide

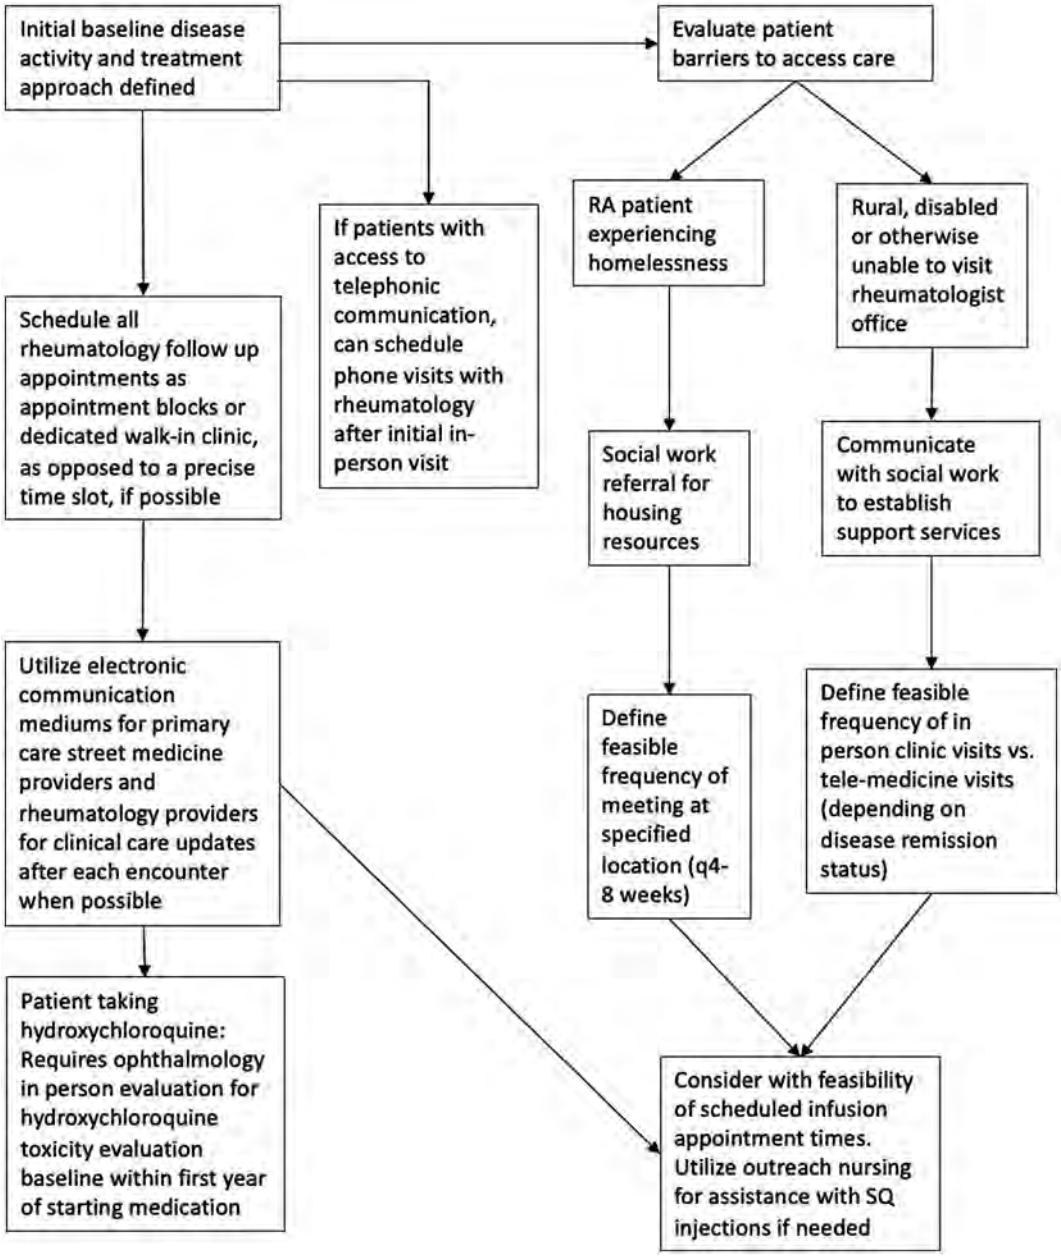

Figure 2. Proposed Rheumatoid Arthritis Continued Care Guideline

and sulfasalazine; alternatives are hydroxychloroquine, minocycline, methotrexate, auranofin, steroids (intermittently, low dose, or IA/IM), janus kinase inhibitors, and, for some, rituximab or other biologics. Figure 2 presents a proposed algorithm for continuity of care, individualized to patients' contexts. Referrals for certain adjunctive/assistance equipment are included.

Conclusion: Our efforts to care for our homeless patients led us to consider what is minimally adequate or acceptable rheumatologic care, how is it defined and quantified, and how might we conceive more innovative ways to provide/deliver it or its equivalent (i.e., SM, tele-medicine, or other). We propose guidelines for providers caring for those vulnerable patients unable to see rheumatologists or follow current treatment regimens, those for whom available guidelines do not apply or are not realistic. SM practice and limited experience with homeless patients suggest that

our proposed approach could be salutary for those patients worldwide who are challenged to see a rheumatologist or use (some of) our medications.

Abstract Number: 0607

Validation Studies of Rheumatoid Arthritis Patient-Reported Outcome Measures in Diverse Populations at Risk for Inequity: A Systematic Review

Cheryl Barnabe[1], Aimee Wattiaux[2], Jennifer Petkovic[3], Dorcas Beaton[4], Beverley Shea[3], Regina Greer-Smith[5], Jennifer Humphreys[6], Christie Bartels[7], Peter Tugwell[3] and Valerie Umaefulam[1], [1]University of Calgary, Calgary, AB, Canada, [2]University of Wisconsin, Madison, WI, [3]University of Ottawa, Ottawa, ON, Canada, [4]University of Toronto, Toronto, ON, Canada, [5]Healthcare Research Associates, Hazel Crest, IL, [6]University of Manchester, Manchester, United Kingdom, [7]University of Wisconsin School of Medicine and Public Health, Madison, WI

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Healthcare Disparities in Rheumatology Poster (0594–0622)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Existing patient-reported outcome measures (PROMs) in rheumatoid arthritis (RA) may be limited in their applicability to populations that experience inequities. We conducted a systematic review to identify validation studies for PROMs in populations at risk for inequity.

Methods: A systematic review of MEDLINE and EMBASE was completed. The search strategy was developed to identify measurement property studies for PROMs of interest (selected pain, disease activity, global evaluation and quality of life scales) in patients with RA. We identified experimental, observational, and qualitative studies reporting analysis of feasibility, construct validity and discriminant ability metrics for populations at risk for inequity by various factors including race, ethnicity, culture or language; employment status; gender and sex identity; education level; socioeconomic status; social support; age; health literacy and disability. A narrative synthesis was conducted.

Results: From 19,786 titles and abstracts screened, we identified 14 unique studies reporting validation metrics for pain (n=3), DAS28-ESR or DAS28-CRP (n=2), ACR20 (n=1), patient global assessment (n=2), EQ5D (n=4), and PROMIS® (n=3) by race (n=10 studies), age (n=6 studies), sex and gender identity (n=5 studies), education level (n=2 studies), and disability, literacy, employment status, social support level and socioeconomic status (n=1 study each). Most studies reported construct validity metrics (n=13), with 5 studies reporting on feasibility and 3 studies reporting on discriminant validity metrics. A visual summary of results is presented in the OMERACT Summary of Measurement Properties (SOMP)-Equity Extension table (Table 1). Overall, studies by culture or language demonstrated good measurement property metrics. There was significantly limited assessment of measurement property metrics for other populations at risk for inequity.

Conclusion: Our study highlights important gaps in patient representation in rheumatology research for accepted patient-reported outcome measures. New PROMs being developed for research and clinical practice should ensure

Adaptation of a Shared Decision-Making Tool for Early Rheumatoid Arthritis Treatment Decisions with Indigenous Patients

Valerie Umaefulam[1], Terri-Lynn Fox[1], Glen Hazlewood[1], Nick Bansback[2], Claire Barber[1] and **Cheryl Barnabe**[1], [1]University of Calgary, Calgary, AB, Canada, [2]University of British Columbia, Vancouver, BC, Canada

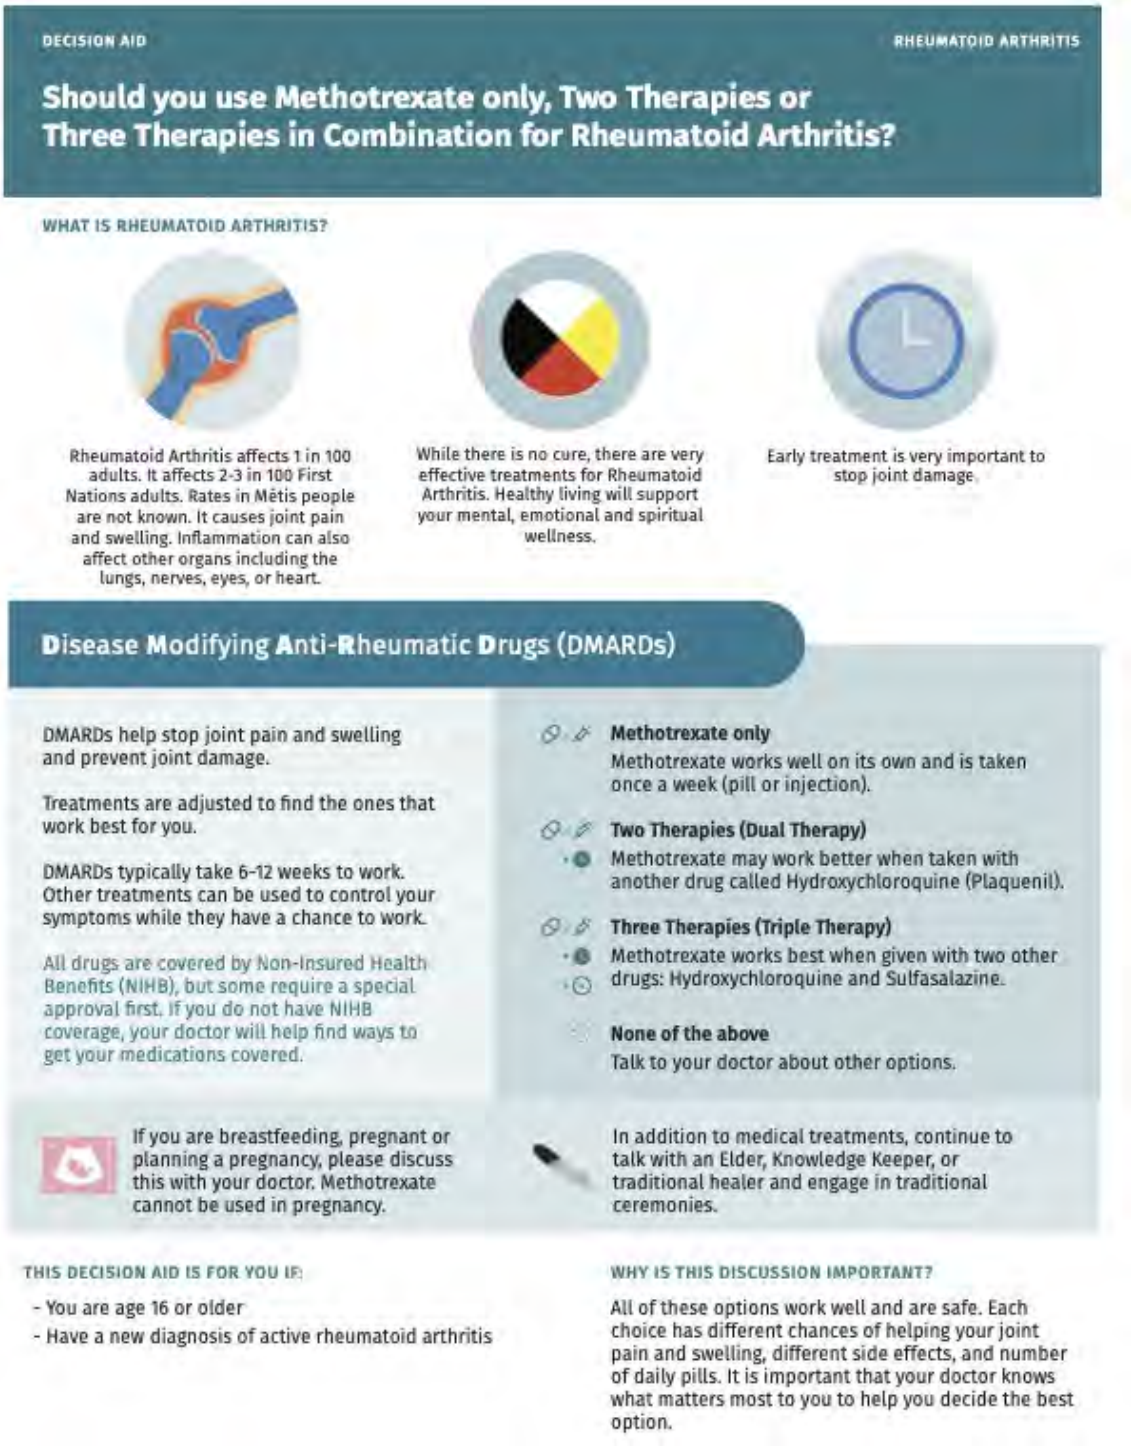
SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Healthcare Disparities in Rheumatology Poster (0594–0622)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Patient decision aids (PtDA) can enable shared decision-making between patients and healthcare providers. We have previously developed a PtDA for first-line methotrexate-based treatment options in rheumatoid arthritis (RA). Adaptations to PtDAs for use with populations facing inequities in healthcare can improve the relevancy of information presented, incorporate appropriate cultural context, and address health literacy concerns. Our objective was to adapt the Early RA PtDA for use with Canadian Indigenous patients making initial disease-modifying treatment choices.

Methods: The Early RA PtDA was modified through an iterative process using data obtained from semi-structured interviews with Indigenous patients with RA using an interview guide. A thematic analysis of interview transcriptions was completed using NVivo 12 software. Initial modifications were made based on the input of a first cohort of patients, with the revised Early RA PtDA verified by a second cohort of patients.

Results: The initial directions for modification were provided by 7 participants, while 9 participants were recruited for the verification cohort. All participants were women living with RA and self-identified as First Nations, Plains Cree, or Indigenous. In the first iteration, the revisions made were to 1) clarify medication names and routes of administration; 2) include Indigenous traditional healing practice options; 3) provide information on formulary coverage for Indigenous patients; 4) simplify text; and 5) include Indigenous images, and use colors aligned with Canadian Indigenous community representation. The second cohort perceived the revised Early RA PtDA to be acceptable for layout and information content, with appreciation expressed by participants for including Indigenous traditional healing practices as adjuncts to treatment, which was seen as beneficial for advancing communication and relationship building with health practitioners. Additional revisions were requested to increase text legibility, insert more Indigenous images, make further changes in colors, address formulary coverage for non-status First Nations patients, and include information on lifestyle factors in managing RA. Indigenous patient-specific evidence on the efficacy and safety of medication options should be included in future iterations if data available, and translation of key words into the end-users' Indigenous languages should be included for implementation of the PtDA.

Conclusion: Incorporating Indigenous-specific adaptations in the design of PtDAs may increase use and relevancy to support patient focused care and engagement in treatment decisions, thereby supporting health-equity oriented health service interventions.



DECISION AID

RHEUMATOID ARTHRITIS

Should you use Methotrexate only, Two Therapies or Three Therapies in Combination for Rheumatoid Arthritis?

WHAT IS RHEUMATOID ARTHRITIS?

Rheumatoid Arthritis affects 1 in 100 adults. It affects 2-3 in 100 First Nations adults. Rates in Métis people are not known. It causes joint pain and swelling. Inflammation can also affect other organs including the lungs, nerves, eyes, or heart.

While there is no cure, there are very effective treatments for Rheumatoid Arthritis. Healthy living will support your mental, emotional and spiritual wellness.

Early treatment is very important to stop joint damage.

Disease Modifying Anti-Rheumatic Drugs (DMARDs)

DMARDs help stop joint pain and swelling and prevent joint damage.

Treatments are adjusted to find the ones that work best for you.

DMARDs typically take 6-12 weeks to work. Other treatments can be used to control your symptoms while they have a chance to work.

All drugs are covered by Non-Insured Health Benefits (NIHB), but some require a special approval first. If you do not have NIHB coverage, your doctor will help find ways to get your medications covered.

Methotrexate only
Methotrexate works well on its own and is taken once a week (pill or injection).

Two Therapies (Dual Therapy)
- Methotrexate may work better when taken with another drug called Hydroxychloroquine (Plaquenil).

Three Therapies (Triple Therapy)
- Methotrexate works best when given with two other drugs: Hydroxychloroquine and Sulfasalazine.

None of the above
Talk to your doctor about other options.

If you are breastfeeding, pregnant or planning a pregnancy, please discuss this with your doctor. Methotrexate cannot be used in pregnancy.

In addition to medical treatments, continue to talk with an Elder, Knowledge Keeper, or traditional healer and engage in traditional ceremonies.

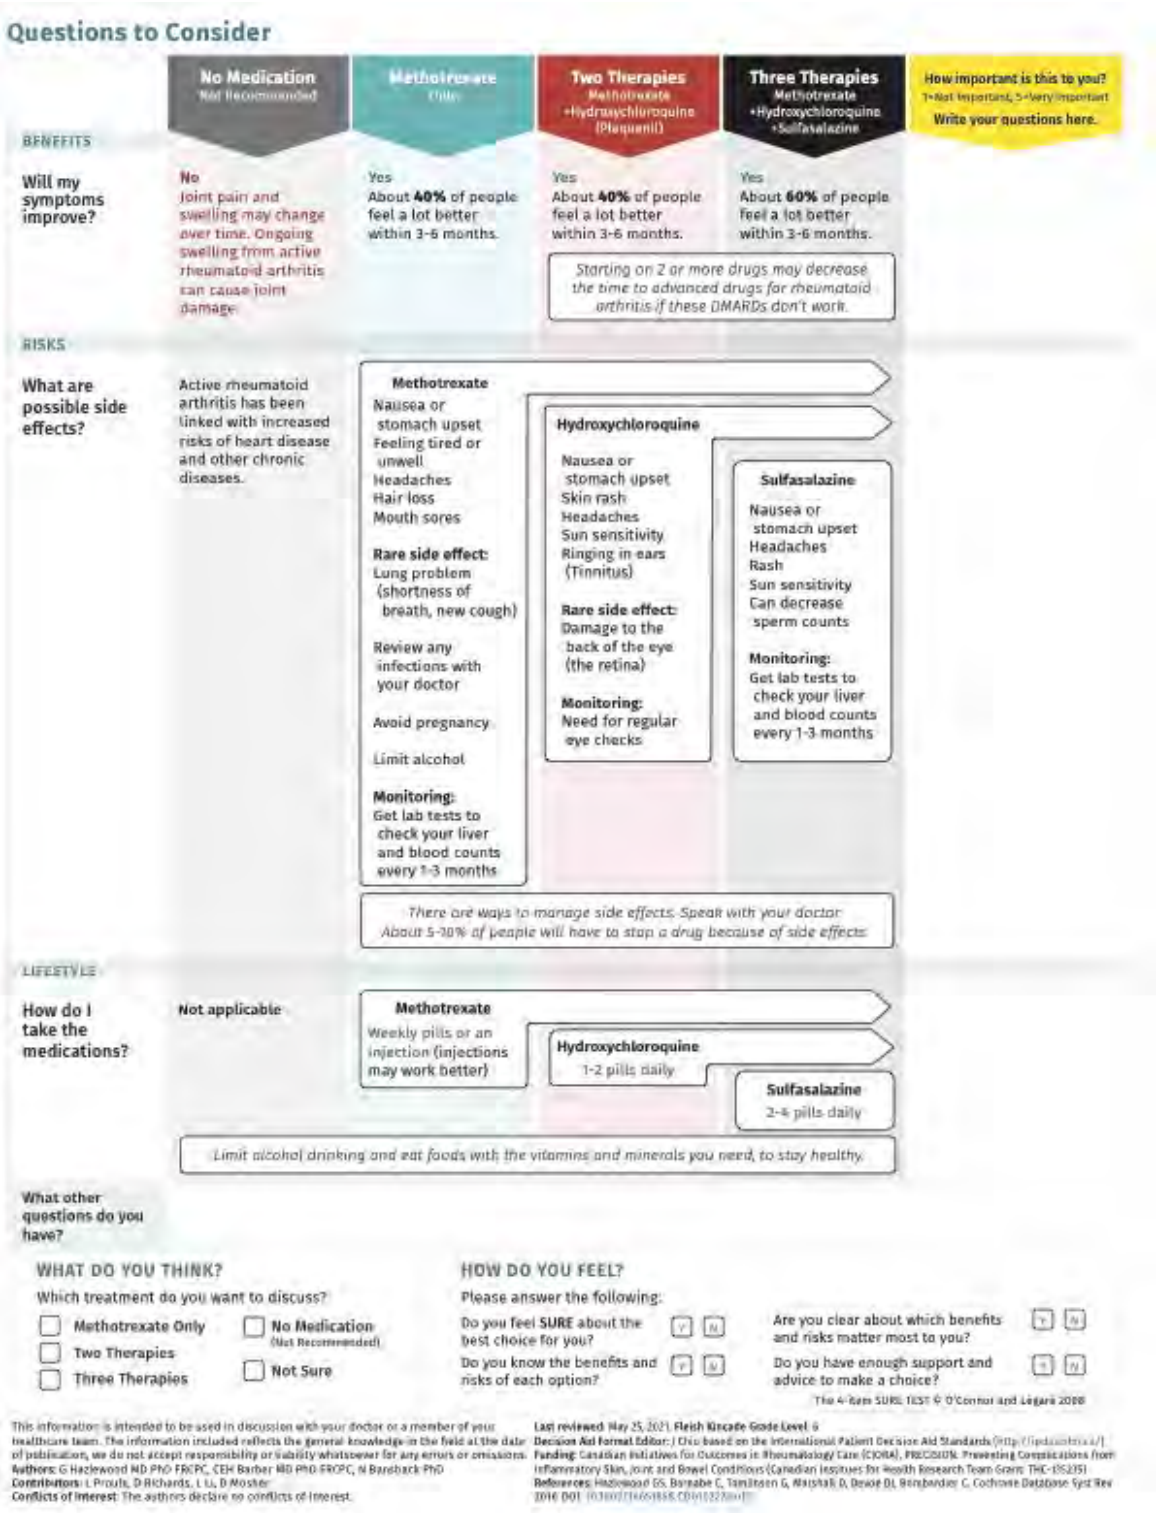
THIS DECISION AID IS FOR YOU IF:

- You are age 16 or older
- Have a new diagnosis of active rheumatoid arthritis

WHY IS THIS DISCUSSION IMPORTANT?

All of these options work well and are safe. Each choice has different chances of helping your joint pain and swelling, different side effects, and number of daily pills. It is important that your doctor knows what matters most to you to help you decide the best option.

Adapted Early RA Decision Aid for Indigenous Patient Use (Page 1)



Adapted Early RA Decision Aid for Indigenous Patient Use (Page 2)

Abstract Number: 0609

Challenges of Caring for Patients with Inflammatory Arthritis Experiencing Homelessness: Preliminary (12- Month) Follow-up Observations and Identification of Certain Barriers to Care

Baljeet Rai[1], Nicole Zagelbaum Ward[2], Abhimanyu Amarnani[2], Corinne Feldman[2], Brett Feldman[2] and Richard Panush[2], [1]LAC+USC Medical Center, Modesto, CA, [2]LAC+USC Medical Center, Los Angeles, CA

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Healthcare Disparities in Rheumatology Poster (0594–0622)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Homelessness is a public health crisis. Those with housing insecurity have unique barriers to healthcare that confound their outcomes. Because of the paucity of data about rheumatic disease patients (pts) with housing insecurity, we sought to better understand these challenges and develop approaches to improve their care.

As rheumatologists and "street medicine" providers, we identified homeless pts with rheumatic diseases to improve management and outcomes, reflecting responsibilities to promote social justice and equitable healthcare. We previously reported observations on 17 pts with inflammatory arthritis (15 rheumatoid arthritis [RA], 2 psoriatic arthritis [PsA]) (Clin Rheum 40:413-20, 2021). Here, we provide follow up on our pts and their perspectives on barriers to care.

Methods: We obtained follow-up clinical information from our original 17 pts and compared this to data summarized and published about them from 12 months previously. We also created a 100-question survey to assess pts' challenges and needs.

Results: Follow-up 12-month clinical information was available from 13/17 homeless (H) and 13/17 randomized, non-homeless (NH), controls. H were 54% and NH 92% female; H mean age was 57 (±9) and NH 61 (±8) years old; H 38% and NH 31% African American; H 38% and NH 23% Latino; and H 15% and NH 8% Caucasian.

H remained less well with more disease than NH-- poorer clinic appointment compliance (80% vs 91%, $p< 0.05$), more emergency services use (20 vs 5 ED visits), less use of DMARDs (43% vs 100%, $p< 0.01$), more steroid use (29% vs 0%, $p< 0.01$), and higher inflammatory markers (ESR 32 vs 26 mm/hr and CRP 17 vs 5 mg/L). 78% of H were assessed as stable, 14% improved, and 7% worse; 21% had stable controlled and 57% stable active disease vs 62% and 0% in NH ($p< 0.01$).

Among the H, 6 (4 RA, 2 PsA) completed the survey, 2 declined, and 9 could not to be reached. All 6 had found housing although all still had housing insecurity; 4 (67%) were homeless in the past. 3/6 (50%) obtained housing from social assistance during hospitalization following disease exacerbation while homeless. Average monthly income was $873. 5/6 (83.3%) were unable to work due to health and were in considerable pain that adversely impacted their physical and mental health and ability to perform ADLs. Their perceived "greatest need" included dental care, physical therapy, knee surgery, employment, socialization secondary to isolation, and stable housing.

Conclusion: These observations, while limited to modest numbers of pts and difficulties sustaining contact, add to our understanding of the unique challenges of homeless pts and provide a framework for strengthening collaboration between "street medicine" and rheumatology care providers to improve treatment and outcomes. This is supported

by the fact that half of surveyed pts obtained housing following hospitalization while homeless. Moreover, pts' perceived "greatest needs" went beyond housing and rheumatological care and indicate the importance of access to social and specialty services (ie, mental health, physical therapy, dental care, and employment). Collectively, these data suggest exciting opportunities to offer our homeless pts better quality and more equitable care.

Abstract Number: 0610

Evaluating Patient No Show Rates to Rheumatology Appointments Across a Regional Healthcare System

Osman Bhatty[1], Rebecca Schorr[2], Tarun Sharma[1] and Mary Chester Wasko[1], [1]Allegheny Health Network, Pittsburgh, PA, [2]Highmark Health, Pittsburgh, PA

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Healthcare Disparities in Rheumatology Poster (0594–0622)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: No-show visits in various clinical settings are costly to providers and to health care systems, potentially representing between 3-14% of a clinic's yearly income. This revenue challenge is compounded in rheumatology, as barriers to care delivery include socioeconomic factors for patients and prolonged wait times for appointments due to a growing shortage of rheumatologists nationwide. If patients at high risk for missing a referral appointment can be prospectively identified, then a strategic intervention to reduce the likelihood of a missed appointment will be fiscally advantageous and more effectively deliver rheumatic disease care to those in need. This study aims to characterize "no show" patients referred for outpatient rheumatology evaluation so that such a strategic intervention ultimately can follow.

Methods: Our electronic health record was queried for all patients who received ambulatory care referrals to a rheumatology provider within our healthcare system from January to December 2019. Basic demographic information, appointment characteristics and appointment outcomes were collected. Two patient groups were created based on their appointment outcomes; the first was comprised of all referred patients that no-showed, and the second included cancellations and completions. Patient and appointment characteristics were then compared between groups. Descriptive data is presented as mean (standard deviation) or median (interquartile range) for continuous variables and frequency (percentage) for categorical variables. Continuous variables were compared using a t-test or Mann-

Characteristics of Patients that No Showed and those that Cancelled/Completed

Variables	OR [95% CI]	P-Value
Age (with every 1 year)	0.984 [0.974, 0.99]	0.0019
Sex	0.871 [0.62, 1.2]	0.437
African American	2.352 [1.7, 3.3]	<0.001
Appointment Made to Appointment Date, days	1 [0.998, 1.0]	0.073
Referral Generated to Appointment Made, days	1.00 [1,1]	<0.0001
Month	1.0 [0.97, 1.1]	0.476

Multivariable Analysis to Determine Odds of Patient No Show

Whitney U test, as appropriate. Categorical data were analyzed using a chi-squared test or Fisher's exact test, as appropriate. A multivariable regression model finally was constructed to determine odds of no-show using those variables that statistically differed between groups.

Results: Across Allegheny Health Network, 2167 unique patients received ambulatory referrals to rheumatology in 2019 [Table 1]; 186 were no-shows. The month of the appointment nor the time between the date the appointment was made and the actual appointment date reached significance in regards to higher risk of no showing, although November did have the highest rates (12% vs. 8.2%, p=0.09) [Table 2]. In multivariable analysis, younger age (50.7 y vs 53.7 y, p=0.009) and African American race (24% vs. 9.15%, $p < 0.0001$) increased the odds of no-showing to an appointment [Table 3]. Longer duration from when the referral was generated by the physician to when the patient called to make the appointment was noted in the group of patients that no showed (33.4 days vs 9 days, p=0.0002) [Table 2].

Conclusion: Demographic (younger age, African American race) and appointment features (delay in patients calling for an appointment) characterized practitioner-referred rheumatology patients at high risk for no-showing for a new patient appointment. Future strategies to reduce no-show rates should address socioeconomic barriers to health care in high-risk individuals and improve access to new patient appointments.

Abstract Number: 0611

Association of Area Deprivation Index and Practice Patterns of Medicare Part D Rheumatologists

Shannon Tai[1], Ikechukwu Mbonu[2] and Michael Putman[3], [1]Medical College of Wisconsin, Milwaukee, WI, [2]Medical College of Wisconsin, West Allis, WI, [3]Medical College of Wisconsin, Brookfield, WI

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Healthcare Disparities in Rheumatology Poster (0594–0622)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Geographic disparities in the distribution and practice patterns of rheumatology providers may negatively impact patients with rheumatic diseases. The objective of this study was to describe the distribution of rheumatologists with respect to the area deprivation index (ADI) and to identify differences in practice patterns among Medicare Part D rheumatologist prescribers.

Methods: Prescriber data from the Medicare Part D Prescriber Public Use Files from 2013-2018 were downloaded. These data were joined to zip code level area deprivation index (ADI) data from the University of Wisconsin-Madison Neighborhood Atlas and presented as means and standard deviations (SDs). The ADI per zip code and number of rheumatologists per zip code were analyzed using Pearson's correlation. The average number of rheumatologists

Comparison Practice Patterns by ADI Quintile

and the average ADI values for each zip code were stratified by year and analyzed using one-way ANOVAs. Prescribing rates per 100 beneficiaries were calculated for corticosteroids, non-steroidal anti-inflammatory drugs (NSAIDs), gabapentinoids, opioids, conventional synthetic disease modifying anti-rheumatic drugs (csDMARDs), and targeted synthetic or biological (ts/bDMARDs) and analyzed using one-way ANOVAs.

Results: This study identified 5,642 rheumatologists who participated in the Medicare Part D program from 2013 to 2018. These rheumatologists served an average of 302.9 +/- 223.8 beneficiaries with an average age of 69.5 +/- 3.6 years (Table 1). In an unadjusted linear model of the number of rheumatologists per zip code, there was no significant relationship with ADI ($p = 0.159$). In two one-way ANOVA models, there was no relationship between year and the average number of rheumatologists per zip code ($p = 0.313$) or the average ADI ($p = 0.621$) (Table 2). Per 100 beneficiaries, providers who practiced in a higher ADI quintiles cared for significantly more patients and prescribed more conventional synthetic disease modifying anti-rheumatic drugs, more gabapentinoids, and more opioids ($p < 0.001$ for all comparisons) (Table 3).

Conclusion: There was no significant association between the number of rheumatologists per zip code and the ADI per zip code. Rheumatologists who practice in zip codes with higher deprivation indexes saw more patients and prescribed more csDMARDS, more gabapentinoids, and more opioids. Prescribing rates for biologic and targeted synthetic DMARDs did not vary substantially, suggesting that access to health insurance may mitigate geographical disparities.

Rheumatology Care for the Underserved in Central Texas

Veena Patel, Rajvi Patel and Kevin Hackshaw, Dell Medical School - UT Health Austin, Austin, TX

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Healthcare Disparities in Rheumatology Poster (0594–0622)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Health disparities exist among the uninsured and access to rheumatology is incredibly limited to this patient population. We reside in a state without Medicaid expansion and more than 19% of residents in our county are uninsured. In an effort to improve access, our clinic opened in a federally qualified health center in

Table 1. Demographic information. MAP: medical access program. SFS: sliding fee schedule (health care coverage offered to those who are uninsured and ineligible for MAP).CCHC: another type of healthcare coverage offered to those that do not qualify for MAP

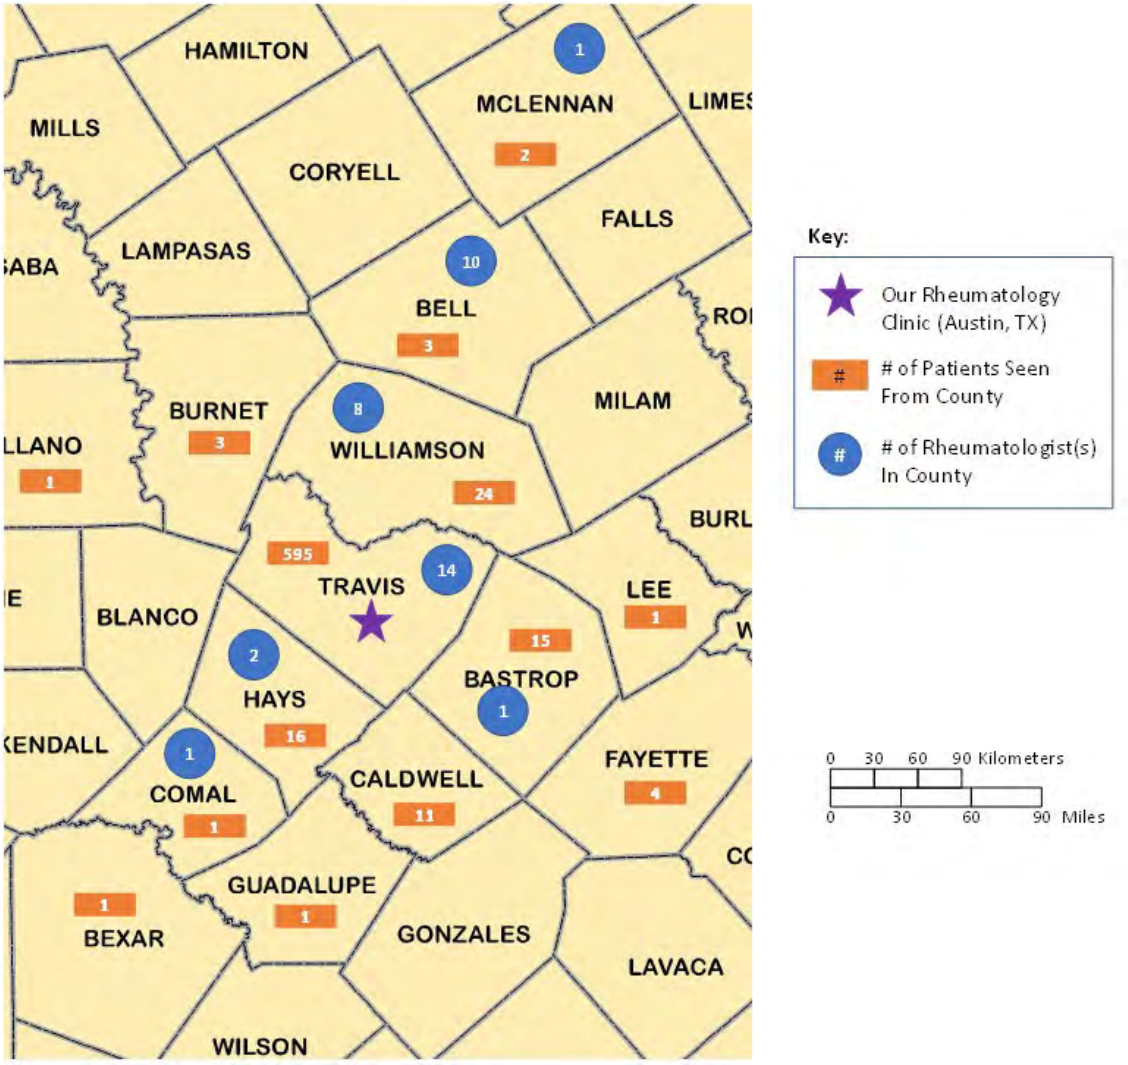
September 2018. In Travis County, uninsured low-income residents can apply for health care coverage through the medical access program (MAP), funded by tax payer dollars. Our division of 3 rheumatologists are the only caregivers in the area who accept MAP patients.

The purpose of this project was to gather baseline data by reviewing referrals and recognize characteristics of this underserved population. Our ultimate goal is to use this information to create future improvements in our clinic to promote health equity.

Table 1. Locations of patients seen by county in relation to our clinic (in Austin,Texas). The majority of patients seen at our clinic reside in Travis county, but there are a number of patients traveling from surrounding counties (many of which have rheumatologists) that travel to see us. *Note: There are 5 patients from counties not shown ranging 170-385 miles from our clinic



Methods: Chart review was done of all rheumatology referrals from 9/2018 – 11/2020. Using REDcap, we collected demographic data, referral information, patient characteristics and visit outcomes. For patients exhibiting active symptoms related to rheumatic disease, we used information noted in the "physical exam" of clinic notes to record the number of swollen/tender joints and disease activity. Using Google, we recorded the number of rheumatologists in each surrounding county and categorized them by main practice location.

Results: There were 1245 referrals by 11/2020 and 682 patients were seen in rheumatology clinic. Fifty-three patients declined appointment, 148 were no-shows, 178 were not able to be reached to schedule, 71 were incomplete and 113 had unknown referral status.

Table 1 reports demographic data. Five hundred forty-six patients (80%) were female, 458 (67.2%) Hispanic, 355 (52%) spoke English and 306 (44.9%) were Spanish speakers. The majority had health care coverage through MAP (53.2%).

Table 2 shows referral and patient information. The majority of patients were referred to establish care for a previously diagnosed rheumatic condition (320/682, 47%). Sixteen percent of referrals led to a new rheumatology diagnosis. Of

patients with rheumatic disease, 78% (275/351) had active disease at initial visit. The majority of RA patients had >3 swollen/tender joints and had therapy started or escalated at first visit. Seventy-one RA patients (39%) had erosive disease at initial visit.

Thirteen percent of patients travelled from outside of Travis county for an appointment. Image 1 shows that many passed other rheumatologists in surrounding counties. The furthest patient travelled from Lubbock county 375 miles away.

Conclusion: This study showed our clinic provided access to a diverse underserved population in need of rheumatologic care. A large portion already held a rheumatic diagnosis and unfortunately many had active, and even erosive disease, at the time of initial visit. While the majority are Travis county residents with MAP coverage, there were many who travelled out of county to see us. To continue to promote health equity, areas identified for improvement include understanding why many patients did not come to their initial visit, accurate referral tracking, learning surrounding county charitable care options, and engaging local rheumatologists in this process.

Abstract Number: 0613

Racial/Ethnic Disparities in Prescription Medications in a Large Urban Medical Center

J. Thomas Berry, William Galanter, Alia Welsh, Sandra Folarin, Reginald Woods and Huan Chang, UIC Medical Center, Chicago, IL

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Healthcare Disparities in Rheumatology Poster (0594–0622)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: African Americans and Hispanics with rheumatoid arthritis (RA) or systemic lupus erythematosus (SLE) continue to have worse disease-related health outcomes relative to Whites. This pilot study investigates the relationship between living in a disadvantaged neighborhood and the frequency of being prescribed a biologic agent or a conventional disease modifying rheumatic drug (DMARD). The objective of this study was to determine if a relationship exists between race/ethnicity, living in a disadvantaged neighborhood, and the frequency of being prescribed disease-specific treatment for RA or SLE.

Methods: Data from the electronic medical record (EMR) of a large urban hospital were analyzed for the period from January 1, 2020 through September 30, 2020. Independent variables included age, insurance information, address with zip code, race/ethnicity, and sex. The area deprivation index score was calculated using the neighborhood atlas website mapping tool. Rheumatologic medications were the dependent variables. Prescribed biologic agents or conventional DMARDs were compared between racial/ethnic groups. Prescriptions of steroids, non-steroidal medications, and opiates were also compared.

Results: Altogether there were 1326 unique patients with RA (n=859) or SLE (n=457). There were 181 non-Hispanic Whites, 671 non-Hispanic Blacks, and 347 Hispanic patients.

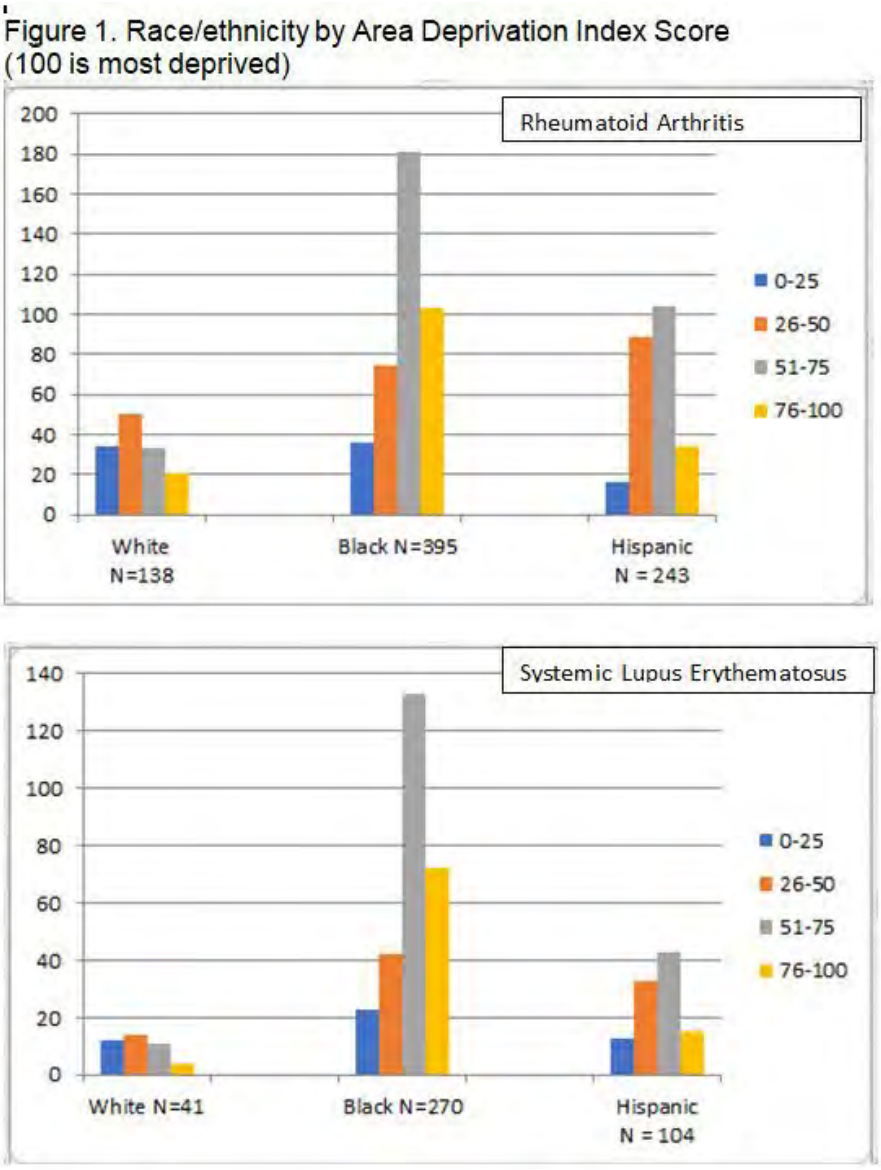

Figure 1. Race/ethnicity by area deprivation index score.

Area deprivation index scores were higher among Black and Hispanic patients compared to White patients for both RA and SLE patients ($p < 0.00001$ RA and SLE) . Minorities with RA were also more likely to have Medicaid health insurance than Whites ($p < 0.00005$ RA; $p < 0.59$ SLE). Results showed that physician prescribing patterns did not vary with area deprivation index scores ($p< 0.878$ RA; $p < 0.08$ SLE).

Conclusion: Among patients with RA and SLE, Blacks and Hispanics are more likely to live in an area with a higher area deprivation index score. Black RA patients were more likely to have Medicaid as their insurance. Physician prescribing patterns did not vary with area deprivation scores. Future studies with larger sample sizes are needed to help quantify the relationships between area deprivation scores and insurance in order to better understand physician prescribing patterns in patients, particularly among minority groups living in these areas, and to understand how these factors may influence disease-related health outcomes in RA and SLE.

Sex and Race Based Utilization of Healthcare for Ocular Inflammation and Infection: Comparing the Results from the Medicare and the IRIS Data

Krati Chauhan[1] and James T. Rosenbaum[2], [1]Southern Illinois University - School of Medicine, Springfield, IL, [2]Departments of Ophthalmology, Medicine, and Cell Biology, Oregon Health & Sciences University and Chair Emeritus, Legacy Devers Eye Institute, Portland, OR

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Healthcare Disparities in Rheumatology Poster (0594–0622)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Health care utilization has an impact on disease progression and outcome in rheumatologic care. Disparities based on race, sex, education and income level affect care of our patients. Ocular inflammatory diseases increase disease burden in many rheumatologic conditions. We have compared Medicare and Intelligent Research in Sight (IRIS) data to identify similarities and differences in healthcare utilization for ocular inflammatory and infectious diseases. IRIS is a clinical registry, assembled by the American Academy of Ophthalmology. Registry

Annual utilization for infectious and inflammatory eye diseases: Medicare: By Race: 2016-2017

Medicare and IRIS Utilization by Race and Sex: 2016

uses Health Insurance Portability and Accountability Act (HIPAA) compliant methods to collect data directly from participating Ophthalmology practices' individual electronic medical record (EMR) systems. In 2018, the registry collected data from more than 90% of ophthalmologists nationally

Methods: We have used Medicare and IRIS data available through National Vision and Eye Health Surveillance System (VEHSS). Medicare data are collected from research identifiable files obtained through the Center for Medicare and Medicaid Services (CMS) and include all fee for service beneficiaries.

VEHSS uses ICD-10 codes to identify ocular disorders and organizes them into two level categorization, which are category and subgroup. Each code is categorized in one subgroup and multiple subgroups are combined to form a category. The inflammatory and infectious eye disease category includes subgroups of ocular inflammatory conditions, lacrimal system and orbital inflammation, keratitis, conjunctivitis, eyelid inflammation and infection and endophthalmitis.

Annual utilization for infectious and inflammatory eye diseases by Race and Sex: Medicare: 2017.

Medicare and IRIS Utilization by Race and Sex 2017

Utilization for the the Medicare and IRIS data was compared for the years 2016-2017. We have identified the impact of utilization for both the databases when stratified by sex and race alone and when stratified by race and sex together.

Results: Females have higher utilization across all races for the inflammatory and infectious eye diseases for both Medicare and IRIS data, for both 2016 and 2017. Asians have higher utilization for both males and females in both the databases. Whereas Hispanics have second highest utilization for Medicare data and North American Natives have second highest utilization for the IRIS data for both the years 2016-2017.

When the Medicare and IRIS databases are stratified by both race and sex, Asian females have the highest utilization, followed by Asian males for both the databases for both the years.

For the IRIS database, North American females have the second highest utilization followed by the North American males for both the years. For Medicare database, other females and other males have the second highest utilization followed by the Hispanic females and Hispanic males.

Conclusion: Comparing the Medicare and the IRIS data provides significant complimentary information on eye care utilization for inflammatory and infectious eye diseases. Females, Asians, Hispanics and Native Americans having

higher utilization for both the years 2016-2017. This may be due to higher disease prevalence or higher service utilization. Further studies are needed to clarify this and to help in making informed policy decisions.

Abstract Number: 0615

Socioeconomic Characteristics Associated with Electronic Health Care Utilization in an Urban Rheumatology Clinic During the COVID-19 Pandemic

Jenna Thomason[1], Bryanna Mantilla[2], Alison Bays[1], Irvin Huang[1] and Grant hughes[1], [1]University of Washington, Seattle, WA, [2]George Washington University, Arlington, VA

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Healthcare Disparities in Rheumatology Poster (0594–0622)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: In the US, the COVID-19 pandemic has prompted increased utilization of telemedicine (TM), electronic patient portals (EPPs), and other electronic modalities of health care delivery. Here, we assessed for socioeconomic inequities in TM and EPP utilization in an urban county hospital rheumatology clinic during COVID-19.

Methods: Using the electronic health record (EHR), demographic features (age, sex, race, ethnicity, language, distance from hospital, payor) on all patients completing visits between 3/1/2019 and 2/28/2020 (pre-COVID period) and 4/1/2020 and 3/31/2021 (COVID period) were analyzed. Bivariate logistic regression analysis was performed to obtain adjusted odds ratios (aORs) for primary outcome (completion of ≥ 1 TM visit during COVID) and secondary outcome (any utilization of the EPP from its inception in 2013 through date of data pull, 4/1/2021).

Results: 1,503 patients completed 3,837 visits in the pre-COVID period (all in-person visits). During COVID, 1,442 patients completed 3,406 visits (40.6% in-person, 20.4% TM, 29.1% telephone visits). 864 patients were seen in both periods. Demographic and visit characteristics are shown in Table 1. During COVID, younger age, farther distance from hospital, female sex, English language preference, White race identity, and commercial payor were associated with TM use (Table 2). White-identifying patients were 2.1x and 2.3x more likely than Black/African-American and American Indian/Alaska Native patients, respectively, to use TM. English-preferring patients were 3.8x and 3.0x more likely than Spanish-preferring and other non-English-preferring patients to use TM, respectively. Among patients seen during COVID, EPP use was associated with younger age, female sex, non-Hispanic/Latinx ethnicity, White race identity, English language preference, and commercial payor (Table 3). White-identifying patients were 3.5x and 3.7x more likely than Black/African-American and American Indian/Alaska Native patients, respectively, to use EPP. English-preferring patients were 14.1x and 4.7x more likely than Spanish-preferring and other non-English-preferring patients to use EPP.

Conclusion: We observed significant age-, sex-, race-, and language-related inequities in TM and EPP use during COVID-19 among patients in an urban county hospital rheumatology clinic. The strongest single predictor of both TM and EPP use was English language preference. Given the growing importance electronic health care delivery, it is

in the top quintile for both percentage of African American population and poverty rates. The COVID-19 pandemic has highlighted the impact of these disparities, particularly in those with rheumatic disease who, on average, already have a high utilization of healthcare services. A study nested within a voluntary U.S. physician registry showed poorer outcomes in racial/ethnic minority patients. However, data on socioeconomic status for registry patients was not

Table 2. Association of Race/Ethnicity and Census-tract Socioeconomic Status with Hospitalization due to COVID-19 Among Rheumatology Patients at a Tertiary Care Center in the Deep South

	OR	95% CI	P value
Hospitalized (n=256)			
Race (Black vs White)	1.15	0.59-2.24	0.68

ADI-Nation >Q75 vs <Q25	1.33	0.53-3.32	0.79

reported. Our study examined the impact of race and socioeconomic status on COVID-19 outcomes in patients with rheumatic disease from a large tertiary care rheumatology practice in the Deep South.

Methods: We systematically identified rheumatology patients established at our medical center with a history of COVID-19 infection, confirmed by PCR. A retrospective medical record review was conducted to extract demographic characteristics, rheumatic disease type and treatment, comorbidities, and COVID-19 outcomes. COVID-19 outcomes studied included hospitalization, need for supplemental oxygen, need for mechanical ventilation, and death. Race/ethnicity was categorized as white, Black, or other. Census-tract socioeconomic status using area deprivation index (ADI) was calculated. Multivariate logistic regression was performed adjusting for the effect of age, sex, body mass index (BMI), comorbidities (by Charlson Comorbidity index), rheumatic disease type, rheumatic disease medications taken prior to COVID-19 infection, prednisone use prior to infection, and ADI.

Results: A total of 256 rheumatology patients who had tested positive for COVID-19 at our institution were included, of whom 104 (40.6%) were Black and 152 (59.4%) were white (Table 1). Eight patients identified as "other" race were excluded from this analysis. Mean national area deprivation index for white patients was 46, while Black patients were more disadvantaged with a mean ADI of 76. Black patients also had higher baseline comorbidities and had a higher rate of hospitalization. However, after multivariate adjustment, Black race and ADI were not associated with hospitalization, need for supplemental oxygen, or need for mechanical ventilation. Variables noted to be significantly associated with hospitalization in multivariate analysis included age, BMI, and comorbidities (Table 2).

Conclusion: Although Black patients had a higher rate of hospitalization compared to white patients, race and census-tract socioeconomic status were not associated with significantly worse COVID-19 outcomes after accounting for confounders in this analysis. Possible explanations for these findings are lack of patient-level socioeconomic data, small sample size, and unmeasured confounding. Further investigation is needed to address this complex relationship between race and socioeconomic status and COVID-19 outcomes.

Abstract Number: 0617

Concerns and Beliefs About COVID-19 Vaccination Among Racial and Ethnic Minority Patients with Rheumatic Disease

Maria I. Danila, Lesley Jackson, Amy Mudano, Giovanna Rosas, Jeanne Merchant, Jeffrey Foster and Kenneth Saag, University of Alabama at Birmingham, Birmingham, AL

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Healthcare Disparities in Rheumatology Poster (0594–0622)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Alabama lags behind many other states in COVID-19 vaccination uptake and racial/ethnic minority groups face COVID-19 vaccine access disparities. Moreover, lack of vaccination access and medical mistrust among Alabama's large African American population, a vestige of the devastating Tuskegee Syphilis study, further perpetuate health care disparities. We examined concerns and beliefs about COVID-19 vaccination among racial and ethnic minority patients receiving rheumatology care at a large academic medical center in the Deep South and factors associated with COVID-19 vaccine receipt.

Table 1: Characteristics of Rheumatology Clinic Patients from Racial and Ethnic Minority Groups.

Variable	N=150
Female, yes	130 (86.7%)
Age, years, mean (SD)	54 (15.9)
Black or African American	141 (94.0%)
Education, some college or more	103 (68.7%)
Flu vaccine ever, yes	121 (80.7%)
Flu vaccine 2020 - 2021, yes	91 (60.7%)
Medical mistrust, no	75 (50%)
Vaccine confidence, mean (SD)	3.9 (0.95)
Received COVID-19 vaccination	100 (66.7%)
No COVID-19 vaccine receipt	
Did not plan to get vaccinated	16 (32%)
Common reasons for not getting vaccinated	
Side effects of the vaccine	19 (55.9%)
Disease flare	18 (52.9%)
Know someone who had side effects	11 (32.4%)
Vaccine will give me COVID-19	7 (20.6%)
Will modify my DNA	6 (17.6%)
Reactions to other vaccines	5 (14.7%)
Key information needed during COVID-19 vaccine deliberation	
Long term efficacy	18 (52.9%)
Desire to talk to my doctor	17 (50.0%)
Side effects in people with my health condition	15 (44.1%)
Efficacy in people with my health condition	14 (41.2%)

Frequency (%) or mean (standard deviation) shown. Vaccine confidence scale ranges from 1 (strongly disagree to 7 strongly agree); higher scores are better.

Table 2. Factors Associated with Receipt of COVID-19 Vaccine Among Racial and Ethnic Minority Patients in Rheumatology Clinic.

	Model 1			
Variable	Odds Ratio	95% Confidence Interval		P value
Age, years				
<45	Ref.			
45 - 64	2.84	1.06	7.58	0.04
65+	3.95	1.05	14.91	0.04
Sex, women	3.16	0.82	12.18	0.09
COVID-19 vaccine safety concerns, yes	0.27	0.09	0.83	0.03
Past influenza vaccination, yes	3.47	1.20	10.00	0.02
Vaccine confidence	3.71	2.07	6.66	<0.0001
Medical mistrust, no	0.56	0.17	1.82	0.33

Methods: In April 2021, we invited racial and ethnic minority patients to complete a survey on a tablet computer during an in-person visit to the rheumatology clinics at our center. Vaccination confidence was assessed using the confidence scale from the validated 5C psychological antecedents of vaccination. Descriptive statistics summarized attitudes and beliefs about COVID-19 vaccination and multivariable logistic regression determined factors associated with receipt of a COVID-19 vaccine. The following factors were examined: age, sex, education, vaccine confidence, safety concerns, medical mistrust, past flu vaccine receipt.

Results: Of the 156 racial and ethnic minority patients approached between April 19 and May 6, 2021, 150 agreed to complete the survey. Mean (standard deviation) for age was 54 (15.9) years, 86.9% were women, 94% identified themselves as Black or African American, 69% had at least some college, and 22% said they believed they would have gotten better medical care if they belonged to a different race or ethnic group (**Table 1**). Although 81% of respondents reported prior receipt of flu vaccine, only two thirds reported having had the COVID-19 vaccine. Of those who were not yet vaccinated (N=50), half had been offered the vaccine and a third said they did not plan were to be vaccinated. The most common reasons for not getting vaccinated included concerns about side effects (56%), fear of disease flare (53%), knowing someone who had a bad experience with the vaccine (32%), concern of getting COVID-19 from the vaccine (21%), and concern that the vaccine would "modify my DNA" (18%). Those not yet vaccinated expressed a need to obtain information about the efficacy and safety of this vaccination in people with rheumatic disease. After multivariable adjustment, older age, not having safety concerns about COVID-19 vaccine, past flu vaccine receipt, and higher vaccine confidence were associated with COVID-19 vaccination (**Table 2**). There was no association between reporting medical mistrust and COVID-19 vaccine receipt.

Conclusion: During the COVID-19 vaccine roll out in Alabama, one in ten racial and ethnic minority patients in a large academic rheumatology clinic said they were unlikely to get vaccinated. Older age, past flu vaccine receipt, higher confidence in and lack of safety concerns about the COVID-19 vaccine were associated with COVID-19 vaccination. Our findings highlight the need for tailored COVID-19 vaccination programs for individuals with rheumatic diseases in these subpopulations susceptible to health disparities to help ensure individual and societal protection against COVID-19.

Post-acute Sequelae of SARS-CoV-2 and Serological Response in a Cohort of Patients with Rheumatic Diseases

Alice Fike[1], Omer Pamuk[2], Yiming Luo[3], Jun Chu[4], Yanira Ruiz-Perdomo[3], Sarfaraz Hasni[3], Pravitt Gourh[3] and James Katz[4], [1]National Institutes of Arthritis and Musculoskeletal and Skin Diseases (NIAMS), National Institutes of Health (NIH), Washington, DC, [2]NIH/NIAMS, Bethesda, MD, [3]National Institutes of Health, Bethesda, MD, [4]National Institutes of Arthritis and Musculoskeletal and Skin Diseases (NIAMS), National Institutes of Health (NIH), Bethesda, MD

SESSION INFORMATION

Session Date: Sunday, November 7, 2021

Session Title: Healthcare Disparities in Rheumatology Poster (0594–0622)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Background/Purpose: The longitudinal experience of COVID-19 illness in patients with rheumatic diseases is emerging. Reports from the general population have described post-acute sequelae of SARS-CoV-2 (PASC) including de novo autoimmunity but evidence in patients with pre-existing rheumatic diseases is limited. We sought to characterize PASC in patients with rheumatic diseases in our majority Latino patient cohort. Further, we investigated the relationship between COVID-19 illness, the subsequent development of new autoantibodies, and increased rheumatic disease activity.

Methods: This is a retrospective study of patients with rheumatic diseases from an existing observational cohort, comprising of 72.4% Latino patients. Patients seen between April 1, 2020 to May 15, 2021 were included in analyses. We reviewed demographics, rheumatic disease, immunomodulatory therapies, and PASC symptoms. Antibodies to SARS-CoV-2 were measured for patients reporting infection. Antibodies to extractable nuclear antigens and anti-phospholipid antibodies were repeated once in the post-acute period when feasible. Data for continuous variables were expressed as the mean ± SD and categorical variables were summarized by computing counts of patients (%). Fisher's exact test was used, and significance threshold was 0.05.

Results: During the study period, 54 patients reported COVID-19 illness, representing 17.5% of our cohort of 307 active patients (Table 1); 53 were Latino patients. Most patients had mild illness with 8 patients (14.8%) requiring inpatient management. There were no COVID-19 related deaths. SARS-CoV-2 IgG was assessed in sera in 52 individuals, and 5 patients (9.6%) were found to have negative titers while 83.3% of initially positive patients maintained their antibodies 9 months post infection. Of 47 patients assessed, 27 (57.4%) reported PASC symptoms and 24 of those patients (37.5%) had persistent PASC six months post infection. Autoantibody tests were performed in 39 patients after acute COVID-19 infection and a new autoantibody was detected in 8 patients (18.6%). Anti-RNP developed in 5 patients, anti-Scl70 in one patient, and anti-phospholipid antibodies in 2 patients. Subgroup analysis revealed a significantly higher frequency of autoantibody development in patients with RA when compared to other patients with COVID-19 (7/18 vs 1/21, p=0.01). This autoantibody development was higher than RA patients without COVID-19. The frequency of self-reported worsened rheumatic symptoms was higher among patients who developed a new autoantibody in the post-COVID-19 period than in other patients (6 of 8 vs 8 of 37, p=0.006).

Conclusion: Latino patients not only have an increased rate of COVID-19 infection but also shoulder an outsized burden of its post-acute sequelae. The finding of de novo autoantibody production in 18.6% of patients, post-COVID-19, could foretell the development of a new autoimmune phenomenon. Patients in high-risk groups for COVID-19, particularly marginalized groups, will require closer monitoring, early identification, and therapeutic intervention for detecting this new autoimmune phenotype. This likely will be an ongoing, long term effort.

Racial and Ethnic Disparities in Pregnancy Outcomes Among Women with Rheumatic Diseases: A Systematic Literature Review and Quantitative Analysis

Maya Swaminathan[1], Gloria Shen[2], Irvin Huang[2], Diana Louden[2], Waqas Tahir[3] and Namrata Singh[4], [1]MultiCare Good Samaritan Hospital, Newcastle, WA, [2]University of Washington, Seattle, WA, [3]Rochester General Hospital, Rochester, MN, [4]University of Washington, Bellevue, WA

SESSION INFORMATION

Session Date: Sunday, November 7, 2021
Session Title: Healthcare Disparities in Rheumatology Poster (0594–0622)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Women are disproportionately affected by rheumatic diseases (RD), with many of them carrying the diagnosis in their childbearing years. Pregnant women with RD have a high prevalence of adverse pregnancy outcomes (APO) owing to a multitude of factors. Racial/ethnic disparities in APO are well-recognized in the general population, however the understanding for this among women with RD is limited. While there are studies which have explored the impact of race/ethnicity on APO among patients with RD, limitations of RD type and race ascertainment

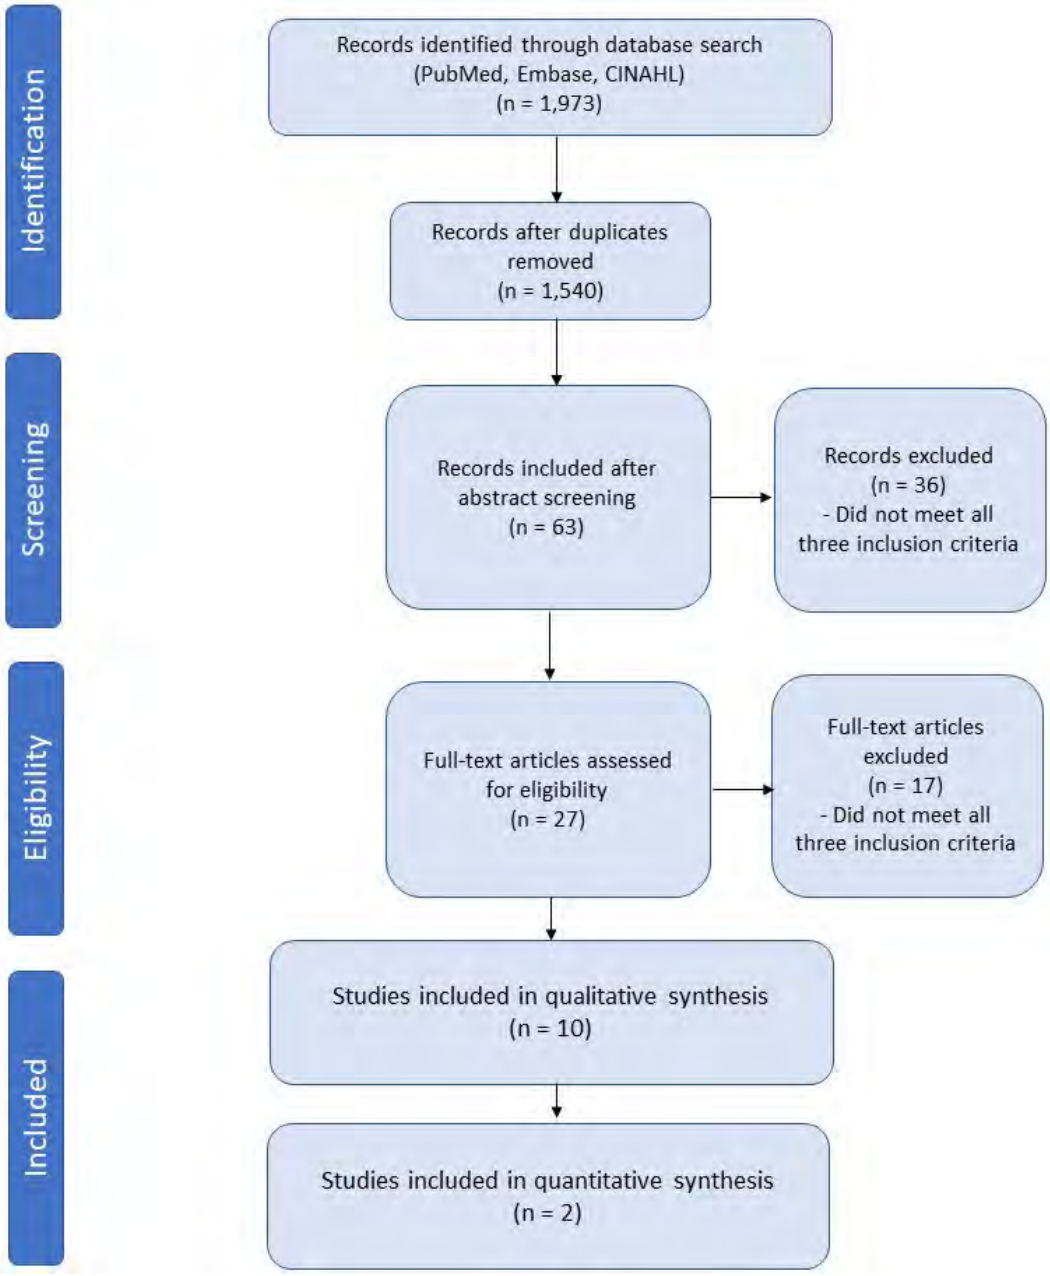

Figure 1. PRISMA Flow Diagram showing study selection process.

Table 1. Characteristics of studies included in the systematic literature review

Author last name /Publication year	Continent/Country	Rheumatic disease studied	Study period	Race/ethnicity	Adverse Pregnancy Outcomes
Kaplowitz 2017	North America	SLE, APS	Sept 2003–July 2014	White (non-hispanic), African American, Hispanic, Asian, American Indian	Fetal death after 12 weeks of gestation, neonatal death before hospital discharge due to complications of prematurity, preterm delivery before 36 weeks gestation due to pregnancy-induced hypertension, preeclampsia, placental insufficiency, and small for gestational age (SGA) neonate
Buyon 2015	North America	SLE	Sept 2003–Dec 2012	Non-Hispanic White, Hispanic White, African American, Asian, other	Fetal death after 12 weeks' gestation unexplained by chromosomal abnormalities, anatomical malformation, or congenital infection; neonatal death before hospital discharge due to complications of prematurity, placental insufficiency, pre-term delivery or termination of pregnancy at less than 36 weeks due to gestational hypertension, preeclampsia, or placental insufficiency; and 4) SGA neonate, defined as one with a birthweight below the fifth percentile without anatomical or chromosomal abnormalities.
Clowse 2016	US	SLE	2008-2010	White, Black, Hispanic	Preterm labor, preeclampsia, fetal growth restriction, stillbirth, premature rupture of membranes, chorioamnionitis, cervical incompetence, placental abruption, postpartum hemorrhage, gestational diabetes mellitus
Andrade 2008	US (Alabama, Texas, Puerto Rico)	SLE	Unknown – June 2005	Hispanic-Texan, Hispanic-Puerto Rican, African American, Caucasian	Miscarriage or abortion (<20 weeks), a stillbirth (≥ 20 weeks) and/or a moderate to severe preterm baby (<34 weeks)
Vinet 2011	Multiple (US, Canada, UK, Sweden)	SLE	Unknown	White, Black, Asian, Other	Standardized incidence ratio (SIR) of observed to expected live births
Shaharir 2020	Malaysia	SLE	Jan 2016 – Dec 2019	Malay, Chinese, Indian	APO includes early pregnancy loss (first 13 weeks), late pregnancy loss (after 13 weeks), intra-uterine death (fetal loss >= 20 weeks), intrauterine growth restriction (below 10th percentile), premature birth (before 37 weeks), pre-eclampsia, maternal death
Mohammed 2016	US	Juvenile rheumatoid arthritis (JRA)	2011 - 2012	Caucasian, African American, Hispanic	Preterm birth (delivery > 22 wks AND <37 weeks), SGA
Manzano-Gamero 2018	Spain	SLE and SLE plus APS	Sept 2013–Oct 2014	Caucasian, Roma	Fetal death, abortion
Anastasiou 2020	US (California)	SLE and RA	2016-2017	Caucasian, African American	Intrauterine fetal demise, pre-eclampsia/eclampsia
Sabih 2020	US (California)	SLE and RA	2007-2012	White, Black, Hispanic, Asian	Preterm Birth (less than 37 weeks)

prevent single studies from synthesizing a complete analysis. We conducted a systematic literature review to evaluate the impact of race/ethnicity on APO in women with RD.

Methods: Systematic literature searches in PubMed, Embase, and Cumulative Index for Nursing and Allied Health Literature (CINAHL) Complete were conducted to identify potentially eligible studies. Inclusion criteria consisted of all

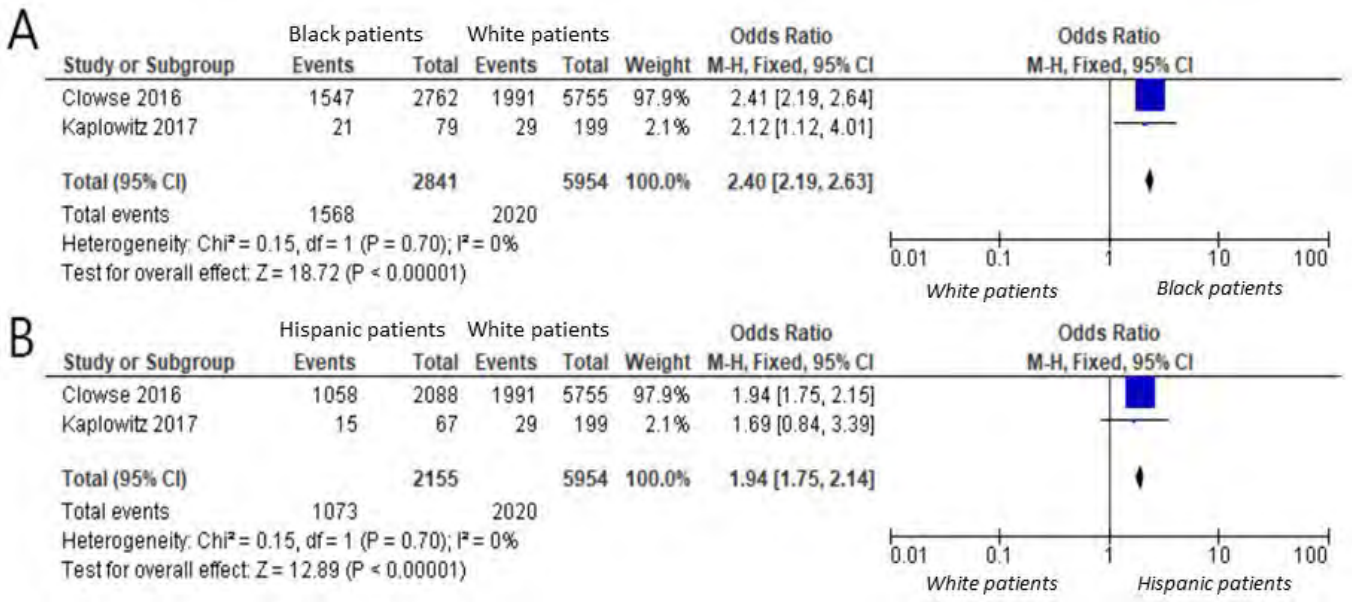

Figure 2. Forest plot comparing adverse pregnancy outcomes in SLE between A) Black and White patients, and B) Hispanic and White patients.

study designs except for case reports and narrative reviews, presence of RD and APO, and data pertaining to race/ethnicity. Conference abstracts published before 2015 and non-English articles were excluded.

Results: A total of 1540 references remained after duplicates were removed of which full text review was done for 27 articles (Figure 1). These were independently reviewed by three co-authors (GS, IJH, and MS) and discrepancies were resolved by a fourth co-author (NS). Study quality was assessed using Newcastle-Ottawa Scale. Ten studies met our eligibility criteria to be included in the literature review (Table 1).

Of the 10 studies, 7 were from North America, 1 from Europe, 1 from Asia, and 1 multicontinental. Most of them were cohort studies, except one that was a cross-sectional study. One study examined racial/ethnic disparities among patients with juvenile idiopathic arthritis (JIA). The remaining 9 studies looked at patients with systemic lupus erythematosus (SLE) of which 2 included patients with antiphospholipid antibody syndrome (APS), and 2 included patients with rheumatoid arthritis (RA).

Because of the significant differences between the studies, pooled analysis could only be carried out using two studies (Figure 2). Among patients with SLE, Black patients had higher odds of APO compared to White patients, with a pooled odds ratio (OR) of 2.40 [95% CI 2.19 - 2.63]. Similarly, Hispanic patients had higher odds of APO compared to White patients with a pooled OR of 1.94 [95% CI 1.75 - 2.14].

Conclusion: This systematic literature review highlights that racial/ethnic minority populations with RD are more prone to APO compared to their White counterparts. Eight out of the nine studies involving White patients are consistent with these findings. Pooled analysis was limited due to multiple factors including heterogeneity in the study population, variation in the outcomes of interest, and different definitions for APO. Standardized criteria for APO are necessary to allow direct comparisons between studies. SLE has been the focus in most of these studies and there is a paucity of data looking at other RDs. Further research is needed to explore the causes for the racial/ethnic disparities and how these can be addressed.

Is There a Difference in Disease Activity Between Genders in Axial Spondyloarthritis? 6-year Longitudinal Data from a Large National Cohort

krystel aouad[1], Anne Tournadre[2], Florian LUCASSON[1], Daniel Wendling[3], Anna Molto[4], Bruno Fautrel[5] and Laure Gossec[6], [1]Sorbonne Université, INSERM, Institut Pierre Louis d'Epidémiologie et de Santé Publique, Paris, France, [2]Rheumatology Department, Université Clermont Auvergne, CHU Clermont-Ferrand, INRAE, UNH UMR 1019, Clermont-Ferrand, France, [3]Service de rhumatologie, CHU de Besançon, Besançon, France, [4]Rheumatology department, Cochin hospital, APHP, Paris, France, [5]Pitié Salpêtrière Hospital, APHP, Sorbonne Université, Paris, France, [6]Sorbonne Université; APHP, Rheumatology Department, Pitié-Salpêtrière Hospital, Paris, France

SESSION INFORMATION

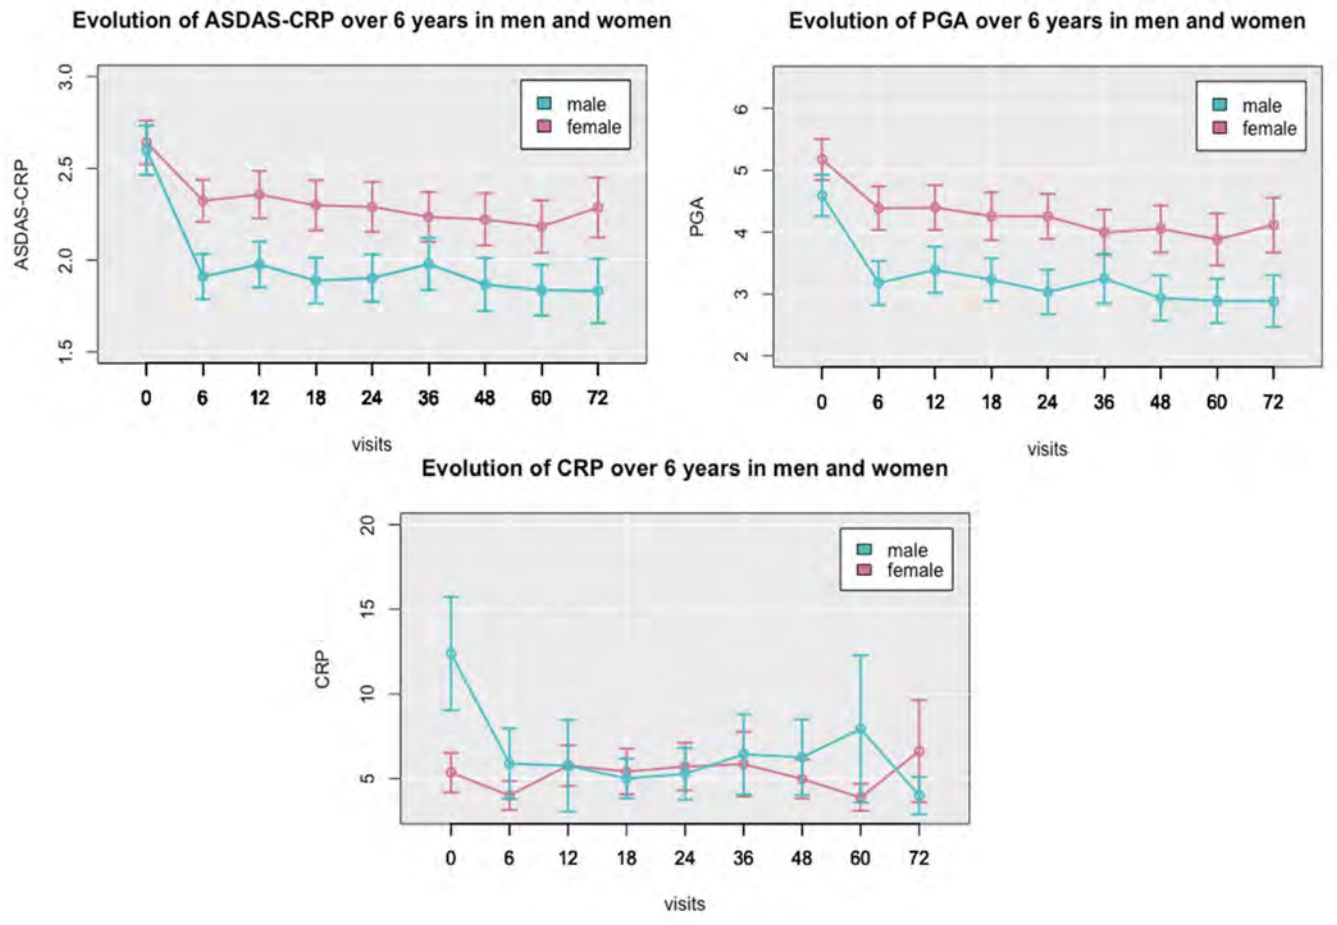
Session Date: Sunday, November 7, 2021

Session Title: Healthcare Disparities in Rheumatology Poster (0594–0622)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Background/Purpose: Recent data suggest differences between men and women with axial spondyloarthritis (axSpA), in terms of disease activity, disease progression and treatment response [1-3]. Overall, women tend to show



Comparison of evolution of disease activity (ASDAS, PGA, CRP) over 6 years of follow-up between genders.

higher perceived disease activity (mostly on the Bath Ankylosing Spondylitis Disease Activity Index: BASDAI) and extra-articular manifestations (mostly enthesitis), whereas men with axSpA tend to show more structural progression [2-3]. The objective of this study was to determine gender differences in disease activity in recent axSpA over 6 years of follow-up.

Methods: We analysed data collected during the first 6 years of follow-up of the prospective national multicentric DESIR cohort for patients with early inflammatory back pain suggestive of axial SpA and fulfilling the ASAS classification criteria for axSpA at any time (1) (n= 494). Self-reported gender was collected at baseline. Three main outcomes were compared between men and women: ASDAS-CRP (to assess disease activity), patient global assessment (PGA: ranging from 0-10), and CRP. To compare genders longitudinally and account for repeated measures over time (mo 6, 12, 18, 24, 36, 48, 60 and 72), a linear mixed-effect model analysis (LMM) was performed (using lme4 R package) with gender and time as fixed effects and subjects as random effect. There was no imputation of missing data.

Results: Of 708 at baseline, 494 patients (70%) were analysed: mean age was 31.9±7.5 years, mean disease duration 20.7±11.7 months; 50.4% were men. At baseline, mean ASDAS-CRP score was 2.6±1.0 in men versus 2.6± 0.9 in women (p=0.75), mean PGA score was 4.6±2.6 and 5.2±2.6 (p< 0.0001) and mean CRP was 10.7 ± 16.5 and 6.2 ± 8.3 (p< 0.0001) respectively. Over time, ASDAS-CRP, PGA and CRP all decreased in both men and women. However, there was more decrease in all aspects in men than women (Figure 1). The difference was significant in LMM for ASDAS-CRP and PGA (both p< 0.0001) but not for CRP (p=0.089). As an illustration, the mean ASDAS-CRP score was 1.8±1.0 in men versus 2.3±0.9 in women at 6 years, with mean PGA score of 2.9±2.6 versus 4.2±2.7 respectively.

Conclusion: Although disease activity was similar between genders at baseline, there were more improvements in all aspects of disease in men than in women over 6 years of follow-up, leading to higher disease activity and symptoms in women at 6 years, with similar CRP levels. Further research is needed to explore differences in disease activity between genders using imaging data. Gender is an important contextual factor in axSpA and should be taken into account.

Case Series of IgG4-related Disease in African American Patients at Two Large Academic Centers

Jonathan Thaler[1], Sunita Dia[2] and Florina Constantinescu[2], [1]MedStar Georgetown University Hospital, Washington, DC, [2]Medstar Washington Hospital Center, Washington, DC

SESSION INFORMATION

Session Date: Sunday, November 7, 2021
Session Title: Healthcare Disparities in Rheumatology Poster (0594–0622)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: IgG4-related Disease (IgG4-rD) is a fibroinflammatory disease with highly variable manifestations that can be difficult to diagnose. Response to treatment with prednisone and/or rituximab is generally favorable. Unfortunately, it has not been well studied in African American patients, a population already affected by wider healthcare disparities. Better understanding how IgG4-rD may present and respond to treatment in African American patients is therefore of particular importance, especially in light of the meaningful phenotypic differences already described among other sub-populations including self-identifying Asians and women. Our aim is to describe manifestations and course of disease in a retrospective cohort of African American patients with biopsy-proven or highly suspected IgG4-rD.

Methods: The EMR systems for two academic centers in Washington, DC were queried for self-identifying African American patients with IgG4-rD by ICD-9 and ICD-10 codes applied from 2010 to present. IgG4-rD diagnosis (as documented by a treating rheumatologist) was then confirmed by manual chart review. Clinical data relevant to presentation, course, and management of disease were reviewed and recorded.

Results: 122 patients met initial screening criteria, 11 of whom (4 male) were confirmed to carry a diagnosis of IgG4-rD by manual chart review. 8 of these 11 patients met 2019 ACR classification criteria for IgG4-rD. The most commonly involved organs were lymph nodes (8) and orbits (5), and the mean number of organs involved was 2.8 +/- 1.3 (Figure 1). All 11 patients underwent tissue biopsy; common findings included lymphoplasmacytic infiltrate (5), >50/hpf IgG4-positive plasma cells (5), storiform fibrosis (2), no typical features (2), and obliterative phlebitis (1). Mean age at diagnosis was 51.5 +/- 11.3 years. Median time from symptom onset to diagnosis was 821 days (mean 1130 +/- 1149 days). 8 patients have achieved disease remission to date; mean time from diagnosis to remission was 222 +/- 97 days. Treatments included systemic steroids (10), rituximab (7), surgery (6), mycophenolate mofetil (1), and

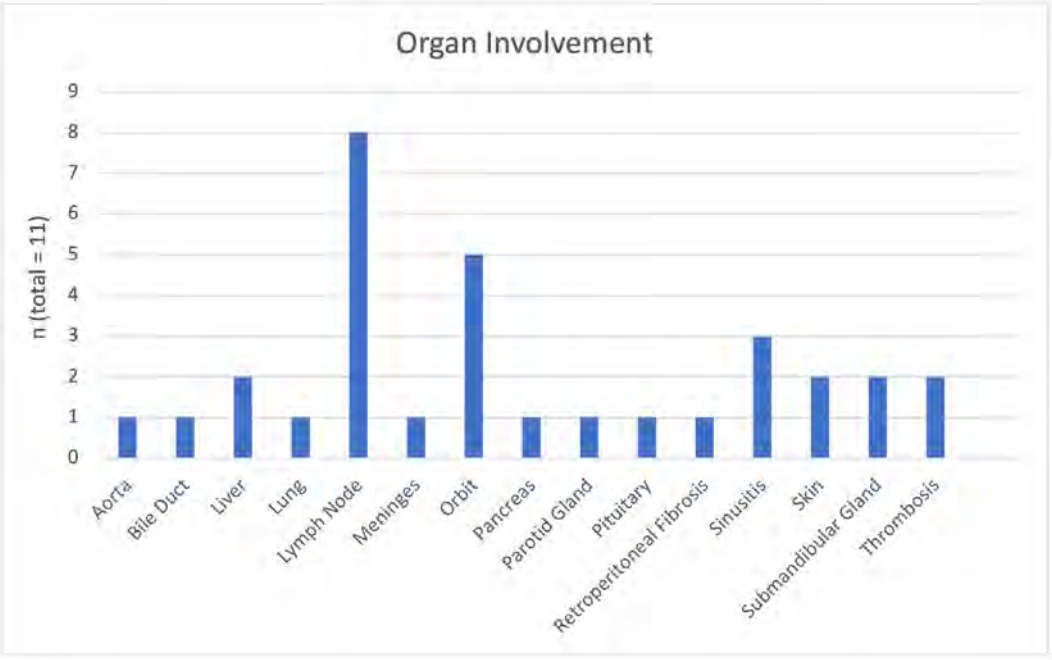

Figure 1. frequency of organ involvement in a case series of African American patients with IgG4-rD.

azathioprine (1). Serum IgG4 level was measured at or before the time of diagnosis in 8 patients (mean 304 +/- 220 mg/dL). A subsequent serum IgG4 was measured in 5 patients, all of whom had levels in the normal range by 1 year after diagnosis.

Conclusion: Presentation of IgG4-rD in this case series of African American patients was notable for prominent involvement of lymph nodes (73%), more than in previous analyses of largely Caucasian and Asian cohorts (estimated at 25-45%) [1,2]. Response to prednisone and/or rituximab was robust. The long median time from symptom onset to diagnosis of over 2 years may reflect underlying healthcare disparities but comparison data in other populations is lacking. This study was limited by small sample size. Inclusion of larger numbers of African American patients in future IgG4-rD research is needed.

Abstract Number: 0622

Ethnic Disparities in Giant-Cell Arteritis: A Clinical Comparison Among Caucasian and Hispanic Patients in the Inland Empire of Southern California

Kathleena D'Anna and Mehrnaz Hojjati, Loma Linda University Health, Loma Linda, CA

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Healthcare Disparities in Rheumatology Poster (0594–0622)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Giant-Cell Arteritis (GCA) is the most common systemic vasculitis among North Americans, historically described in Caucasian populations, with limited clinical data in other ethnic backgrounds. Despite ongoing research in the field of Rheumatology many disparities remain. Our objective was to compare the demographic, clinical characteristics, comorbid conditions, and side effects to treatment in GCA patients with different ethnic backgrounds specifically Hispanics and Caucasians.

Methods: A single center retrospective chart analysis was performed on 400 patients with associated ICD10 code diagnosis of GCA seen at Loma Linda University Health from 2013 to 2020. 53 patients with a diagnosis of GCA, based on a positive temporal artery biopsy or meeting the ACR 1990 GCA classification criteria confirmed by an expert Rheumatologist were identified. We used Pearson's chi-square to test for independence between demographic and clinical categorical variables and ethnicity. We used independent samples t-test to test for mean differences in the continuous clinical variables between Caucasians and Hispanics and set alpha equal to 0.05 for statistical significance.

Results: We did not detect any proportional differences in average age, BMI, or gender between Caucasians and Hispanics in our cohort. A higher proportion of Caucasians had private insurance compared to Hispanics (70% vs

30%). Clinically, we found that a higher proportion of Caucasian patients reported headaches, visual symptoms, Polymyalgia Rheumatica, and had clinically documented abnormal temporal artery on physical exam at time of diagnosis when compared to Hispanics (Table 1).

We also examined associated risk factors/comorbidities and observed that Hispanics were proportionally more likely to have a diagnosis of Hyperlipidemia (HLD) compared to Caucasians and that this difference was statistically significant (p=0.021). Caucasian patients experienced a higher proportion of steroid side effects, overall, most notably weight gain (p=0.051) while on treatment compared to the Hispanic group (Table 2).

Interestingly our Caucasian cohort was more frequently diagnosed via abnormal biopsy (71% vs 29%) than the Hispanic group. We also investigated relapse data and noted Caucasians were more likely to relapse compared to Hispanics (p=0.066) and the relapse was occurring mostly after twelve months of diagnosis and treatment initiation (Table 3).

Conclusion: We observed some differences in Caucasians and Hispanics, specifically among their comorbidities, long term steroid side effects, and potential to relapse. We found that some conditions such as HLD are statistically

more prevalent in our Hispanic population, while relapse and steroid side effects were more common in the Caucasian group. We also found some variations in the initial clinical manifestations in these two groups.

Further large-scale research across multiple centers with diverse populations could produce valuable insight into whether there is meaningful clinical variations or disease phenotypes based on ethnicity that can potentially affect therapeutic decisions and disease prognosis.

Session Date: Sunday, November 7, 2021

Session Title: Measures & Measurement of Healthcare Quality Poster (0623–0659)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Background/Purpose: Medication nonadherence is as high as 80% among SLE patients and leads to higher morbidity, mortality, and healthcare costs. Both the under-recognition of nonadherence by providers and patient-perceived poor communication with providers contribute to the problem. We developed and pilot tested an adherence intervention to reliably identify nonadherence and improve patient-provider communication regarding SLE medications. To conduct the intervention, the provider used commercial pharmacy refill data available in the electronic health records to monitor nonadherence and prompt a tailored discussion with the patient surrounding SLE medication use during

Table 1. Intervention effects on adherence when considering all SLE medications, HCQ alone, DMARDs combined, and MMF alone

	Improved Adherence	No Benefit	Persistent Good Adherence

PGA = Physician Global Assessment, 0-3; SLAQ = Systemic Lupus Activity Questionnaire

the clinic encounter. In this analysis, we explored the effect of the intervention on adherence and differences between patients who did and did not benefit from the intervention.

Methods: The intervention was pilot tested over 12 weeks at an academic lupus clinic during regular follow-up visits. Consecutive patients on SLE medications, including HCQ, MTX, AZA, MMF, LEF, and belimumab, were included. Adherence was assessed by medication possession ratio (MPR) based on pharmacy refill data, using MPR ≥80% as a cutoff for adherence.

MPRs 3-months before (pre-) and after (post-) the intervention visit for each SLE medication were collected. Patients were grouped into 1) Improved Adherence (MPR < 80% pre-intervention but ≥80% post-intervention), 2) No Benefit from the intervention (MPR < 80% both pre- and post-intervention, or MPR ≥80% pre-intervention but < 80% post-intervention), and 3) Persistent Good Adherence (MPR ≥80% both pre- and post-intervention).

Results: Among 130 patients included in the analysis, median age was 43, 95% were female, 59% were non-White, and 40% were married or cohabiting. A significant proportion of patients had < college education (41%), were medically disabled (29%), and the majority had income < $50,000/year (55%). During the 3-month periods before and after the intervention visit, 92% patients were prescribed HCQ, 28% MMF, 22% AZA, 12% MTX, 7% belimumab, and 2% LEF. Most (59%) were on ≥2 SLE medications.

Improved Adherence was found in 27% of patients, while 32% had No Benefit and 42% had Persistent Good Adherence when considering all SLE medications. A notable proportion of patients experienced Improved Adherence when

considering HCQ alone, MMF alone, or all DMARDs combined (Table 1). Compared to those who had No Benefit, those who had Improved Adherence after the intervention visit were more likely to be older, married or cohabitating, White, and have income >$50,000 (Table 2).

Conclusion: This simple intervention made routine use of a measurable, objective indication of adherence through pharmacy refill data and showed promising preliminary results in improving adherence in a significant proportion of SLE patients. However, additional research is needed to refine the intervention to best serve younger, non-White, and lower income patients, who often have more severe disease and are at highest risk for nonadherence.

Validation of a Self-reported Measure of Extent and Reasons for Nonadherence in SLE

Kai Sun[1], Amanda Eudy[2], D. Ryan Anderson[3], Rebecca Sadun[2], Lisa Criscione-Schreiber[1], Jayanth Doss[2], Jennifer Rogers[1], Theresa Coles[2], Corrine Volis[4] and Megan Clowse[5], [1]Duke University School of Medicine, Durham, NC, [2]Duke University, Durham, NC, [3]Duke University Medical Center, Durham, NC, [4]University of Wisconsin School of Medicine and Public Health, Madison, WI, [5]Duke University, Chapel Hill, NC

SESSION INFORMATION

Session Date: Sunday, November 7, 2021

Session Title: Measures & Measurement of Healthcare Quality Poster (0623–0659)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Table 1. Construct validity correlating the refined DOSE-nonadherence measure of the extent of nonadherence with subjective and objective measures of adherence and the BMQ

	Pearson's correlation	p-value
Adherence measures		
MASRI (n=90)	0.60	<0.001
HCQ blood level (n=15)	-0.73	0.003
HCQ MPR (n=86)	-0.48	<0.001
Beliefs in Medicines Questionnaire		
Specific Necessity	-0.26	0.01
Specific Concern	0.32	0.002
General Overuse	0.29	0.005
General Harm	0.36	<0.001

MASRI = medication adherence self-report inventory;
MPR = medication possession ratio

Background/Purpose: Medication nonadherence is common in SLE and leads to increased hospitalizations, morbidity, and mortality. To better recognize nonadherence and address adherence barriers, there is a need for a validated and easily implemented tool. Based on our prior mixed-methods results and literature review, we adapted the Domains of Subjective Extent of Nonadherence (DOSE- nonadherence) questionnaire, a previously validated (in patients with hypertension and hepatitis C) self-reported measure of *extent of nonadherence* and *reasons for nonadherence,* to better illuminate nonadherence in SLE. This study aimed to refine and assess the validity of the DOSE-nonadherence in the context of SLE.

Methods: We refined the DOSE-nonadherence questionnaire through cognitive interviewing with SLE patients recruited from an academic lupus clinic and feedback from six lupus clinic rheumatologists. The instrument was then administered to patients taking any oral SLE medications. To assess its validity, we compared the results of the refined DOSE-nonadherence questionnaire to the Beliefs about Medicines Questionnaire (BMQ), the Medication Adherence Self-Report Inventory (MASRI), an existing self-reported adherence, medication possession ratio (MPR) based on pharmacy refill data, and available HCQ blood levels.

Results: Sixteen patients (median age 43, 100% female, 50% Black) participated in cognitive debriefing interviews to refine the DOSE-nonadherence. The refined DOSE-nonadherence was administered to 99 patients (median age 50, 96% female, 42% Black, 33% < college education, 55% married or cohabiting, 51% < $50K annual household income, 44% on Medicaid/Medicare). Of these, 85% were prescribed HCQ, 31% MMF, 14% AZA, 12% MTX, 1% LEF, and 5% belimumab.

Forty-four percent of patients reported nonadherence based on the refined DOSE-nonadherence. The *extent of nonadherence* score was highly correlated with MASRI (r=0.60) and HCQ blood levels (r=-0.73) and moderately correlated with HCQ MPR (r=-0.48), demonstrating convergent validity. The correlation between *extent of nonadherence* and BMQ was small (r=-0.26-0.36), demonstrating discriminant validity (Table 1).

Nonadherent patients reported on average 3.5 [IQR 1-6] reasons for nonadherence. The most common reasons were busyness and forgetting (n=25), physical fatigue (n=19), pill fatigue (n=15), feeling well (n=12), irregular schedule (n=11), and noticing no difference when skipping a dose (n=10).

Conclusion: Our results support the validity of the DOSE-nonadherence in assessing extent and reasons for nonadherence among SLE patients. In comparison to the MASRI, the DOSE-nonadherence helps identify *reasons for nonadherence*. This instrument can be used to identify, rigorously study, and guide the development of interventions to target the most common reasons for nonadherence in SLE.

Abstract Number: 0625

Brief Tailored Clinic Intervention (A-MATIC) Targets Nonadherence During SLE Visits: Two-year Sustainability and Outcomes

Shivani Garg[1], Betty Chewning[1], Shelby Gomez[1] and Christie Bartels[2], [1]UW Madison, Madison, WI, [2]University of Wisconsin School of Medicine and Public Health, Madison, WI

SESSION INFORMATION

Session Date: Sunday, November 7, 2021
Session Title: Measures & Measurement of Healthcare Quality Poster (0623–0659)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Up to 83% of SLE patients are nonadherent to hydroxychloroquine (HCQ) which can result in up to 8-fold higher risk of early death. Yet, adherence is *never* assessed during routine SLE visits. Current adherence tools are time-consuming and offer no guidance to clinicians for adherence discussions. Our prior study reported feasibility of using an adapted seven-item Assessing Medication Adherence & Tailoring Intervention in Clinic (A-MATIC) process that identifies nonadherence and facilitates tailored adherence discussions in 2.6 mins. This study examined the impact and sustainability of using A-MATIC during SLE visits.

Table 1. A-MATIC* Intervention Process. *A-MATIC is adapted from 2 validated gold-standard adherence tools (MASRI & BMQ). MASRI Medication Adherence Self-Report Inventory; BMQ Brief Medication Questionnaire

Step 1. Patient reports last month's adherence (0-140%) on MASRI Visual Analogue Scale (VAS)	
If <80% adherence – Proceed to **Step 2;** If ≥80% – **Stop**	
Step 2. Patient chooses barrier(s) category below (6 BMQ categories):	**Step 3.** Crosswalks clinician from Step 2. to categorized strategy options
1. System Inability to get refills	1. Give 90-day supplies; Use mail order pharmacy
2. Motivation Short-term med side effects	2. Conduct motivational interview; Use strategies to manage adverse effects
3. Understanding Lack of clarity on med role & response	3. Use teach back; Leverage visual aids on risk vs. benefits
4. Motivation & Understanding Long-term side effects & damage concerns	4. Discuss expected outcomes and timing; Use simple language
5. Recall Forgetfulness	5. Consolidate doses; Use pillboxes
6. Financial Inability to afford med	6. Offer low cost alternatives; Offer coupons
Step 4. Patient & clinician prepare personalized adherence plan using categorized strategy options. To complete intervention, clinician circles strategy options used and enters time spent	

Table 2. Patient Demographics

Table 2. Patient Demographics	
Total Patient-Visits	250
No. of Patients	87
Age (Mean ± SD)	46±17
Female	89%
Caucasian	87%
Hispanic/Other Ethnicities	18%
Active Smoker	4%
Baseline SLEDAI (Mean ± SD)	2.1±2.6

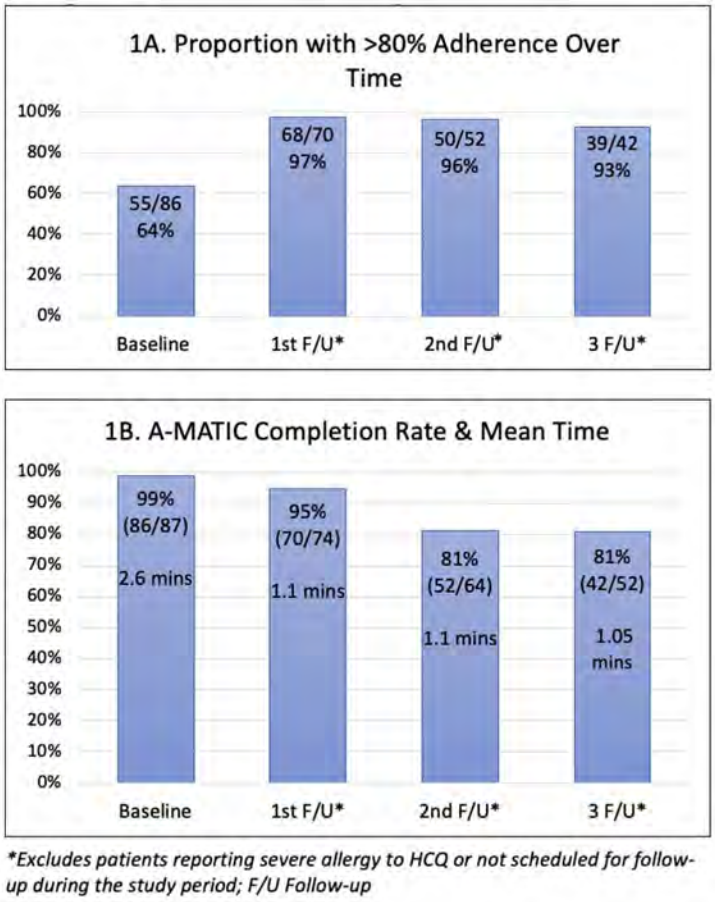

Figure 1. 1A. Graph showing impact of A-MATIC defined as proportion of adherence over two years; 1B. Graph showing sustainability of using A-MATIC during routine SLE visits over two years.

Methods: Our study included all patients seen at the UW SLE Clinic between 3/2019-5/2021. A-MATIC intervention is adapted from two standard adherence tools, Medication Adherence Self-Report Inventory (MASRI) and Brief Medication Questionnaire (BMQ), and includes 4 steps (Table 1): Step 1, assesses adherence using 0-140% MASRI visual analogue scale (VAS). The tool prompts patients reporting adherence < 80% to proceed to Step 2. Step 2, has 6-items BMQ-derived to identify key barriers. Step 3, contains adherence planning strategies that crosswalks from Step 2 barriers. Using these strategies, clinician can tailor an adherence plan based on patient choices in Step 4. Last, the clinician circles strategies used and time spent.

To assess impact, we examined the change in adherence across 3 follow-up (f/u) visits after patients participated in tailored patient-clinician discussions using A-MATIC compared to baseline adherence. We calculated the mean difference in adherence and examined the trend of adherence over time. To assess sustainability, we calculated the mean time spent and percentage of intervention completed at baseline, 1st, 2nd, 3rd f/u visits. Intervention completion was defined as patients and clinicians completing all steps.

Results: In study period there were 250 visits of 87 SLE patients with demographics shown in Table 2.

Impact – We found 36% (31/87) of the patients reported nonadherence at baseline. All patients reporting nonadherence participated in tailored adherence planning with their clinician. During the 1st f/u, 96% of these patients reported >80% HCQ adherence and resolution of underlying barriers; these patients reported HCQ adherence on their

subsequent f/u. We found 93% lower odds of reported nonadherence after completing the A-MATIC intervention and participating in adherence discussions (OR 0.07, CI 0.01-0.24, p < 0.001). Significant improvement in adherence was noted over time (Mean diff. 27%, CI 16%-38%, p < 0.001) (Fig. 1A). Finally, over 2 years, 95% of patients reported >80% adherence compared to 64% at baseline.

Sustainability – Over 2 years, the mean time to complete the intervention was 2.6±1 mins, 1.1±0.2 mins, 1.1±0.2 mins, 1.05±0.2 mins. during baseline, 1st, 2nd, 3rd f/u; the intervention was completed during 99%, 95%, 81%, 81% of the baseline, 1st, 2nd, 3rd f/u visits. (Fig. 1B).

Conclusion: A-MATIC intervention is a sustainable and impactful way to assess and facilitate adherence discussions between a patient and clinician, and helps sustain adherence over time. Next study will examine A-MATIC's role in targeting nonadherence in diverse SLE clinics.

Does Higher Quality of Care in SLE Translate to Better Patient Outcomes?

Shilpa Arora[1], Joel Block[1], Ailda Nika[1], Winston Sequeira[1], Patricia Katz[2] and Meenakshi Jolly[1], [1]Rush University Medical Center, Chicago, IL, [2]University of California San Francisco, San Francisco, CA

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Measures & Measurement of Healthcare Quality Poster (0623–0659)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Quality of care (QOC) as measured by quality indicators (QIs) decreases damage accrual in SLE long term. We aimed to assess if high QOC in SLE results prospectively in improved outcomes, specifically patient reported quality of life (QOL) and non-routine health care utilization (HCU).

Methods: 140 consecutive patients meeting 1997 ACR classification criteria for SLE were recruited from the Rheumatology clinic at an academic center. Self-report questionnaires collected information on QOC and QOL (using the disease-specific tool LupusPRO, which assesses both health-related (HR) QOL and non (N)HRQOL) at baseline. Receipt of QIs was confirmed using chart review. Data on demographics, socio-economic and disease characteristics were collected. Disease activity and damage were measured using Safety of Estrogens in Lupus Erythematosus National Assessment (SELENA)- SLEDAI and SLICC-ACR damage index (SDI). Follow up QOL and HCU (routine: rheumatology, primary care physician (PCP) visits and non-routine: ER visits and hospitalizations) were collected prospectively at 6 months. High QOC was defined as those meeting ≥80% of the eligible QIs. Co-variates of high QOC were assessed. Univariate regression analyses were performed with QOC (continuous variable) and high QOC (binary variable) as independent variables and HRQOL and NHRQOL as the dependent variables at baseline and follow up. Multivariable regression models were adjusted for age, gender, public insurance, disease activity, damage, disease duration, fibromyalgia and Charlson comorbidity index. HCU was also included in the multivariate models for QOL at follow up. Similarly, univariate and multivariate regression analyses were performed to evaluate QOC (and high QOC) as the predictors of non-routine HCU and disease activity at follow up. P-value of ≤0.05 was significant.

Table 1. Regression analyses between QOC and LupusPRO at baseline

	LupusPRO-HRQOL			LupusPRO-NHRQOL

*QOC (continuous variable); high QOC (binary variable those meeting ≥80% eligible QIs). *Multivariate models adjusted for age, gender, public insurance, disease duration, baseline SELENA- SLEDAI, SDI scores, Charlson comorbidity index, fibromyalgia, PCP and Rheumatology visits.									

Table 3. Regression analyses between OQC at baseline and secondary outcomes at follow up

Results: Baseline and follow up data on 140 and 94 patients respectively were analyzed. Mean (SD) age was 45.3 (13.5) years, with 88.6% females. Mean (SD) cumulative performance rate (QOC) was 78.6 (13.4) with 52% patients in the high QOC group. Older age and longer disease duration were the only significant predictors of high QOC. On univariate analysis QOC (and high QOC) were associated with better NHRQOL at baseline but not with HRQOL (Table 1). QOC remained a significant correlate of baseline NHRQOL, even after adjusting for co-variates. Of all the NHRQOL domains, high QOC was associated with better treatment satisfaction.

QOC (or high QOC) was not predictive of HRQOL or NHRQOL at follow up on univariate analysis; however, high QOC at baseline predicted better NHRQOL at follow up on multivariate analysis (Table 2). QOC was not associated with non-routine HCU at follow up (Table 3). High QOC, baseline disease activity and number of PCP visits were significantly associated with higher disease activity at follow up on multivariate analysis.

Conclusion: Higher QOC predicted better NHRQOL by directly impacting treatment satisfaction, which has been noted to influence health behaviors and improve adherence and outcomes in SLE patients. Higher QOC was not associated with HRQOL, ER visits, hospitalizations, or improvement in disease activity at follow up.

Increasing Rates of Standardized Depression Screening in Adolescents and Young Adults with Childhood-Onset Systemic Lupus Erythematosus in a Pediatric Rheumatology Clinic

Emily Datyner[1], Manda Mitchell[1], Brooke Fine[1], Barron Patterson[1], T. Brent Graham[1] and Alaina Davis[2], [1]Vanderbilt University Medical Center, Nashville, TN, [2]Vanderbilt Universty Medical Center, Nashville, TN

SESSION INFORMATION

Session Date: Sunday, November 7, 2021

Session Title: Measures & Measurement of Healthcare Quality Poster (0623–0659)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Background/Purpose: Depression is common and adversely affects health outcomes in adolescents and young adults with childhood-onset systemic lupus erythematous (cSLE).[1,2] The aim of our quality improvement project was to increase rates of standardized depression screening for adolescents and young adults with cSLE in our pediatric rheumatology clinic.

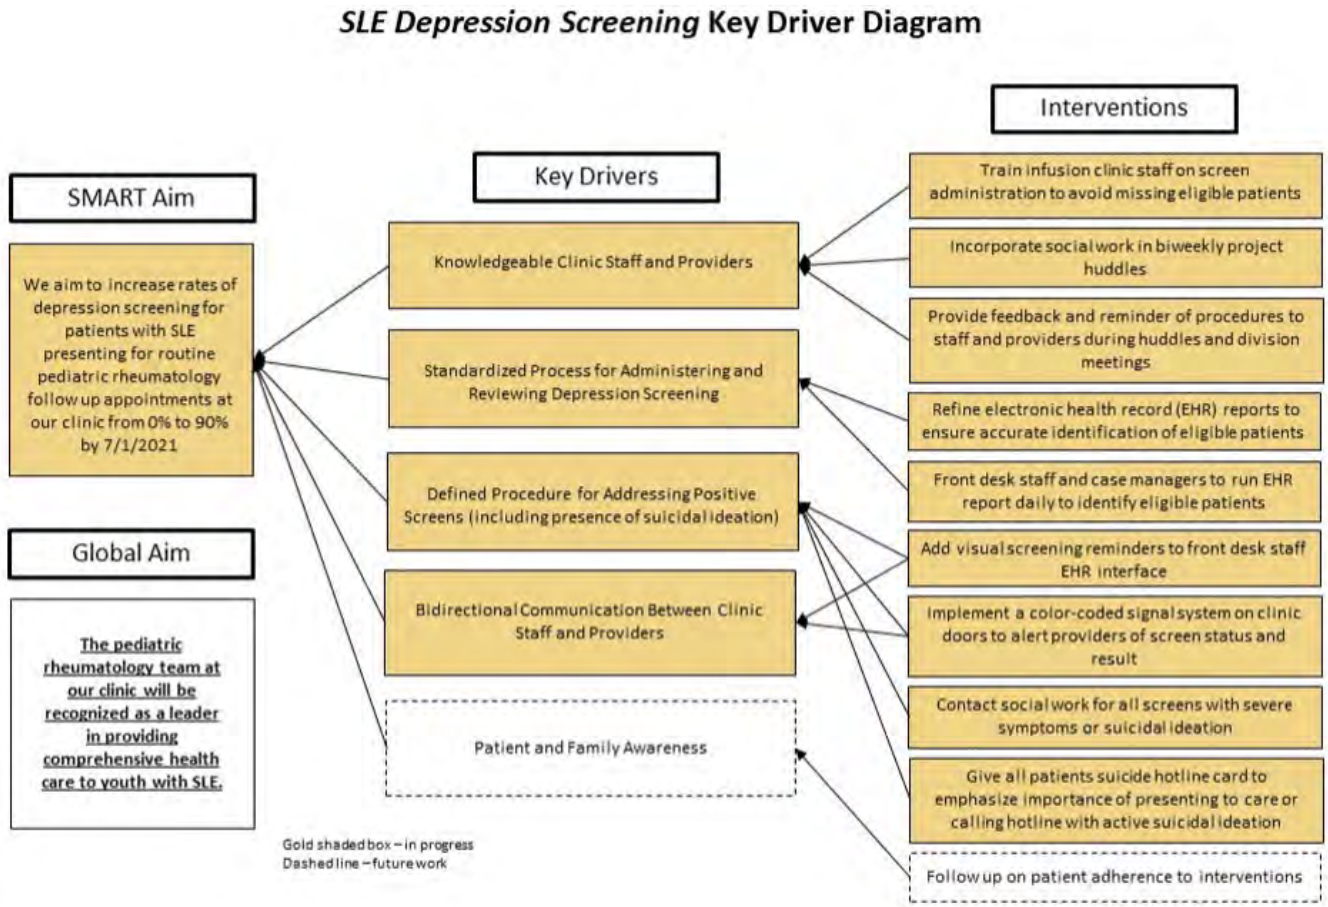

Figure 1. Key Driver Diagram - Depression Screening for Youth with SLE.

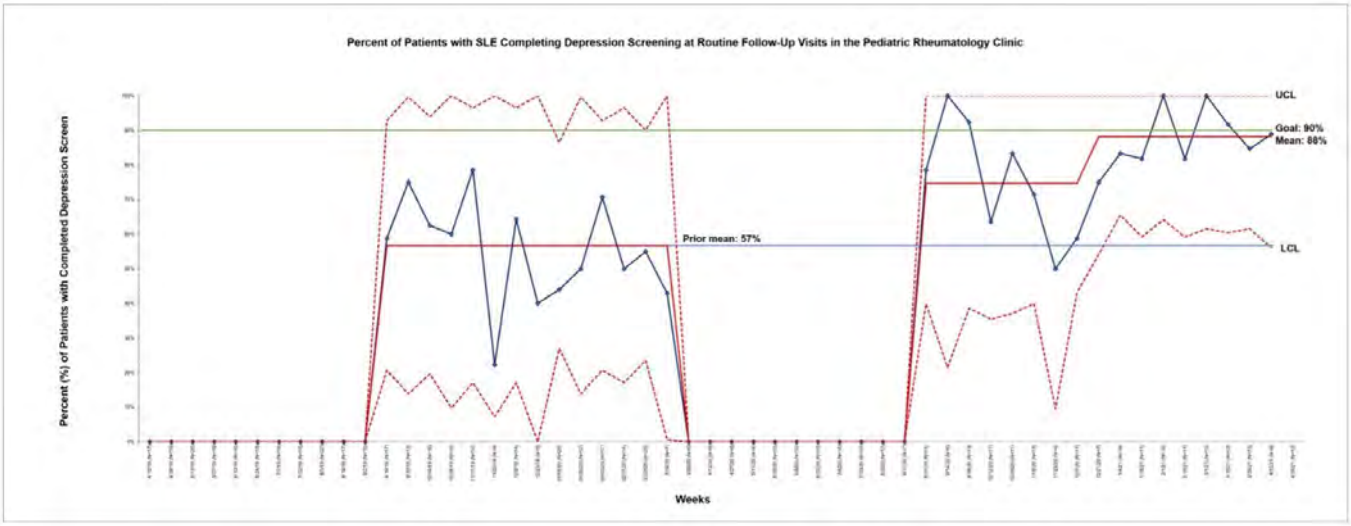

Figure 2. Control Chart - Percent of Patients Completing Depression Screening.

Methods: This was a second phase of an existing project that was halted March 2020 due to the SARS-COV2 pandemic. All patients with cSLE aged 12 years and older who were seen for routine follow-up in our pediatric rheumatology clinic August 31, 2020 through May 7, 2021 were included. Eligible patients were identified prior to their visit by an Electronic Health Record (EHR) generated report using ICD-10 codes for SLE. The Patient Health Questionnaire-9 modified for adolescents (PHQ-A) was used to screen for depressive symptoms. Patients completed the PHQ-A via an electronic tablet to maintain confidentiality. A designated clinic nurse immediately scored it and uploaded to the EHR for provider review. A multidisciplinary team developed a key driver diagram to organize potential interventions to improve rates of screening (Figure 1). Plan-Do-Study-Act (PDSA) cycles were used to prepare, implement, and evaluate these interventions. Statistical process control methods were used for data analysis.

Results: The percentage of eligible patient encounters where depression screening was completed increased from 57% to 88% following process improvements generated through PDSA cycles. This increase in completed screening represents special cause variation as evidenced by two separate data shifts on the control chart (Figure 2). Notable interventions included implementing a color-coded signal system to alert providers of screen status, adding screen reminders to front desk staff EHR interface, incorporating social work in biweekly huddles, and refining EHR reports to ensure accurate identification of eligible patients. Of the 176 depression screens completed, 33 (19%) were positive for moderate to severe symptoms and 16 (9%) were positive for suicidal ideation (SI). Clinic staff intervened on all screens that were positive for SI. Interventions for SI included social work consult, home safety planning, and referral to a behavioral health provider (or ensuring close follow up with an established behavioral health provider).

Conclusion: Rates of depression screening for adolescents and young adults with cSLE increased with process improvements made to our PHQ-A screening system. Future work will focus on improving rates further via full integration into the EHR.

SESSION INFORMATION

Session Date: Sunday, November 7, 2021

Session Title: Measures & Measurement of Healthcare Quality Poster (0623–0659)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Background/Purpose: Healthcare quality for systemic lupus erythematosus (SLE) is a modifiable target for improving patient outcomes. Disease-specific subspecialty lupus clinics may offer experienced healthcare professionals, collaborative multidisciplinary teams and streamlined care processes. Superior performance of a subspecialty lupus clinic in the provision of quality care has been shown in the United States, where access to care based on insurance status is a major factor. We aimed to compare quality of care provided in a subspecialty lupus clinic with hospital and private general rheumatology clinics in a universal healthcare setting.

Methods: Patients with SLE (n = 258) were recruited in 2016 from various clinic settings in Australia, including a subspecialty lupus clinic (n = 147), two hospital general rheumatology clinics (n = 56) and two private rheumatology clinics (n = 55). Quality of care was assessed using 31 validated SLE quality indicators (QI) encompassing diagnostic work-up, disease and comorbidities assessment, drug monitoring, preventative care and reproductive health. Data were collected from both medical records and patient questionnaires. Overall QI performance was calculated as a percentage of the number of QIs met relative to the number of eligible QIs for each patient. Individual QI performance was measured as a percentage of the number of patients that met the QI relative to the number of patients eligible. Overall and individual QI performance were compared between the three clinic settings, and multivariable regression performed to adjust for sociodemographic, disease and healthcare factors.

Results: QI performance was generally high across clinic types for diagnostic work-up, comorbidity assessment, lupus nephritis, drug monitoring, prednisolone taper, osteoporosis management and pregnancy QIs. However, median [IQR] overall performance on eligible QIs was higher in the lupus clinic (66.7% [57.1-74.1]) than the hospital general rheumatology (52.7% [47.5-58.1]) and private rheumatology (50.0% [42.9-60.9]) clinics ($p < 0.01$) and remained significant after multivariable adjustment. The subspecialty lupus clinic significantly outperformed the other clinic settings on eligible individual QIs for disease activity, disease damage, cardiovascular risk factor and drug toxicity as-

sessments, pre-immunosuppression hepatitis and tuberculosis screening, new medication counselling, vaccinations, sun avoidance education and contraception counselling.

Conclusion: SLE patients managed in a subspecialty lupus clinic received higher quality of care compared to hospital and private general rheumatology clinics.

Abstract Number: 0629

Patient and Physician Satisfaction with Telemedicine Utilization for Delivery of Care in Patients with SLE – A Single Centre Experience

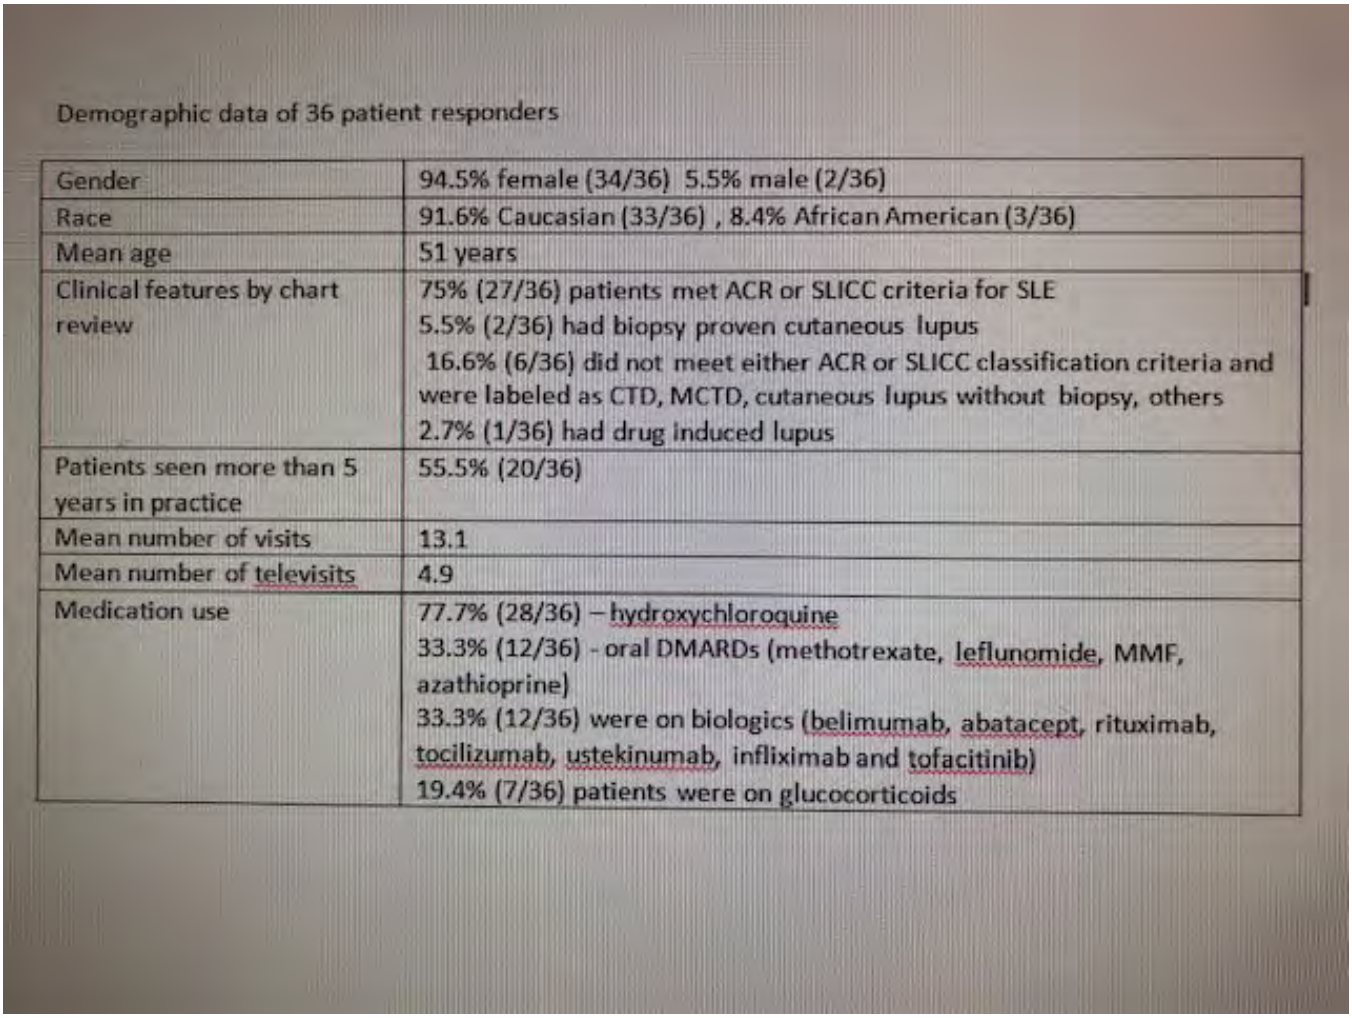
Tanmayee Bichile[1], Amanda Bembic[2], Susan Manzi[1] and Sonia Manocha[1], [1]Allegheny Health Network, Pittsburgh, PA, [2]Allgheny Health Network, Pittsburgh, PA

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Measures & Measurement of Healthcare Quality Poster (0623–0659)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: COVID 19 has forced the healthcare system to utilize telemedicine to provide dependable and timely care for patients with SLE. Telemedicine has been used in patient care for RA, gout and CTD including SLE. Data on the use of telemedicine in patients with SLE is limited. The purpose of this study is to evaluate patient and physician satisfaction with use of telemedicine for SLE. This understanding can be utilized to provide timely access to care, improve gaps in delivery of care and address healthcare disparities.

Methods: After IRB approval,we queried EMR to identify patients with SLE (ICD10 codes M32.0-M32.9, L93.0-L93.2) seen as video visits (CPT codes 99201-99205,99211-99215) with providers in our division (Physicians and PAs= 18). Patients 18 years or older were included from 3/17/2020. Satisfaction Surveys were distributed to both patients and physicians. Chart review was performed on patient responders. A Likert scale was used to collect responses.

Results: 171 patients got the Patient satisfaction survey. 39 patients completed the survey, response rate was 22.8%. Chart review was done on 36 patients. 76.9% used telemedicine for the first time to seek care for SLE. 65.7% strongly agreed with ease to set up phone/computer. 94.8% visits started on time. 76.9% strongly agreed with visit convenience. 79.4% strongly agreed with adequate time to discuss questions/concerns . 69.2% strongly agreed with being comfortable with provider taking medical decisions. 66.6% strongly agreed with the satisfaction of the quality of care they received. 76.9% strongly agreed with the comfort of discussing problems. 47.2% patients received their telemedicine visit within a week from calling for appointment. 66.6% patients strongly agreed to another telemedicine visit but only 23.3% preferred telemedicine over in person visit. With Provider Satisfaction survey, 18 of 20 responded. 44.4% had used telemedicine to provide any medical care prior to pandemic while 22.2% had used telemedicine to provide care for SLE prior to the pandemic. 50% agreed and 22.2% strongly agreed with ease to set up hardware and software. 100% agreed that visits start on time. 61% agreed and 33.3% strongly agreed that visit was convenient. 55.5% agreed while 16.6% strongly agreed with the quality of care they provided. 100% were willing



Demographic data of 36 patient responders

Gender	94.5% female (34/36) 5.5% male (2/36)
Race	91.6% Caucasian (33/36) , 8.4% African American (3/36)
Mean age	51 years
Clinical features by chart review	75% (27/36) patients met ACR or SLICC criteria for SLE 5.5% (2/36) had biopsy proven cutaneous lupus 16.6% (6/36) did not meet either ACR or SLICC classification criteria and were labeled as CTD, MCTD, cutaneous lupus without biopsy, others 2.7% (1/36) had drug induced lupus
Patients seen more than 5 years in practice	55.5% (20/36)
Mean number of visits	13.1
Mean number of televisits	4.9
Medication use	77.7% (28/36) – hydroxychloroquine 33.3% (12/36) - oral DMARDs (methotrexate, leflunomide, MMF, azathioprine) 33.3% (12/36) were on biologics (belimumab, abatacept, rituximab, tocilizumab, ustekinumab, infliximab and tofacitinib) 19.4% (7/36) patients were on glucocorticoids

to order diagnostic and laboratory tests, prescribe medications. 61.1% were able to do some physical exam. 38.8% disagreed with preference of telemedicine over in person visit, 38.8% were neutral and 11.1% agreed and the rest 11.1% strongly disagreed.

Conclusion: Our study shows that telemedicine has an overall favorable satisfaction for SLE care among patients and providers. Our results indicate that patients with complex disease and medications and the providers could utilize telemedicine with favorable overall satisfaction. Over 50% patients had seen their rheumatologist for more than 5 years which indicates that an established patient-provider relationship is favorable for telemedicine use. Despite the overall satisfaction, both patients and providers seem to prefer an in person care over telemedicine only care for SLE.

SESSION INFORMATION

Session Date: Sunday, November 7, 2021

Session Title: Measures & Measurement of Healthcare Quality Poster (0623–0659)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Table 1. Summary of patient reported outcomes of included studies investigating use of telerheumatology. CCT, controlled clinical trial; CI, confidence interval; CSQ-8, Client Satisfaction Questionnaire-8; EQ-5D, EuroQol 5-domain questionnaire; GRC; Global Rating of Change Score; HAQ, Health Assessment Questionnaire; HAQ-DI, Health Assessment Questionnaire disability index; mHAQ, modified health assessment questionnaire; OR, odds ratio; RCT, randomized clinical trial; VSQ-9 score, 9-item visit-specific satisfaction questionnaire; WPAI; Work Productivity and Activity Impairment Questionnaire

Author (citation)	*Design (n)*	*Outcome and inference*
Patient Satisfaction		
Chew 2019	Observational (186)	Mean patient satisfaction score increased from 7.70 to 8.16 ($p < 0.05$) on 11-point Likert scale.
deThurah 2018	RCT (275)	>80% of patients in all groups (rheumatology or nursing telemedicine vs usual care) were "very satisfied".
Kavadichanda 2020	Observational (373)	90% reported satisfied or very satisfied with telemedicine on a 5-item Likert scale.
Kulcsar 2016	Observational (176)	Patient satisfaction for telerheumatology was 66%.
López-Medina 2020	Observational (644)	Mean patient satisfaction 64.7±35.8 (VAS scale 0-100).
Nguyen-Oghalai 2018	Observational (38)	37/38 patients rated highest level of satisfaction (10 out of 10) with telemedicine visit.
Palcu 2020	Observational (69)	87% agreed or strongly agreed that quality of care with telemedicine was same as in-person.
Phang 2020	Observational (127)	High patient satisfaction 4.0 and physician satisfaction 4.5 (on 5-point Likert scale).
Ramelet 2017	RCT (52)	Satisfaction by CSQ-8 significantly higher when receiving telemedicine (OR = 7.7, 95% CI: 1.8–33.6).
Shenoy 2020	Observational (100)	Median patient satisfaction 9 (IQR 8–10) on 0–10 scale.
Taylor-Gjevre 2018	RCT (54)	No significant between-group differences in VSQ-9 scores.
Wood 2019	CCT (85)	Patient satisfaction not statistically different between telemedicine and usual care groups.
Quality of Life		
Cuperus 2015	RCT (147)	No significant differences in HAQ-DI (mean group difference HAQ-DI (95% CI): -0.03 (-0.14, 0.07)).
deThurah 2018	RCT (275)	No differences between telehealth interventions and conventional follow-up by HAQ, EQ-5D, or self-efficacy.
Ferucci 2020	Observational (74)	No significant difference in functional status score with telemedicine versus in-person follow up.
Howren 2020	Observational (20)	No significant trends observed in WPAI, HAQ, or EQ-5D.
Kennedy 2017	CCT (76)	Immediate improved arthritis self-efficacy (mean change (95% CI): telemedicine 1.07 (0.67, 1.48) and usual care 1.48 (0.74, 2.23) with standardized effect size -0.24.
López-Medina 2020	Observational (644)	Patients who considered the phone consultation to be useful showed lower levels of axial pain (52.4±32.8 vs 63.7±29.8), peripheral stiffness (47.2±29.4 vs 56.1±29.0) and axial stiffness (47.6±32.7 vs 62.1±29.5).
Palmer 2021	Observational (25)	44% reported improvement in symptoms (GRC of ≥2); 52% reported symptoms had not changed (GRC Score of − 1, 0 or + 1); and 4% reported worsening of symptoms (GRC Score ≤ −2) after being provided with foot orthoses.
Ramelet 2017	RCT (52)	Morning stiffness (OR = 3.2, 95% CI: 0.97–7.15) and pain (OR = 2.64, 95% CI: 0.97–7.15) lower in the telemedicine group.
Taylor-Gjevre 2018	RCT (54)	No significant between-group differences in mHAQ, EQ-5D scores.
Preference (Telemedicine vs. usual care)		
Chew 2019	Observational (186)	61.5% preferred virtual monitoring clinic vs usual follow up.
Kavadichanda 2020	Observational (373)	76.1% considered that telemedicine better than in-person consultation in setting of COVID-19 pandemic.
Nguyen-Oghalai 2018	Observational (38)	67% of patients with inflammatory, rheumatic condition preferred face-to-face visit.

Table 2. Summary of objective outcomes of included studies investigating use of telerheumatology. €, Euro; £, Pound; CCT, controlled clinical trial; CI, confidence interval; CQR-5, 5-item Compliance Questionnaire Rheumatology; CRP, C-reactive protein; DAS28, disease activity score 28; ESR, erythrocyte sedimentation rate; MARS-5, Medication Adherence Report Survey; RADAI, rheumatoid arthritis disease activity index; RAPID3; Routine Assessment of Patient Index Data 3; RCT, randomized clinical trial; SGD; Singapore dollar

Author (citation)	*Design (n)*	*Outcome and inference*
Disease Activity		
Chew 2019	Observational (186)	Mean DAS28 increased from 2.56 to 2.78 (P < 0.05) and mean RAPID3 increased from 5.28 to 6.03 (P < 0.05) at 1-year.
deThurah 2018	RCT (275)	Noninferiority established; DAS28 score improved in telemedicine versus control -0.10 ([90% CI] -0.30, 0.13) (P = 0.45).
Ferucci 2020	Observational (74)	No significant difference in RAPID3.
Song 2020	RCT (77)	No significant difference in DAS28, ESR, CRP.
Taylor-Gjevre 2018	RCT (54)	No significant differences in DAS28-CRP, RADAI scores.
Wood 2019	CCT (85)	RAPID-3 not statistically different between telemedicine and usual care groups.
Cost, Travel, and Time Savings		
Cuperus 2016	RCT (147)	Difference in total societal costs non-significantly in favor of face-to-face program (difference €708; 95% confidence interval [95% CI] -€5,058, €3,642).
Kessler 2016	Observational (280)	Telemedicine group with smaller percentage spent on food compared to in-person visit (p < 0.001) and missed less time from work and school (p = 0.028, p = 0.003). Telemedicine group with significantly less median distance travelled (60 vs 175 miles, p < 0.001).
Kulcsar 2016	Observational (176)	Telemedicine services allowed savings of 200 driving miles per session (round trip), and average monetary savings of approximately $66.90 per session.
Nguyen-Oghalai 2018	Observational (38)	Patients travelled less distance for telemedicine compared to face-to-face visits (35 vs 63 miles).
Palmer 2021	Observational (25)	Cost savings with telephone consultation of £11.80 compared to face-to-face follow-up visit.
Phang 2020	Observational (127)	Cost savings estimate for patients requiring three telemedicine calls to reach target SUA would range from SGD$88.50 to SGD$273.00 for subsidized and private patients.
Wood 2019	CCT (85)	Significantly savings in mean distance travelled (Δ = −384.8 miles/visit, p < 0.01) and visit costs (Δ = −$113.8/visit, p < 0.01).
Medication Adherence		
deThurah 2018	RCT (275)	Medication nonadherence addressed in 31% of telemedicine and physician consultations .
Howren 2020	Observational (20)	No significant trends in CQR-5 level over 12 months (p = 0.31).
Phang 2020	Observational (127)	Median MARS-5 score was 24 (Q1:Q3 23-25).
Song 2020	RCT (77)	Significantly higher medication adherence (CQR score) in telemedicine compared to control group at 12th week (t = −2.528, p = 0.014) and 24th week (t = −2.073, p = 0.042).
Goal Serum Uric Acid		
Howren 2020	Observational (20)	72% achieved target serum uric acid < 360 µmol/L at 12 months.
Phang 2020	Observational (127)	57.5% achieved target serum uric acid < 360 µmol/L.

Background/Purpose: Coronavirus disease 2019 (COVID-19) pandemic led to a dramatic uptake of telemedicine in rheumatology. Given the impact of the pandemic on care delivery, we analyzed the recent published literature on the use of telemedicine for the diagnosis and management of inflammatory, noninflammatory and/or autoimmune rheumatic diseases.

Methods: We performed a registered systematic search (CRD42020202063) for interventional or observational studies in MEDLINE, Scopus, Cochrane Trials, Embase databases, and MedRXiv published between August 2015 and January 2021. We included studies that reported relevant outcomes (e.g., satisfaction, disease activity, quality of life) in ten or more people and that utilized telemedicine by rheumatologists for people with rheumatic disease. Pairs of reviewers screened manuscripts, extracted data and assessed studies for risk of bias using the Cochrane Collaboration's tool for randomized controlled trials and the Newcastle-Ottawa scale for nonrandomized studies.

Table 3. Results of Bias Assessment using the Risk of Bias 2.0 tool for randomized controlled trials

Authors and year of Publication	Randomization process	Deviations from intended interventions	Missing outcome data	Measurement of outcome	Selection of reported result	Overall Risk of Bias Judgement
Cuperus 2015	Low risk	Low risk	Low risk	Some concerns	Low risk	Some concerns
Cuperus 2016	Low risk	Low risk	Low risk	High risk	Low risk	High risk
DeThurah 2018	Some concerns	Low risk	Low risk	Low risk	Low risk	Some concerns
Ramelet 2017	Low risk	Some concerns	Low risk	High risk	Low risk	High risk
Song 2019	Some concerns	Some concerns	Low risk	High risk	Some concerns	High risk
Taylor-Gjevre 2018	Low risk	Some concerns	High risk	High risk	Low risk	High risk

Results: Of the 1,674 potentially eligible studies, 20 reports were included: eight observational trials (74%), six randomized clinical trials (21%), and two controlled clinical trials (6%) (Table 1). Studies included general rheumatology patients (n=9), rheumatoid arthritis (n=5), gout (n=2), osteoarthritis (n=2), unspecified inflammatory arthritis (n=1), and osteoporosis (n=1). Patient satisfaction with telemedicine was the most commonly reported outcome (n=12) with majority of studies demonstrating high levels of satisfaction. Disease activity was assessed in 6 studies with most demonstrating no significant difference between telemedicine and usual care groups. Seven studies included some component of cost analysis and found telemedicine to be generally cost-effective. Among interventional studies, the effect of telemedicine on the primary outcomes varied, with most finding that telemedicine was as good as usual or in-person care (in regards to disease activity, patient satisfaction, total societal costs, and other patient reported outcomes). One study demonstrated noninferiority of telemedicine relative to usual care (based on disease activity), and two studies demonstrated superiority of telemedicine over usual care (in regards to patient satisfaction and medication adherence). Effectiveness and feasibility were high across studies, though most demonstrated high risk of bias (Table 2 and Table 3). Meta-analysis was not feasible given heterogeneity of interventions and outcome instruments utilized.

Conclusion: Although the number of high quality studies to date is small, telemedicine may be an effective mode of care delivery for diagnosis and management of inflammatory, non-inflammatory, and autoimmune rheumatic disease. More randomized clinical studies are needed to determine the best uses of telemedicine for the diagnosis and management of rheumatic conditions.

Abstract Number: 0631

Provider Assessment of Telehealth Utility During COVID-19

Catherine Howe[1], Isaac Smith[1], Robert Overton[2], Ricardo Henao[2], Nicoleta Economou-Zavlanos[2], Jayanth Doss[3], Megan Clowse[4] and David Leverenz[3], [1]Duke University Hospital, Durham, NC, [2]Duke Clinical Research Institute, Durham, NC, [3]Duke University, Durham, NC, [4]Duke University, Chapel Hill, NC

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Measures & Measurement of Healthcare Quality Poster (0623–0659)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: The COVID-19 pandemic forced the provision of telehealth care to rheumatology patients with a broader range of diagnoses and disease activity than previously studied. In this study we seek to understand factors that associate with providers' perceptions of telehealth utility.

Methods: From 10/1/2020 – 1/31/2021, six providers at an academic medical center rated their telehealth visits according to perceived utility in making treatment decisions using the following Telehealth Utility Score (TUS) (1 = very low to 5 = very high). Ratings were entered immediately following each visit. 'Low telehealth utility' visits had a TUS between 1- 3 and 'high telehealth utility' visits had a TUS between 4-5. Providers also documented a provider global assessment of disease activity (0 = no activity to 10 = high activity). Data were obtained through the electronic data warehouse and manual chart review. Modified poisson regression models with robust error variance were used to assess the association between low versus high TUS and encounter diagnoses, current and prior patient-reported disease activity (RAPID3), provider global, and medication changes during the visit. Each analysis was performed unadjusted and adjusted according to age, race, insurance, and encounter mode (video/phone).

Results: A total of 481 telehealth encounters were included, of which 191 (39.7%) had a low telehealth utility score (Table 1). Patients with a diagnosis of inflammatory arthritis (IA) were more likely to have low telehealth utility compared to those with other diagnoses in unadjusted and adjusted models (aRR 0.806, 95% CI: 0.695-0.934, p=0.004). Furthermore, in patients with IA, the addition of a non-inflammatory musculoskeletal diagnosis made a telehealth encounter more likely to be of low utility in unadjusted and adjusted models (aRR 0.537, 95% CI: 0.344-0.838, p=0.006).

Higher patient and provider-reported measures of disease activity were significantly associated with low telehealth utility in unadjusted and adjusted models (Table 2), as follows: current RAPID3 (aRR 0.87, CI: p< 0.001), prior RAPID3 (aRR 0.89, p< 0.001), and provider global (aRR 0.83, 95% CI 0.79-0.87, p< 0.001).

An escalation in rheumatologic treatment was associated with low telehealth utility (aRR 0.7, p=0.015) and a de-escalation in rheumatologic treatment was associated with high telehealth utility (aRR 1.24, p=0.009), see Table 3.

Conclusion: Overall, telehealth was rated as a useful mode of care delivery for the majority of visits. A diagnosis of IA was associated with low telehealth utility, especially if a non-IA musculoskeletal diagnosis was also present, highlighting the need for in-person care for patients with active musculoskeletal symptoms. Intriguingly, higher disease activity by current and prior RAPID3 was associated with lower telehealth utility, suggesting that disease activity measures could help determine appropriateness for telehealth care. Finally, medication changes were associated with TUS, suggesting that providers feel comfortable decreasing medications during telehealth visits but prefer to escalate therapy in-person.

Table 1. Encounter Characteristics by Telehealth Utility Score (TUS)

Description	Low (N=191)	High (N=290)	Overall (N=481)
Age in years, Mean (SD)	56.5 (15.71)	56.0 (16.09)	56.2 (15.93)
Race, N (%)

RAPID3 Value Present, N (%) **			
Current	105 (55.0%)	196 (67.6%)	301 (62.6%)
Prior	163 (85.3%)	264 (91.0%)	427 (88.8%)
Change from prior to current	94 (49.2%)	181 (62.4%)	275 (57.2%)
RAPID3 Scores, Mean (SD) **			
Current	4.3 (1.85)	2.6 (1.98)	3.2 (2.10)
Prior	4.5 (2.41)	3.1 (2.25)	3.6 (2.41)
Change from prior to current	0.1 (1.50)	-0.3 (1.71)	-0.1 (1.64)
Provider Global Score, Mean (SD)	4.0 (2.30)	1.6 (2.07)	2.6 (2.45)
Medication Actions During Visit			
De-escalation	14 (7.3%)	49 (16.9%)	63 (13.1%)
Escalation	41 (21.5%)	30 (10.3%)	71 (14.8%)
No Change	136 (71.2%)	211 (72.8%)	347 (72.1%)

Table Notes:

*Patients could have more than one diagnosis. IA=inflammatory arthritis, includes RA, juvenile arthritis, psoriatic arthritis, IBD-associated arthritis, ankylosing spondylitis, and reactive arthritis; Non-IA MSK=non-inflammatory arthritis musculoskeletal, includes OA, fibromyalgia, and regional MSK issues; CTD=connective tissue disease, includes SLE, MCTD, UCTD, Sjogren's syndrome, systemic sclerosis, inflammatory myopathy

**RAPID3: Current was within 7days of encounter, Prior was within 13 months, Delta was difference between current and prior RAPID3. The RAPID3 scale used was 0-10, where 0-1 = remission, 1.01-2 = low disease activity, 2.01-4 = moderate disease activity, and 4.01-10 = high disease activity

Table 2. Higher patient-reported disease activity, as measured with the RAPID3, is associated with lower utility of a telehealth visit. Model adjusted for age, race, insurance type, and encounter mode (video/phone).

Description	Unadjusted		Adjusted	
	RR (95% CI)	p-value	RR (95% CI)	p-value
Per unit increase				
Current	0.87 (0.83,0.90)	<.001	0.87 (0.83,0.91)	<.001
Prior	0.88 (0.85,0.92)	<.001	0.89 (0.86,0.93)	<.001
Delta	0.96 (0.91,1.01)	0.104	0.94 (0.89,1.00)	0.067
Any	0.87 (0.84,0.90)	<.001	0.87 (0.84,0.91)	<.001

Table Notes
*We accounted for missing RAPID3 scores by centering all available RAPID3 scores about the mean and setting the derived value to 0 for all patients with missing scores. An indicator and interaction term were added, and the beta coefficient associated with the indicator was the relative risk given the presence vs absence of a RAPID3 score, while the interaction term was the change in risk per unit increase in RAPID3 among patients for whom the RAPID3 score is available.

Table 3. Treatment changes were associated with telehealth utility: providers rated telehealth visits in which they escalated treatment as having lower utility and visits in which they de-escalated therapy as having higher utility. Model adjusted for age, race, insurance type, and encounter mode (video/phone).

Description*	Unadjusted		Adjusted	
	RR (95% CI)	p-value	RR (95% CI)	p-value
Escalation** vs no change	0.69 (0.52, 0.92)	0.012	0.70 (0.53, 0.93)	0.015
De-escalation*** vs no change	1.28 (1.09, 1.50)	0.002	1.24 (1.05, 1.45)	0.009

Table Notes
*Medications included prednisone, conventional DMARDs, biologic DMARDs, and targeted synthetic DMARDs
**Increase=medication started or dose increased
***Decrease=medication stopped, or dose decreased

Abstract Number: 0632

Impact of COVID-19 and Telehealth on RAPID3 Screening in an Academic Rheumatology Practice: Identifying Disparities in Care

Poorva Apte[1], Robert Overton[2], Ricardo Henao[1], Nicoleta Economou-Zavlanos[2], Jayanth Doss[1], Megan Clowse[3] and David Leverenz[1], [1]Duke University, Durham, NC, [2]Duke Clinical Research Institute, Durham, NC, [3]Duke University, Chapel Hill, NC

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Measures & Measurement of Healthcare Quality Poster (0623–0659)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Measuring disease activity in patients with inflammatory arthritis is important for providing optimal treat-to-target care. The COVID-19 pandemic has widened disparities in care among racial minorities. The purpose of this study is to understand the impact of the COVID-19 pandemic and the resultant transition to telehealth on disease activity measurement to assess disparities in care.

Table 1. Patient Demographics, RAPID3 Documentation, and Mean RAPID3 Scores for Outpatient Rheumatology Encounters From July 1 to October 31 in 2019 and 2020

Description	2019 All Visits (N=4554)	2020 In Person (N=3548)	2020 Phone (N=688)	2020 Video (N=749)
Age Group, N (%)				
18 to 30	288 (6.3%)	199 (5.6%)	23 (3.3%)	65 (8.7%)
30 to 50	1293 (28.4%)	926 (26.1%)	148 (21.5%)	294 (39.2%)
≥50	2973 (65.3%)	2423 (68.3%)	517 (75.2%)	390 (52.1%)
Insurance, N (%)				
Commercial	2150 (47.2 %)	1696(47.8%)	238(34.6%)	438(58.5%)
Medicare / Medicare Advantage	2033 (44.6%)	1590(44.8%)	384(55.8%)	247(33%)
Medicaid / Self-Pay / Other	371(8.2%)	262(7.4%)	66 (9.6%)	64(8.5%)
Race, N (%)				
Black/African American	1267 (27.8 %)	929 (26.2%)	237 (34.5%)	179 (23.9%)

Other/Multi	309 (6.7%)	239 (6.7%)	34 (4.9%)	58 (7.7%)
Race Not Reported	43 (0.9%)	43 (1.2%)	8 (1.1%)	13 (1.7%)
RAPID3 Documentation by Race, N (%)*				
Overall	76.4%	74.8 %	23.8 %	83.3%
Black/African American	67.7%	70.5%	18.1%	75.4%
Caucasian/White	79.9%	76.4%	27.3%	88%
Other/Multi	77.7%	77.4%	26.5%	73.4%
Race Not Reported	79%	69.8%	0%	61.5%
RAPID3 Score by Race, Mean (SD)**				
Overall	3.7 (2.33)	3.7 (2.14)	3.6 (2.11)	3.4 (2.27)
Black/African American	4.2 (2.45)	4.3 (2.26)	4.3 (2.33)	3.9 (2.47)
Caucasian/White	3.5 (2.24)	3.5 (2.06)	3.3 (1.98)	3.2 (2.17)
Other/Multi	3.4 (2.41)	3.5 (2.10)	3.3 (2.14)	3.4 (2.15)
Race Not Reported	3.8 (2.75)	3.9 (2.13)	-	2.8 (3.50)

Table Notes:
*Percentages for RAPID3 availability by race reflect the percentage of each group with a RAPID3 documented within 7 days of the encounter.
**RAPID3 scores in this study range from 0 – 10, where 0-1 = remission, 1.01-2 = low disease activity, 2.01-4 = moderate disease activity, and 4-10 = high disease activity

Table 2. Relative Risk (RR) for Unadjusted and Adjusted Association with RAPID3 Documentation

Description	Unadjusted		Adjusted	
	RR (95% CI)	p-value	RR (95% CI)	p-value
Year - 2020 vs 2019	0.91 (0.88, 0.93)	<0.001	0.69 (0.66, 0.73)	<0.001
2020 - Phone vs. In-Person	0.32 (0.28, 0.36)	<0.001	0.32 (0.28, 0.37)	<0.001
2020 – Video vs. In-Person	1.10 (1.06, 1.14)	<0.001	1.09 (1.05, 1.13)	<0.001
Black vs. White	0.85 (0.83, 0.88)	<0.001	0.87 (0.84, 0.89)	<0.001
Medicare vs. Comm	0.87 (0.85, 0.90)	<0.001	0.87 (0.84, 0.89)	<0.001
Age - 50+ vs. 18-<30	1.03 (0.98, 1.09)	0.238	1.07 (1.01, 1.13)	0.027
Male vs. Female	1.05 (1.02, 1.08)	<0.001	1.03 (1.00, 1.06)	0.032

Methods: This study assessed outpatient encounters at a single academic rheumatology practice between July 1st and October 31st in 2019 and 2020. Patients were included if they had a visit diagnosis of inflammatory arthritis (RA, JIA, PsA, AS, ReA, IBD-associated arthropathy) or SLE. All visits in 2019 were done in-person. Visits in 2020 were stratified by encounter type (in-person, phone telehealth, and video telehealth). Patient reported disease activity was

measured by RAPID3 (scale 0-10) either at clinic intake (in-person) or through the patient online EMR portal (phone, video, in-person). Descriptive statistics were used to evaluate the proportion of visits with a RAPID3 documented and average RAPID3 scores, stratified by race and visit modality. Modified Poisson regression was used to assess the association between RAPID3 documentation and year seen, age, race, insurance, and encounter type in unadjusted and adjusted models. We also calculated unadjusted year-over-year changes in RAPID3 documentation from 2019 to 2020 for each of these groups.

Results: There were 4554 visits during the study period in 2019 (all in-person) and 4985 in 2020 (3548 in-person, 699 phone, and 749 video; Table 1). In 2020, the proportion of visits completed by telehealth (phone or video) was similar among Black (31%) and white (28%) patients. However, telehealth encounters among Black patients were mostly by phone (60% of telehealth visits) whereas phone visits were the minority among white patients (45% of telehealth visits). In both 2019 and 2020 the RAPID3 was less likely to be completed by Black patients, though their RAPID3 score was higher, suggesting more rheumatic symptoms.

Encounters in 2020 were less likely to have a RAPID3 documented versus 2019 (adjusted risk ratio, aRR 0.69, $p< 0.001$, Table 2), driven by the absence of RAPID3 documentation among phone visits (phone vs. in-person: aRR 0.32, $p< 0.001$). The RAPID3 score is collected by electronic survey or during in-person check-in and our clinic did not have a systemic method to collect RAPID3 scores for phone visit patients. Over the entire study period, Black patients were significantly less likely to have a RAPID3 documented than White patients (aRR 0.87, $p< 0.001$, Table 2).

Conclusion: As telehealth use accelerated in 2020 in this academic clinic, the collection of patient-reported measure of disease activity remained stable for in-person and video visits, but decreased for patient visits completed by phone. The high use of phone visits among Black patient exacerbated the pre-existing disparity in RAPID3 collection between Black and White patients. These data necessitate a change in RAPID3 collection procedures to reduce systematic disparities in care for patients with inflammatory arthritis.

Disclosure: P. Apte, None; **R. Overton**, Pfizer, 5; **R. Henao**, Pfizer, 5; **N. Economou-Zavlanos**, Pfizer, 5; **J. Doss**, Pfizer, 5; **M. Clowse**, UCB Pharma, 2, Pfizer, 5, GSK, 2, 5; **D. Leverenz**, Pfizer, 5.

Abstract Number: 0633

Value of the Routine Assessment of Patient Index Data 3 (RAPID3) as a Disease Activity Measure in Patients with Psoriatic Arthritis

Johny Fares[1], Andrea Healy[1] and Martin Bergman[2], [1]Main Line Health, Wynnewood, PA, [2]Martin Jan Bergman, MD, Ridley Park, PA

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Measures & Measurement of Healthcare Quality Poster (0623–0659)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: The RAPID3 is a patient-reported pooled index of three measures: function, pain, and patient global estimate of status, that is used to classify disease severity[1]. It was developed in rheumatoid arthritis, but multiple studies have shown that it is useful in many rheumatic diseases, including Psoriatic Arthritis (PsA)[2,3]. We assessed the correlation of RAPID3 with other standard scores used in PsA in a private clinical practice setting.

Patients' demographic characteristics and disease activity measures

Patient Characteristics	N	mean	SD	Min	Max
Age	100	58.3	12.08	19.37	90.37
Disease duration (years)	91	9.85	7.97	0.21	39.9
Education (years)	100	13.64	1.89	10	17
CDAI	92	11.74	7.31	1	38
Rapid 3 (0-30)	97	10.91	6.9	0	25.99
cDAPSA	91	12.73	8.44	0	40
DAPSA	43	12.53	8.16	1.28	35.16

Methods: Adult patients with a diagnosis of PsA seen between February 2012 and November 2020 were retrospectively identified. We collected data including demographics, clinical measures and 4 disease activity measures: RAPID3,DAPSA, cDAPSA and CDAI from random routine care visits.

Spearman's correlations were calculated between RAPID3 and the other scores. Cross-test consistency of disease activity (remission, low, moderate, high) between different scores using kappa agreement analysis was calculated. Using ROC, we assessed the values of RAPID3 which best correlated with these levels of consistency. All calculations were performed using Stata Software v14 (Plano TX). IRB approval was obtained.

Results: The study included 100 patients with PsA. Patients' characteristics and scores are presented in table 1.

Spearman correlation analysis demonstrated a very strong correlation between RAPID3 and both DAPSA and cDAPSA (r=0.86) as well as a strong correlation between RAPID3 and CDAI (r=0.77).

There was strong agreement between RAPID3 remission score and DAPSA and cDAPSA remission scores, Kappa: 0.78 ($p < 0.0001$) and 0.71 ($p < 0.0001$) respectively.

The level of agreement dropped when we combined remission and low activity scores together, Kappa 0.56 ($p < 0.0001$) and 0.55 ($p < 0.0001$) respectively, although this remained in the moderate range.

Based on the ROC analysis, we redefined the RAPID3 score categories. A score of ≤3 was considered remission. >3 and ≤11 was considered low disease activity. >11 and ≤15 was considered moderate disease activity and >15 was considered high disease activity. Based on these categories, the level of agreement between RAPID3 and DAPSA and cDAPSA, when combining remission and low activity scores, significantly increased, Kappa 0.72 ($p< 0.0001$) and 0.71 ($p < 0.0001$) respectively.

Conclusion: This study supports the hypothesis that RAPID3 is as an effective disease activity measure in PsA. Our results show a strong to very strong correlation between RAPID3 and other standard scores such as DAPSA and cDAPSA used as a quantitative assessment of PsA disease activity at baseline and to measure treatment response. The advantage of RAPID3 compared to other disease activity measures is that it is a simple score that can be filled out entirely by the patients with minimal time or effort from the rheumatologist1,2,3.

We suggest that redefining the RAPID3 score categories to a score < 11 for low disease activity and >15 for high disease activity, will categorize disease activity more accurately.

Correlation Between the Functional Component of the Multidimensional Health Assessment Questionnaire (FN), Modified Health Assessment Questionnaire (MHAQ), Health Assessment Questionnaire II (HAQ-II) and a Single Functional Question (PF) in Patients with Rheumatic Disease

Andrea Healy[1], Johny Fares[1], Martin Bergman[2], Kaleb Michaud[3], Alison Petro[3] and Harlan Sayles[3], [1]Main Line Health, Wynnewood, PA, [2]Martin Jan Bergman, MD, Ridley Park, PA, [3]University of Nebraska Medical Center, Omaha, NE

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Measures & Measurement of Healthcare Quality Poster (0623–0659)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: There has been significant work developing questionnaires to find effective and reliable ways of characterizing the functional status of patients, to track disease progression and to measure response to treatment. However, these are often lengthy and difficult to perform, especially via telemedicine. We studied whether a VAS response (0-10) to a single question (Physical Function: "PF"): "We are interested in learning how your disease is affecting your ability to function in daily life" could replace the MDHAQ-FN (FN), MHAQ, HAQ-II to reliably predict the functional status of patients with rheumatic disease.

Methods: Pertinent data for adult patients with rheumatic disease collected as part of the routine practices from both a single private practice and an academic site was reviewed. Patients were asked to complete the MHAQ, FN, HAQ-II, and the single question. MHAQ is composed of 8 ADL items. FN is the functional component of the MDHAQ composed of the MHAQ plus 2 additional items. HAQ-II is composed of 10 ADL items. MHAQ, FN, and HAQ-II are scored by taking the mean item score, range 0-3. Spearman's correlations were used to compare scores from the MHAQ, FN, HAQ-II and the PF. All calculations were performed using Stata Software v14 (Plano TX). IRB approval was obtained.

Results: 1,298 patients (29% male, mean age = 60.87 years, mean disease duration 8.7 = years) were analyzed. Patient characteristics are presented in table 1. The FN, MHAQ and HAQ-II all had a very strong correlation to each other. The PF correlated strongly to scores of the FN, MHAQ and HAQ-II (Table 1.1). These correlations were generally maintained, regardless of the underlying diagnosis. Similar results were found at the UNMC.

Table 1. Pooled Data: Patient Characteristics

	Patient Characteristics		
Variable	N	Mean	Standard Deviation
Age	1298	60.87	15.20
Sex (% male)	1275	29.02	
Disease Duration (yrs)	1140	8.70	9.90
RA	214		
PsA	100		
AS	151		
OA	164		
FM	26		
SLE	27		
FN	1288	2.03	1.88
MHAQ	1269	0.41	0.50
HAQ-II	1127	0.81	0.71
PF	1298	7.50	6.05

Table 1.1. Spearman's correlation scores

Table 1.1	FN	MHAQ	HAQ-II
MHAQ	0.9189	1.0	
HAQ-II	0.9026	0.8036	1.0
PF	0.7346	0.6897	0.7217

Conclusion: This study demonstrates the utility of the PF: "We are interested in learning how your disease is affecting your ability to function in daily life" as a substitute for the FN, MHAQ and HAQ-II, questionnaires that have previously been validated as effective measures of functional status. The results were comparable, regardless of the underlying diagnosis. This single question is quick to administer and easy to score. In a time when telemedicine is becoming more prevalent, finding efficient and reliable ways of monitoring patients' wellbeing has become more important than ever. Incorporating this single question into general rheumatologic practice, in conjunction with other clinical tools, such as physical exam and lab values, can help streamline the collection of important data without sacrificing quality of care.

Correlation Between Provider Documentation and Patient Experience with Contraceptive Counseling in an Academic Rheumatology Practice

Guiset Carvajal Bedoya[1], Tara Skorupa[2], Kristin Sturm[2], Ju Young Kwag[2], Kristen Demoruelle[3] and JoAnn Zell[3], [1]University of Colorado, aurora, CO, [2]University of Colorado, Denver, CO, [3]University of Colorado Anschutz Medical Campus, Aurora, CO

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Measures & Measurement of Healthcare Quality Poster (0623–0659)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: In a prior survey of providers and patients (Chakravarty 2014), it became apparent that clear gaps exist in provider-patient communication, affecting the delivery and success of contraceptive counseling for rheumatology patients. It is unclear how best to examine the prevalence of contraceptive counseling in clinical practice, but previous work has mainly relied on either medical chart review or patient survey to determine if counseling occurred. In this study we directly compare provider documentation of counseling with patient reported experience to assess if patient perspectives align with provider documentation. To our knowledge, this is the first study to investigate the prevalence of counseling in this manner.

Methods: Females of childbearing potential (ie, 18-50 years; no self-reported history of surgical sterilization, hysterectomy, menopause) with an established autoimmune condition were invited to complete on-line questionnaires. All patients were asked if they had ever received contraception counseling or been counseled about the potential pregnancy risks of their medications. In addition, a review of electronic medical records was performed for all patients

TABLE 2: COMPARISONS OF PATIENT REPORTED COUNSELING WITH CHART DOCUMENTATION			
	Patient report of contraceptive counseling ever	Chart documentation of contraceptive counseling ever	Agreement*
All women	76/109 (70%)	59/109 (54%)	0.22
Women ever on a teratogenic medication	34/40 (85%)	28/40 (70%)	0.31
Women currently on a teratogenic medication	27/32 (84%)	22/32(69%)	0.41
Women with SLE	30/36 (83%)	21/36 (58%)	0.31
Women with RA	25/36 (69%)	21/36 (58%)	0.17
Women with other autoimmune disease	23/39 (59%)	19/3 (49%)	0.18
Women reporting no desire for pregnancy in the next year	56/84 (67%)	44/84 (52%)	0.27
*Agreement calculated based on Cohen's kappa statistic with 0.01-0.20=slight agreement, 0.21-0.40=fair agreement, 0.41-0.60=moderate agreement, 0.61-0.8=substantial agreement, 0.81-1=almost perfect agreement			

to identify provider documentation of contraceptive counseling. An anonymous on-line questionnaire was also given to clinical providers (8 rheumatology attending physicians, 6 rheumatology fellows and 2 rheumatology nurse practitioners) to assess their perception of how often they provide contraception counseling. Agreement between patient reported counseling and provider documentation of counseling was analyzed by Cohen's kappa (where k=1 is perfect agreement and k=0 is no agreement).

Results: We surveyed 109 women. The mean age was 34 years, 29% were currently or previously taking a teratogenic medication, 64% were non-Hispanic white and 92% had higher than a high school education. Overall, agreement was poor between women reporting having received contraception counseling and women with chart documentation of contraception counseling (Table 2, 70% vs. 54%, k=0.22). Agreement was slightly higher for women taking teratogenic medications (85% vs. 70%, k=0.41) and for women with lupus (83% vs. 58% k=0.31). Providers identified patient complexity as the major barrier to speaking to patients about family planning.

Conclusion: Women in an academic rheumatology practice were more likely to report having received counseling on contraception than was documented in their medical chart, suggesting that chart documentation of counseling may underestimate the true prevalence of this type of counseling that occurs in clinical care. More robust correlation was seen in patients with SLE or those currently on a teratogenic medication indicating that documentation may be more likely to occur for patients at risk for poor outcomes in the event of an unplanned pregnancy. These data showcase the need to improve the ease of documentation of contraception counseling in the medical record and continued commitment to the provision of discussions surrounding contraception with our patients.

Session Date: Sunday, November 7, 2021
Session Title: Measures & Measurement of Healthcare Quality Poster (0623–0659)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Systemic autoimmune conditions affect women of childbearing age, and teratogenic medications are commonly prescribed as treatment. In this study, we surveyed rheumatology patients to identify areas of focus that would be most effective to improve quality of care for female patients of childbearing potential.

Methods: We included 109 female patients who were seen in follow-up at an academic rheumatology practice, were 18-50 years old, had a diagnosis of any systemic autoimmune condition, were English-speaking and had no history of surgical sterilization or hysterectomy. An online survey was used to obtain patient perspectives on pregnancy, contraception, and their experiences with counseling about these topics. Definitions of teratogenic medications and highly effective, effective and less effective contraceptive methods are listed in Table 1.

Table 1. Patient characteristics		**N (%)**
Rheumatologic diagnosis	RA	34 (31)
	SLE	36 (33)
	Other systemic autoimmune disease	39 (36)
Age	<40 years	83 (76)
	≥40 years	26 (24)
Race/ethnicity	Non-Hispanic white	70 (64)
	African American	2 (2)
	Asian	4 (4)
	Hispanic	20 (18)
	Other	4 (4)
	More than one race	9 (8)

	Widowed/Divorced/separated	8 (7)
	Single	38 (35)
Current contraceptive method*	None	32 (29)
	Less effective	18 (9)
	Effective	18 (17)
	Highly effective	48 (44)

*Effectiveness of contraception defined as the following based on patient reporting of contraception used: 1) Highly effective=Intrauterine device, hormonal implant, male sterilization of partner, 2) Effective=oral contraceptive pills, vaginal ring or hormonal injection, 3) Less effective=Condoms or withdrawal method. Of note, 1 subject did not answer the type of contraception she was using.

Table 2. Factors influencing whether patients reported having ever received contraceptive counseling*			
Type of autoimmune disease	SLE (n=36)	Other (n=73)	p-value
	83%	63%	**0.03**
Teratogenic medication use	Ever	Never	
	85%	61%	**<0.01**
Self-reported race/ethnicity	Non-Hispanic white (n=86)	Other (n=22)	
	74%	50%	**0.04**
Marital status	Married (n=47)	Other (n=62)	
	72%	68%	0.61
Age	≥40 years (n=26)	<40 years (n=83)	
	50%	76%	**0.01**
Pregnancy history	Ever pregnant (n=56)	Never pregnant (n=53)	
	64%	75%	0.20
Education level	Completed college (n=76)	Did not complete college (n=33)	
	71%	67%	0.65
*All results represent the % of women in each category reporting that they had ever previously received counseling on contraception or the risks of their medications if they were to become pregnant			

Results: Patient characteristics are in Table 1. In all patients, 70% reported having ever been counseled about contraception or pregnancy risks of their medications by a rheumatologist. Reported rates of counseling were higher in women who took teratogenic medications ($p< 0.01$), had lupus ($p=0.03$), self-reported as non-Hispanic white ($p=0.04$) or were < 40 years old ($p=0.01$) (Table 2). Using multivariate logistic regression, ever use of teratogenic medications (OR=3.2, 95% CI 1.1-9.4, $p=0.03$) and non-Hispanic white race/ethnicity (OR=3.0, 95% CI 1.0-8.8, $p< 0.05$) remained significant predictors of ever counseling, after adjusting for age and lupus. In 31 women currently taking teratogenic medications, 84% reported ever counseling about contraception by a rheumatologist, but only 65% reported using effective or highly effective contraception. Those who reported ever counseling were more likely to be on effective/highly effective contraception compared to those who reported no counseling [24/26 (92%) vs. 2/5 (40%), $p=0.02$, respectively]. Regarding pre-conception counseling, among 56 women who had ever been pregnant, only 43% reported ever receiving pre-conception counseling by a rheumatologist or other health care provider.

Conclusion: In an academic rheumatology practice, women of childbearing potential reported moderately high rates of ever receiving counseling by a rheumatologist about contraception and/or pregnancy-related safety of their medications. However, we identified areas of focus that could improve counseling rates in our clinics, including a need to focus on improving counseling rates for non-white patients. The importance of contraception counseling is highlighted by our patients currently taking teratogenic medications, in whom we found an increased use of effective or highly effective contraception in women who had received counseling compared to women who had not. Our findings also highlight a need to improve pre-conception counseling rates in rheumatology patients, which were quite low at 43%. Further study is needed to determine what interventions will be most effective to ensure that all rheumatology patients with the potential for pregnancy receive appropriate counseling for either the prevention of unplanned pregnancy or planning for pregnancy, depending on each patient's preference.

Abstract Number: 0637

Assessing the Rates of Cervical Cancer Screening in Women with Systemic Lupus Erythematosus and Rheumatoid Arthritis

Tara Skorupa[1], **Sonia Khatter**[2], Alana Freifeld[1] and Elena Weinstein[3], [1]University of Colorado, Denver, CO, [2]University of Colorado, Aurora, CO, [3]University of Colorado, Englewood, CO

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Measures & Measurement of Healthcare Quality Poster (0623–0659)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Prior studies have described increased incidence of cervical dysplasia and cervical cancer in women with systemic lupus erythematosus (SLE) and rheumatoid arthritis (RA), suggesting that these populations are at higher risk due to their disease state, their immunosuppressive medications, or both. The current US Preventive Services Task Force (USPSTF) guidelines recommend cervical cancer screening in women ages 21-65 years at intervals of 3-5 years based on age and HPV co-testing. Our aim was to assess the proportion of women with SLE and RA with documented cervical cancer screening per these guidelines.

Methods: This was a single-system retrospective chart review of women ages 21-65 years with SLE and RA. Included patients had a rheumatologist and primary care provider (PCP) within our university health system. For each patient, we documented the date and result of last Pap smear. We calculated each patient's age at last Pap smear, and for patients ages 21-29, we assessed for Pap smear within the last 3 years. For thoses ages 30-65, we assessed for Pap smear within 3 years or within 5 years with HPV cotesting. We excluded those with hysterectomy for non-cervical cancer reasons, and analyzed the proportion of remaining patients with abnormal cervical cancer screening results.

Results: Of the 371 patients included in the final analysis (Figure 1), 285 (76.8%) had age-appropriate cervical cancer screening documented in the medical record per USPSTF guidelines, compared to 81% of all women nationally. 50

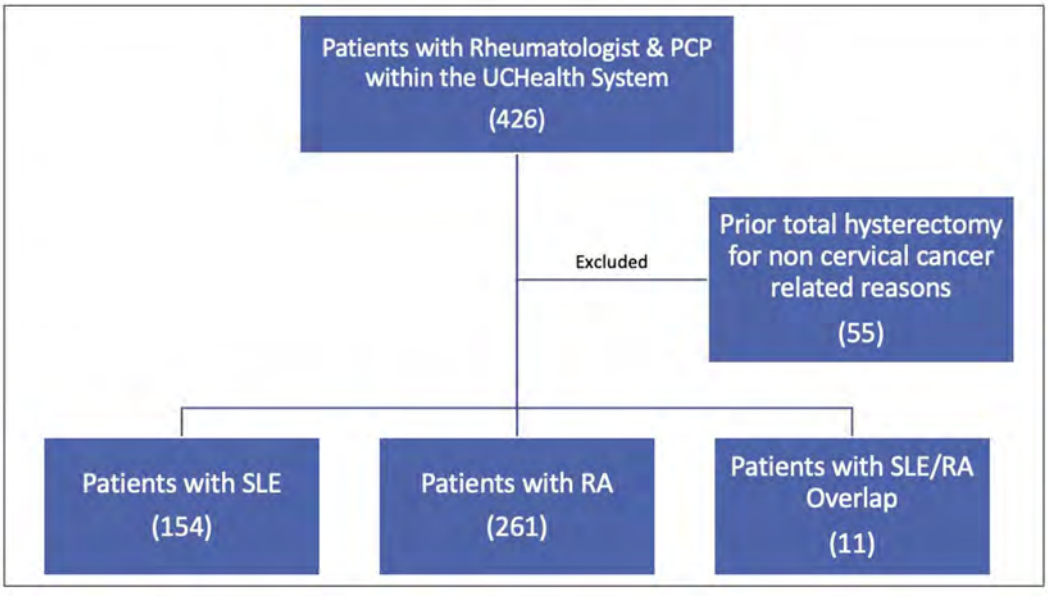

Figure 1. Patients included in the final analysis.

of the 371 patients (13%) had no prior cervical cancer screening data available in the chart. Of all 371 patients, last documented Pap smear was abnormal in 28 (7.5%). Of those patients, 18 had a positive HPV test. 3 rheumatology providers had ever documented the status of last Pap smear, and none documented counseling on cervical cancer screening.

Conclusion: Our results indicate that PCPs within our health system screen for cervical cancer in patients with SLE and RA at rates similar to the national average for all women. We acknowledge that our data may be underestimating the true number for our patients, as 13% had no prior documented Pap smear in the system. The current national average for cervical cancer screening is suboptimal, but it is even more unacceptable in patients with SLE and RA given their increased risk for cervical dysplasia. One barrier may be insufficient education about the association between these disease states and cervical cancer risk. We propose that there is an underutilized role for rheumatologists in educating patients and their PCPs about risk mitigation.

Abstract Number: 0638

Improving Safety in Rheumatology Patients by Closing Pre-screening Laboratory Care Gaps

P. Daniel Nicholas[1], Jonida Cote[2], Dante Grassi[1], Swana Thomas[3], Joseph Chronowski[1], David Pugliese[4] and Eric Newman[1], [1]Geisinger Medical Center, Danville, PA, [2]Geisinger Medical Center, Orefield, PA, [3]Geisinger Medical Center, Wilkes-Barre, PA, [4]Geisinger Medical Center, Wilkes Barre, PA

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Measures & Measurement of Healthcare Quality Poster (0623–0659)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: The Centers for Disease Control and Prevention and expert rheumatologists recommend screening for HBV and HCV prior to DMARD initiation and the ACR recommends screening for TB prior to biologic initiation. In our study, we aimed to improve patient safety by closing care gaps in the screening laboratories of our patients starting new DMARDs via collaboration with our pharmacists.

Methods: Hepatitis care gap closure for all patients starting a new DMARD was defined as meeting laboratory screening criteria for both HBV (HBsAg and HBcAb, at least IgM) and HCV (HCV Antibody or quantitative RNA). Additionally, TB screening (Purified Protein Derivative or QuantiFERON) was required to close the care gap in patients starting a new biologic. The study intervention consisted of Rheumatology pharmacist co-management protocols for all DMARDs and a pre-authorization smart-set with screening laboratory checks for new biologics. Data was extracted from our electronic health record (EHR) for patients with completed Rheumatology visits starting a new DMARD 1/1/2019 - 5/31/2020 at baseline and 6/1/2020 - 2/28/2021 post-intervention with pharmacist/physician collaborative screening. Screening was counted as present if there was documentation of completed tests in the chart any time prior to the DMARD initiation and up to one month after. For all new DMARD starts, the percent of HBV and HCV screened patients was calculated respectively. The hepatitis care gap closure for all new DMARDs was defined as meeting both HBV and HCV screening in this population. For all new biologic starts, the percent of HBV, HCV, and TB screened patients was calculated respectively. The care gap closure for new biologics was defined as meeting all three components. Two-sample t-tests were used to measure statistical significance of our screening laboratories.

Total %		462/566 (82%)	515/566 (90%)	452/566 (80%)
p-Value		0.045	0.018	0.047

Results: New DMARD hepatitis screening and new biologic hepatitis/TB screening were examined in 852 and 562 patients at baseline and 566 and 390 patients respectively post-intervention. HBV and HCV screening for all DMARDs increased from 78% and 82% at baseline to 82% (p=0.045) and 90% (p=0.018) respectively post-intervention (Table 1). The care gap closure for total hepatitis screening in all patients starting new DMARDs increased from 76% to 80% (p=0.047) post-intervention (Table 1). For patients starting new biologics, TB screening increased from 88% to 93% (p=0.021) post-intervention while the average care gap closure for hepatitis and TB screening increased from 73% to 81% (p=0.049) post-intervention (Table 2). Figure 1 shows the improvement in care gap closure over time for all new DMARD and all new biologic starts respectively, from baseline through intervention.

Conclusion: Avoiding harm to patients from the care that is intended to help them is essential. Using Rheumatology pharmacists to follow protocols driven by EHR tools, we have significantly improved our patient screening for hepatitis B, hepatitis C, and TB in DMARD-treated rheumatology patients. Today we are one step closer to fulfilling one of the aims of the framework set forth by the Institute of Medicine: Providing safer care for our rheumatic population.

Abstract Number: 0639

Improving Pre-biologic Infection Screening Using a Best Practice Alert in Electronic Health Records

Hailey Baker[1], Rebecca Fine[1], Betty Hsiao[2], Vaidehi Chowdhary[3], Lisa Suter[4] and Abhijeet Danve[5], [1]Yale University, New Haven, CT, [2]Yale-New Haven Medical Center, New Haven, CT, [3]Yale University, East Haven, CT, [4]Yale School of Medicine, New Haven, CT, [5]Yale University, Rocky Hill, CT

SESSION INFORMATION

Session Date: Sunday, November 7, 2021

Session Title: Measures & Measurement of Healthcare Quality Poster (0623–0659)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Background/Purpose: Biologics and small molecules (bDMARDs) are important immunomodulatory medications for management of patients with rheumatic diseases. Use of a bDMARD in patients with infection with pre-existing tuberculosis (TB), hepatitis B (HBV), or hepatitis C (HCV) can have serious consequences. Many national and international societies recommend timely screening for one or all of these exposures prior to initiation of certain bDMARDs, however, adherence to these recommendations varies widely. This quality improvement initiative focused on improving compliance with current standards using a best practice advisory (BPA) in the electronic health records (EHR).

Table 1. Comparison of screening rates of TB, HBV, and HCV captured pre-BPA and post-BPA. Displays captured screening rates of TB, HBV, and HCV before and after the initiation of the BPA

	Pre-BPA (N=758)		Post-BPA (N=63)		
	N	%	N	%	P-value
TB	516	68%	52	83%	0.00753
HBsAb	220	29%	18	29%	1.00000
HBcAB	248	33%	36	57%	0.00001
HBsAg	292	39%	27	43%	0.43639
HCV Ab	462	61%	52	83%	0.00026

Methods: Patients aged 18 years or older with at least two visits with a provider in the section of Rheumatology in the designated time frame were included. Upon a new prescription of a bDMARD, providers were alerted via a BPA pop-up in the EHR about the last available results if any, for TB, HBV, and HCV, and allowed for quick ordering as required. This BPA was implemented starting in December 2020. To assess the impact of the BPA, baseline rates of screening for TB (Quantiferon), HBV, and HCV for patients prescribed a new bDMARD from October 1, 2017 to November 30, 2020 (pre-BPA) were compared with those of patients with prescriptions from December 1, 2020 to April 9, 2021 (post-BPA). Data were collected for various bDMARDs targeting tumor necrosis factor (TNF), interleukin-17 (IL-17), interleukin-6 (IL-6), cytotoxic T-lymphocyte-associated protein 4 (CTLA-4), CD20, and Janus kinase (Jak).

Results: A total of 821 patients met the above inclusion criteria with 768 patients pre-BPA and 63 patients post-BPA implementation. The two patient populations were similar in gender, age, race/ethnicity, rheumatic disease diagnosis,

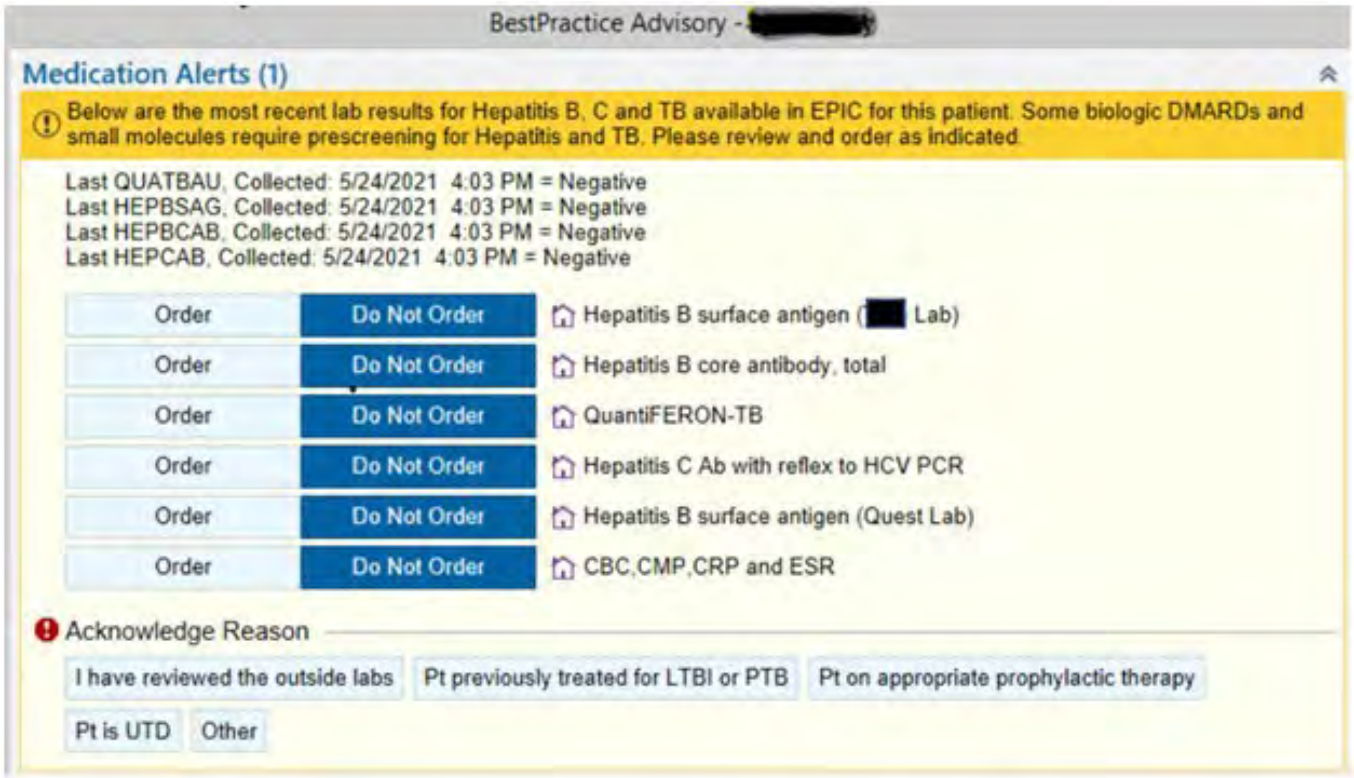

Figure 1. BPA notification. This is a visualization of the best practice advisory that appears on provider screens when ordering a biologic or bDMARD for a patient that does not have up-to-date infection screening within the defined time interval.

and a new bDMARD prescription. Median age of study population was 65 years, 70% were female, majority (77%) were white; most common rheumatic diseases were inflammatory arthritis (88%) and connective tissue disease (7%). TNFi (52%), IL-17 inhibitors (16%) and JAK inhibitors (15%) were most common bDMARDs prescribed. BPA implementation was associated with statistically significant improvement in screening for TB (pre-BPA 68% vs post-BPA 83% p=0.001), HCV (61% vs 83% p=0.0003) and hepatitis B core antibody (HBcAb) (33% vs 57% p=0.00001), numerical improvement in hepatitis B surface antigen (HBsAG) screening (39% vs 43% p=0.44) and no improvement in hepatitis B surface antibody (HBsAb) testing (29% each p=1.0) (Table 1).

Conclusion: Implementation of an electronic BPA in the EHR has the capacity to improve screening rates in patients who are started on a bDMARD. The BPA facilitates rapid review of screening tests and enhances provider experience and efficiency. Limitations include difficulty in capturing laboratory results performed outside the EHR.

Abstract Number: 0640

Implementation of Digital Prompt in Electronic Medical Records Improves Pneumonia Vaccination Rates in Patients Prescribed TNF-Inhibitors

Manjeet Bhamra[1] and Andras Perl[2], [1]SUNY Upstate Medical University, Syracuse, NY, [2]State University of New York, Syracuse, NY

SESSION INFORMATION

Session Date: Sunday, November 7, 2021
Session Title: Measures & Measurement of Healthcare Quality Poster (0623–0659)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Tumor necrosis factor α inhibitors (TNFi) predispose to bacterial infections including pneumonia. In turn, vaccination with pneumococcal 13 valent (PCV13) and pneumococcal 23 valent (PPSV23) afford prevent pneumonia. We evaluated the prevalence of pneumonia and vaccination rates in patients prescribed TNFi. To improve vaccination rates of patients started on TNFi and prevent pneumonia in these patients, we implemented a digital prompt within the Electronic Medical Record (EMR).

Table 1. Pneumonia and vaccination rates in patients exposed TNF inhibitors Before and After Intervention via EMR prompt

	Pneumonia	No Pneumonia	Chi square	p-value
Before Intervention	256	3855	1.578	0.2006
After Intervention	37	433		

	Vaccination	No Vaccination	Chi square	p-value
Before Intervention	181	3930	110.3	<0.0001
After Intervention	76	394		

Methods: To improve vaccination rates of patients started on TNFi and prevent pneumonia in these patients, we implemented a digital prompt within the Electronic Medical Record (EMR). The digital prompt notifies providers of the vaccination status of PCV13 and PPSV23 for any patients for which a TNFi is prescribed at the time of the TNFi order entry. All adult patients from January 1, 2013-August 27, 2020 newly prescribed TNFi were put into a group labeled "Before Intervention." Adult patients prescribed TNFi from August 28, 2020-April 7, 2021 were put into a group labeled "After Intervention". Before and After Intervention corresponds to the start date of the digital prompt within our EMR. Diagnoses of pneumonia on ICD-10 codes, date of pneumonia diagnosis, pneumonia vaccinations, and date of initiation of the TNFi were collected for each group. A two-sided Chi Squared test was performed to find a relationship between vaccination and pneumonia occurrences in patients on TNFi in the before and after intervention groups.

Results: Data Collection shows 470 adults on TNFi from the After Intervention group and 4111 adults on TNFi in the Before Intervention Group. From the Before Intervention group, we assessed there is a 4.4% (181/4111) pneumonia vaccination rate and 6.2% (256/4111) prevalence of pneumonia in patients on TNFα-inhibitor (TNFi). In the After Intervention group, 16% (76/470) of patients on TNFi were vaccinated and there was a 7.9% (37/470) prevalence of pneumonia. There was a statistically significant increase in vaccination After Intervention group [p >0.0001] but there was no difference in pneumonia incidents [p=0.2006].

Conclusion: Our data shows that vaccinations of patients on TNFi improved after the implementation of the digital prompt. The rates of pneumonia did not improve. Our methods include pulling pneumonia based on the ICD-10 code. Notably, our data collection includes the COVID-19 pandemic. As such, there could be confounding factors, such as mask wearing, that might have reduced pneumonia incidence irrespective of receiving PCV13 and PPSV23 vaccines

Title: EHR-Supported Staff Protocol Improves Smoking Cessation in a Diverse Rheumatology Clinic: Updated Results of Quit Connect Dissemination

Jennifer Brandt[1], Edmond Ramly[2], Monica Messina[3], S Sam Lim[4] and Christie Bartels[3], [1]Emory School of Medicine, Atlanta, GA, [2]University of Wisconsin School of Medicine, Madison, WI, [3]University of Wisconsin School of Medicine and Public Health, Madison, WI, [4]Department of Medicine, Division of Rheumatology, Emory University School of Medicine, Atlanta, GA

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Measures & Measurement of Healthcare Quality Poster (0623–0659)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Smoking is a risk factor for rheumatologic conditions like lupus and rheumatoid arthritis and predicts worse outcomes. Smoking and rheumatic disease increase risk for cardiovascular disease, yet rheumatology clinics address smoking cessation in ≤10% of visits. An ACR quality measure reports cessation intervention rates. Tobacco Quit Lines (TQL) can increase cessation 4-fold via free coaching and nicotine replacement. Amid COVID, cigarette sales increased for the first time in years, yet 27% fewer sought TQL help.

Methods: *Quit Connect* (QC) supports rheumatology staff medical assistants or nurses via electronic health record (EHR) tools to *Ask* smokers about 30-day readiness to quit/cut back, *Advise* cessation support, and *Connect* ready

Table 1. Visit-level sociodemographics of population

	All visits
Current smoking	17.4%
Age (mean, SD)	51.27, 14.45
Sex (female)	80.3%
Black race	78.0%
White Non-Hispanic	4.6%
Unknown race	1.5%
Hispanic ethnicity	12.8%
Medicaid/Medicaid	52.7% [b]
Self-Pay	36.7%

[a]Demographic information is from 11/2019 to 1/2021; [b] Payor information is from 2016.

patients via EHR orders to receive cessation support via a TQL call or a cessation class. *QC* increased TQL referrals 26-fold in our prior study, and takes < 90 seconds. We implemented *QC* at a large public hospital rheumatology clinic in Atlanta, GA to test generalizability and increase TQL referrals.

Adults in the rheumatology clinic with current tobacco use were eligible. EHR tags captured process steps when a patient was *Asked* about smoking/quit readiness, *Advised* regarding cessation, and *Connected* via referral to TQL or cessation class. We compared performance pre-pandemic, during the COVID peak, and upon restart of the project. We assessed QC cost-effectiveness for clinics based on staff time and wages per our previous study.

Results: Across clinic visits, 80% were female, 78% Black race, 53% had public insurance, and 37% were uninsured. In 7 of 50 (14%) baseline audited visits, providers acknowledged current smoking, and only 3 visits (6%) included a quit line discussion. During *QC* implementation, across 2887 visits, 85% assessed tobacco use, and 17% identified current smoking (Table 1).

Compared to pre-intervention rates of 0%, after QC implementation, 21% of smokers were asked readiness to quit (Table 2). Questioning increased from 21% pre-pandemic to 35% during the restart phase. Of those asked, 70% were

Table 2. Completion of Quit Connect (QC) implementation process steps at distinct time points

	Baseline [a] Pre-QC	Pre-pandemic[b] n (%)	Pandemic[c] n (%)	Restart[d] n (%)	Total n (%)

Current smoking	535 (20)	206 (17)	93 (18)	130 (17)	429 (17)
Ready to quit asked	(0)*	43 (21)	3 (3)	46 (35)	92 (21)
Ready to quit *(% of current smokers)*	na	30 (70)	2 (67)	32 (70)	64 (70)
e-Referred to Quit Line *(% of ready to quit)*	(6)*	15 (50)	2 (100)	32 (100)	49 (77)
e-Referred to cessation class *(% of ready to quit)*	(0)*	16 (53)	0 (0)	2 (6)	18 (28)
e-Referred to Quit Line or class *(% of ready to quit)*	na	20 (67)	2 (100)	33 (100)	55 (86)

[a]Baseline: no EHR alerts or e-referral available; [b]Pre-pandemic: Nov 2019 through March 2020; [c]Pandemic: April 2020 through Nov 2020; [d]Restart: Dec 2020 through April 2021; [e]During the disruptions of Pandemic phase, intervention was suspended as was the cessation class. *Manually abstracted % from n=50 smokers prior to start of project.

Table 3. Results of offers to e-refer individuals ready to quit

Ready to quit n=64	n (%) Among ready to quit
Accepted e-referral to GA quit line or Grady cessation class	55 (86)
Accepted e-referral to class	18 (28)
Accepted e-referral to GA quit line[b]	49 (77)
Set quit date & accepted nicotine replacement therapy	5 (10)
Already registered/pending/other	16 (33)
Reached but declined services	11 (22)
Unreachable	17 (35)

[a]From Nov 2019 through April 2021. [b]Outcomes captured in EHR only for those e-referred to the GA Quit Line (Grady cessation class outcomes not available).

ready to quit. Among those ready to quit, 77% accepted referral to TQL and 86% accepted referral to TQL or class. Of those referred to TQL, 10% (n = 5) accepted nicotine replacement and set a quit date; 22% declined services, 35% were unreachable (Table 3).

Staff spent 920 seconds (15.3 minutes) to ask 92 patients readiness to quit and 4400 s (73.3 min) to offer referrals to 55 ready patients. With a total 88.6 min (1.47 hrs) multiplied by a staff rate of $15/hour, it cost $22.15 to refer 55 patients to tobacco cessation support ($0.40 each; $4.43 per quit attempt).

Conclusion: In a low resource rheumatology clinic serving predominantly Black patients with public insurance or uninsured, 70% of smokers were ready to cut back/quit when asked, and 86% of those individuals accepted referral to cessation support. Despite pandemic barriers, patients were connected directly to TQL and set a quit date and accepted nicotine replacement. Increasing the number of patients asked about readiness to quit may increase referrals. QC was feasible, cost-effective, and sustainable even during the COVID pandemic and could be considered for future dissemination to help rheumatology patients stop smoking.

Abstract Number: 0642

Prevalence and Risk Factors for Cardio-metabolic Abnormalities in Patients with Inflammatory Arthritis Attending Cardio-rheumatology Primary Prevention Clinics

Lihi Eder[1], Shadi Akhtari[2], Dana Jerome[1], Jacob Udell[1], Patrick Lawler[1], Paula Harvey[3] and Bindee Kuriya[4], [1]University of Toronto, Toronto, ON, Canada, [2]Women's College Hospital, University of Toronto, North York, ON, Canada, [3]Women's College Hospital, University of Toronto, Toronto, ON, Canada, [4]University of Toronto - Toronto, Toronto, ON, Canada

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Measures & Measurement of Healthcare Quality Poster (0623–0659)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

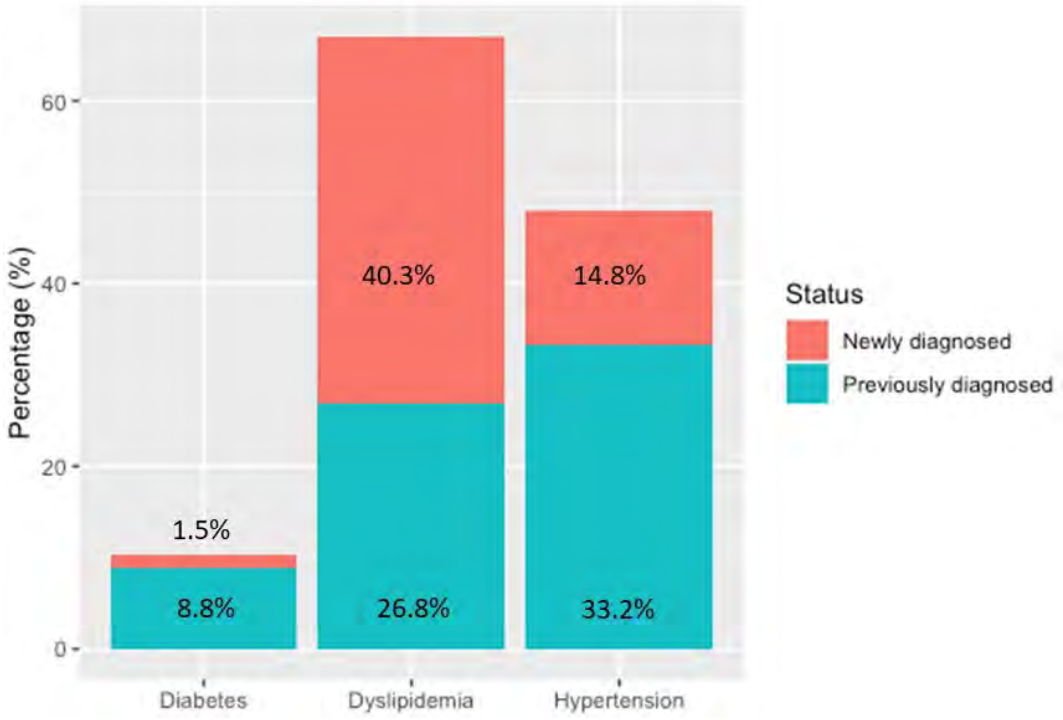

Figure 1. The prevalence of previously and newly diagnosed cardiovascular risk factors.

Background/Purpose: Cardio-metabolic abnormalities are common in patients with inflammatory arthritis (IA) but tend to be under-recognized and under-treated. We aimed to compare the prevalence and risk factors for cardio-metabolic abnormalities between patients with rheumatoid arthritis (RA), psoriatic arthritis (PsA) and ankylosing spondylitis (AS).

Methods: Consecutive patients enrolled in the University of Toronto Cardio-Rheumatology Network from 2017 to 2020 were analyzed. This is a primary prevention program that uses structured clinical, laboratory and multimodal imaging to diagnose and treat cardiovascular disease (CVD). Patients with a rheumatologist-confirmed diagnosis of RA, PsA or AS and no known CVD were evaluated. Information about IA diagnosis, medications and comorbidities was recorded. Each patient was evaluated by a cardiologist focusing on CVD risk assessment. We evaluated the prevalence of previously recorded and newly recognized cardio-metabolic risk factors including hypertension, dyslipidemia, obesity and diabetes. The prevalence of these abnormalities was compared between IA diagnoses. Regression models were used to assess the association between diagnosis and cardio-metabolic abnormalities after adjusting for demographics, smoking, BMI, measures of disease activity and medications.

Results: A total of 376 patients (219 RA, 124 PsA, 33 AS) were assessed (mean age 59±10.4 years, 69.7% female). Hypertension was reported in 33.2%, dyslipidemia in 26.8%, diabetes mellitus in 8.8% and overweight/obesity in 68.7%. Newly diagnosed dyslipidemia (elevated total cholesterol), elevated blood pressure and diabetes occurred in 40.3%, 14.8% and 1.5% of all patients (Figure 1). A total of 32% patients required a change or initiation of medications for their cardio-metabolic abnormalities (21.7% lipid-lowering therapy, 13.4% aspirin, 10.9% anti-hypertension therapy). Patients with PsA had the highest prevalence of cardio-metabolic abnormalities including dyslipidemia, obesity and hypertension (Figure 2). Having hypertension (prior or new diagnosis), elevated levels of triglycerides, non-HDL cholesterol, total cholesterol and BMI were associated with PsA vs. RA after adjusting for potential con-

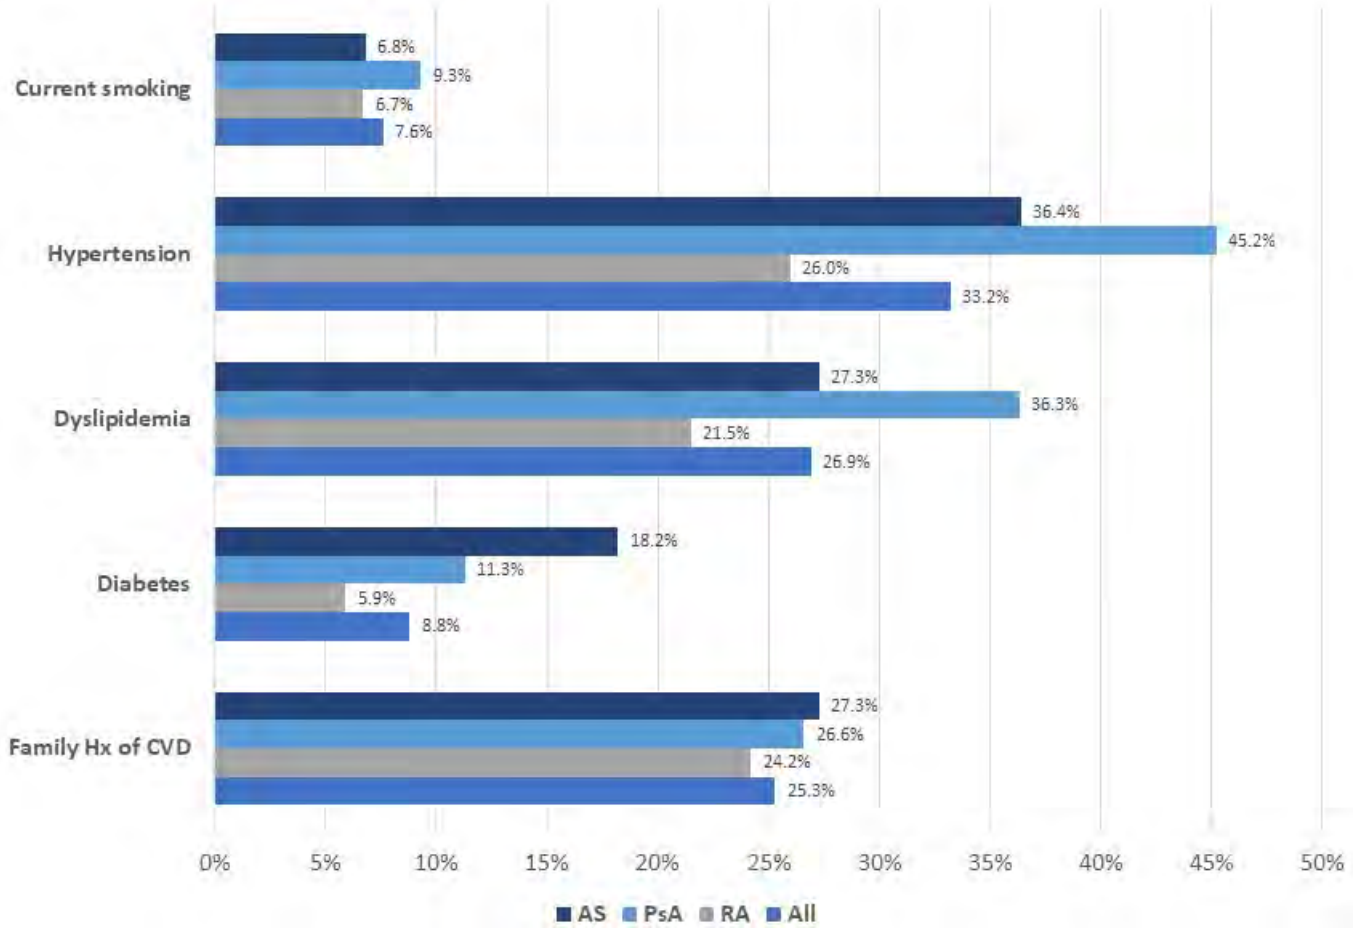

Figure 2. Prevalence of cardio-metabolic risk factors in patients with inflammatory arthritis by disease category.

founders (Figure 3). No significant association was found between cardio-metabolic abnormalities and AS vs. PsA or RA.

Conclusion: Dedicated cardio-rheumatology clinics have improved CVD screening and management in an IA population. The burden of cardio-metabolic abnormalities is elevated in PsA and suggests that tailored strategies to reduce adverse CVD events are particularly needed in this subgroup.

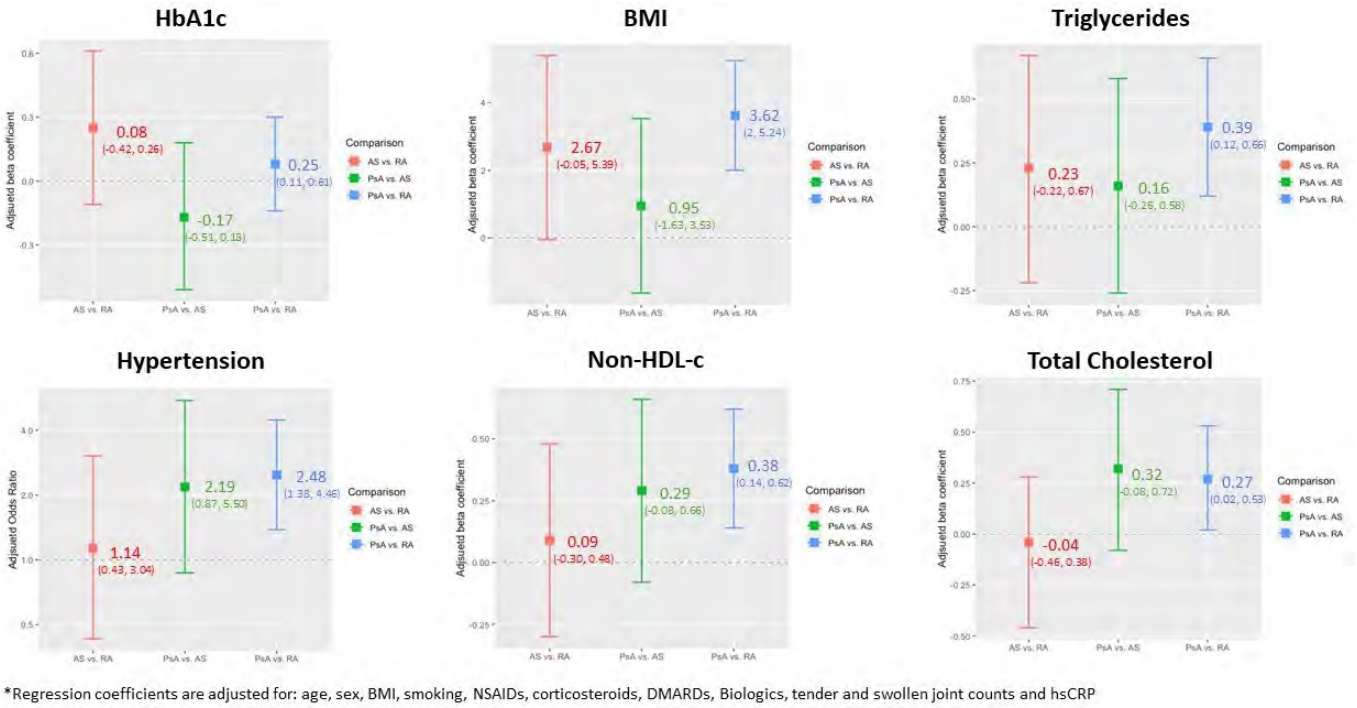

Figure 3. The Association between Disease Category and Cardiovascular Risk Factors by adjusted regression coefficients or Odds Ratio (95% Confidence interval)*.

Tailored BP Connect Protocol with Implementation Support for Rheumatology Clinic Staff Exceeds Non-tailored Protocol at Improving Primary Care Referrals for Blood Pressure Follow-up

David Gazeley[1], Monica Messina[2], Edmond Ramly[2], Ann Rosenthal[1], Laurie Lapp[2], Laura Stewart[3] and **Christie Bartels**[2], [1]Medical College of Wisconsin, Milwaukee, WI, [2]University of Wisconsin School of Medicine and Public Health, Madison, WI, [3]Froedtert & Medical College of Wisconsin, Milwaukee, WI

SESSION INFORMATION

Session Date: Sunday, November 7, 2021

Session Title: Measures & Measurement of Healthcare Quality Poster (0623–0659)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Background/Purpose: Many rheumatic diseases increase risk of cardiovascular disease, yet an important modifiable cardiovascular risk factor, high blood pressure (BP), often remains unaddressed during rheumatology visits. BP

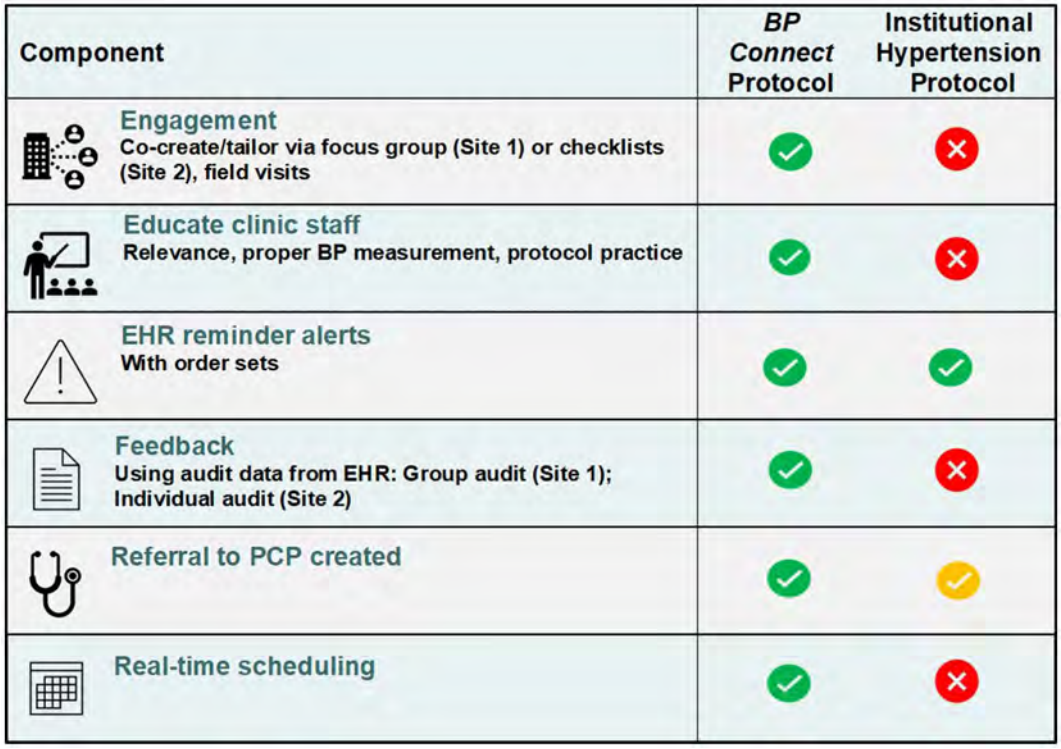

Figure 1. Comparison of protocol components for BP workflow implementation.

follow-up and control are also ACR quality measures. Some clinics have hypertension (HTN) protocols for clinic staff, however, various factors related to time constraints, technology limits, and specialty clinic staff buy-in, threaten uptake and sustainability. Our objective was to implement a tailored EHR-supported specialty clinic staff HTN protocol to empower clinic staff to confirm high BP and connect patients through follow-up orders or direct scheduling with primary care to address high BP.

Methods: We engaged 2 groups of medical assistants at urban (Site 1) and suburban (Site 2) academic rheumatology clinics to participate in the '*BP Connect*' protocol to compare effectiveness vs a prior institutional HTN protocol (Fig 1). Site 1 staff participated in a pre-intervention tailoring focus group and then monthly *group* audit-feedback on performance; Site 2 staff completed a pre-intervention tailoring checklist and monthly *individual* audit-feedback. EHR alerts instructed staff to re-measure BP if ≥ 140/90 and triggered education and offered scheduling of primary care follow-up if 2nd BP ≥ 140/90. Both groups received 1-hour education on HTN, cardiovascular risk in rheumatology, and hands-on BP measurement training and talking point practice. Using EHR data, we assessed how often staff re-measured high BPs, and if primary care follow-up was offered or accepted. The first 2 and last 2 months of the institutional process (protocol duration > 3 yrs) were compared to the 2 month *BP Connect* intervention period to report rate ratios (RR) and 95% CI's.

Results: We compared 269 *BP Connect* eligible intervention period visits with BPs ≥ 140/90 to 310-322 baseline visits at Site 1, and 27 intervention period visits to 15-37 baseline visits at Site 2 (Table 1). Baseline versus *BP Connect* period BP re-measurement rates at Site 1 ranged from 56-79% vs 74%. At Site 2, re-measurement rose from 20-81% baseline to 96% with *BP Connect*. After confirmed high BP, primary care referral offer rates rose at both sites. Site 1 increased from 22-37% to 68%, and at Site 2 offers increased from 50-67% to 100%. Across both sites, offered (RR 1.74 [1.41, 2.17]) and accepted primary care follow-up visits increased (RR 2.00 [1.21, 3.31]) in the *BP Connect* period even post-COVID.

Conclusion: A tailored rheumatology clinic staff intervention at sub/urban academic rheumatology clinics improved frequency of BP re-measurement, offers, and accepted primary care follow-up beyond an untailored HTN protocol.

*Site 1 participated in a focus group for engagement and monthly group audit-feedback sessions. **Site 2 used an engagement checklist and monthly individual audit-feedback sessions.

It appears staff engagement with checklist tailoring was similar to a focus group (Site 2 vs. 1). Overall, *BP Connect*'s engagement, participatory education, and audit-feedback, components absent from the institutional protocol, appeared to improve performance. A trend suggests individual vs group audit-feedback may be more effective at improving performance which could inform future dissemination studies. *BP Connect's* tailored implementation improved rheumatology staff performance to connect primary care follow-up of high blood pressures.

Background/Purpose: To address high blood pressure (BP), target of two ACR quality measures and *the* leading modifiable risk factor for cardiovascular disease, we previously developed *BP Connect*, a brief staff-driven protocol for rheumatology clinics. Across 28,000 visits, *BP Connect* cut rates of high BP visits in half and doubled timely in-system primary care (PC) follow-up [Adj. OR 2.0, (1.4-2.9)]. Yet many patients receive PC and rheumatology care in separate health systems. This study aimed to compare rates of timely outside system PC follow-up after high BP at rheumatology clinics before and after *BP Connect* implementation.

Methods: This post-hoc study examined pre-post rates of timely follow-up of high BP after *BP Connect* implementation among patients whose PC was in an outside Health Maintenance Organization (HMO). All adult patients with

Table 2. Odds of timely follow up (<1 mo.) compared across systems pre-post BP Connect

		Observed %	Unadjusted OR	(95% CI)
Outside PC	Pre Protocol-Any Timely Follow-up	38.0	Referent	
	Post Protocol-Any Timely Follow-up	43.8	1.27	(0.95, 1.69)
	Pre Protocol-PC Timely Follow-up	20.5	Referent	
	Post Protocol-PC Timely Follow-up	23.5	1.19	(0.85, 1.68)
In-System PC	Pre Protocol-PC Timely Follow-up	29*	Referent	
	Post Protocol-PC Timely Follow-up	42*	1.88*	(1.33, 2.66)

**Previously published rate of in-system primary care follow-up*

high rheumatology clinic BP and PC in that HMO were eligible. *BP Connect*'s EHR prompts ask rheumatology medical assistants, nurses, and schedulers to: Check, re-measuring high BP (>/=140/90), Advise CVD risk, and Connect patients to timely PC follow-up (< 1 mo per guidelines) using automated EHR orders in < 4 min. EHR follow-up orders prompt direct scheduling for patients with in-system PC, while outside HMO patients receive standardized recommendations printed on their after visit materials without direct scheduling. Staff steps were reinforced via monthly individual staff audit-feedback for the 6 mo. study period (late 2015-6), and then via email. For this study, we obtained outside EHR data on the next HMO PC visit with BP recorded after an eligible index rheumatology visit to evaluate rates and odds of timely follow-up pre-post using logistic regression. We compared results to our previously published rates and unadjusted OR for timely in-system follow-up.

Results: Across 1,327 rheumatology visits with high BP and outside HMO PC (2013-19), 951 occurred after 2015 *BP Connect* implementation and 400 had confirmed high BP. Differences in the post-implementation cohort included older age (58.7 vs 56.3) and more Black patient visits (7.4 vs 4.3%; Table 1).

After *BP Connect* implementation, among 400 visits with a confirmed high BP and outside HMO PC, any timely follow-up within 1 mo. increased modestly from 38 to 43.8%, and PC follow-up rose from 20.5 to 23.5% (Table 2). This contrasts with our prior published increase from 29 to 42% using a stricter 28-d. definition for in-system PC follow-up. Odds of timely BP follow-up among HMO PC patients changed insignificantly, [Any: OR 1.27, (CI 0.95, 1.69); PC: OR 1.19, (CI 0.85, 1.68)], vs. our prior published unadjusted OR of 1.88 (CI 1.33, 2.66) for timely in-system PC follow-up with direct scheduling.

Conclusion: Findings showed that in contrast to our prior published improvements for timely in-system PC follow-up with direct scheduling, *BP Connect* improvements were not significant for timely follow-up when PC was in an outside system. Printed patient instructions in after visit materials did not appear as effective as direct scheduling which patients with in-system PC received. Next steps include piloting a direct scheduling hotline with the outside HMO to improve timely BP follow-up and outcomes for rheumatology patients who receive PC in other systems.

Abstract Number: 0645

Time Burden of QTc Screening for HCQ Users at a Single VA Rheumatology Clinic

Iziegbe Ehiorobo[1], Anna Montgomery[2] and Gabriela Schmajuk[1], [1]University of California San Francisco, San Francisco, CA, [2]Department of Veterans Affairs, Tiburon, CA

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Measures & Measurement of Healthcare Quality Poster (0623–0659)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Hydroxychloroquine (HCQ) is a commonly used medication in the treatment of rheumatic diseases. New guidance from the ACR supports routine monitoring of the QT interval among HCQ users, especially in patients at higher risk for QT prolongation, in order to avoid potentially fatal events related to Torsade de Pointes.

Table 1. Baseline characteristics of patients on San Francisco Veteran cohort on HCQ (N = 117)

	N (%) or Mean (SD)
Age, Mean [SD]	67 [13]

Cardiovascular disease	15 (12.8)
Alcohol liver disease	3 (2.6)
Hyperthyroidism	3 (2.6)
Receiving other QT-prolonging medications	24 (20.5)
ECG documented in the chart	
Yes - documented within 1 year	30 (25.6)
Yes – documented, but > 1 year	70 (59.8)
No	17 (14.5)
QTc (out of 100 pts with an ECG)	
Abnormal QTc on automated read	24 (24)
*Other included 1-2 pts with each of following diagnoses: Psoriatic arthritis, Osteoarthritis, Undifferentiated connective tissue disease, Lichen Planus, Skin Rash NOS, Joint pain NOS, Lichen sclerosis, Mixed Connective Tissue Disease, Antiphospholipid syndrome	

We assessed the time burden of implementing routine QTc monitoring for patients receiving HCQ in a single VA rheumatology clinic.

Methods: We identified patients receiving HCQ within the past year at our institution. Using chart review, we determined the date of the most recent ECG, the associated QTc interval, and whether it was abnormal (QTc > 450 ms for men and > 470 ms for women). We extracted information about other risk factors for QT prolongation, cardiac, renal, and endocrine comorbidities, and the use of other potential QT-prolonging medications. We implemented an algorithm (Figure 1) for when to order or repeat the ECG or place an e-Consult to cardiology. The total time taken to

Table 2. Average time spent executing the algorithm in Figure 1 to implement routine QTc monitoring for patients receiving HCQ in a single clinic

	N	Time in minutes executing algorithm in Figure 1 (Mean (SD))
No previously documented ECG	17	4.0 (1.0)
Recent ECG (≤1 year)		
With normal QTc	14	6.2 (2.4)
With abnormal QTc	16	11.0 (4.1)
Remote ECG (>1 year)		
With normal QTc	63	Pending
With abnormal QTc	7	4.7 (0.7)

perform each step for each patient was documented, including time for chart review; follow up of newly ordered ECG and consults ordered was not included.

Results: There were a total of 117 HCQ users at our institution, 96% were men, with mean (SD) age 67(13); most patients were using HCQ for the treatment of RA (see Table 1). 100 out of 117 (85.4%) had an ECG previously documented in the chart, with 30 out of 117 (25.6%) with an ECG performed within the last year. Out of 100 patients with an ECG, 24% had a prolonged QTc on the automated ECG read. Most patients with recent ECGs were using other

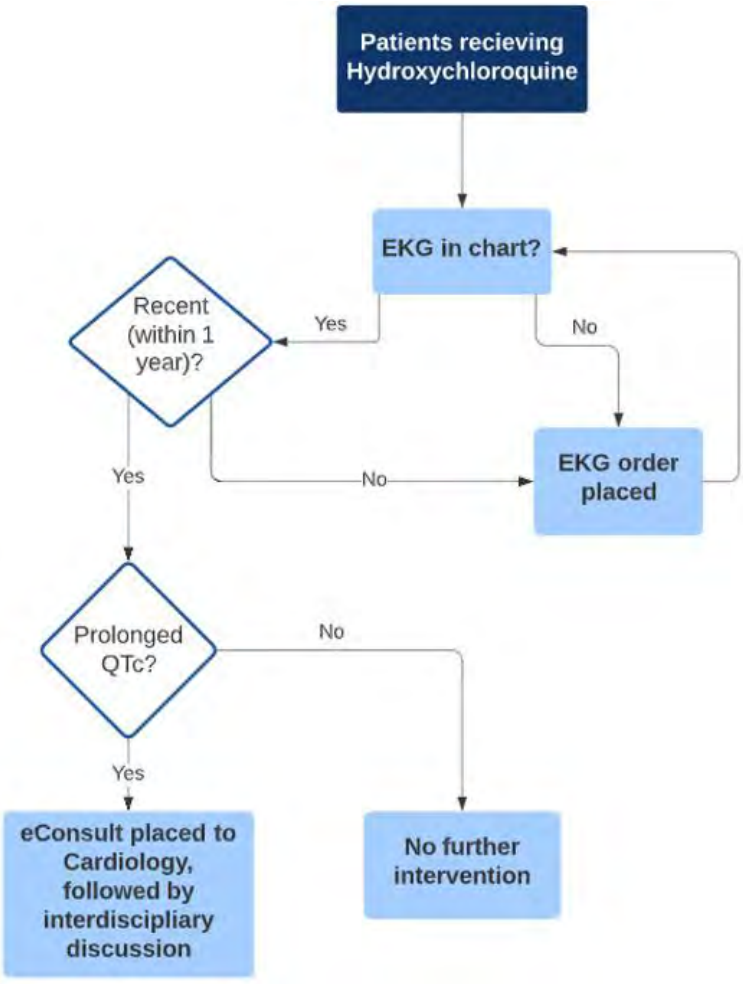

Figure 1. Flow chart depicting a process for implementing routine ECG monitoring patients receiving hydroxychloroquine.

QT-prolonging medications (63.3%); this proportion was higher in those with a prolonged QTc (70.5%). We executed the algorithm in Figure 1 for a subset of HCQ users, including those without any documented ECG (N=17); those with an ECG within the past year (N=30); and those with remote ECGs with a prolonged QTc (N=7), as these were the highest risk patients. We spent 4.1 (1.0) min for patients without any documented ECG; 9.3 (4.8) minutes for patients with a recent (< 1 year) ECG, and 4.7 (0.7) minutes for patients with remote ECGs that were abnormal (Table 2).

Conclusion: The time burden of implementing routine QTc monitoring for patients receiving HCQ in a single VA rheumatology clinic was about 6 minutes per HCQ user in this high-risk clinic population. Consultation with cardiology will result in confirmation of the automated ECG findings followed by a discussion of possible strategies to reduce the risk related to a prolonged QTc, including possible discontinuation of HCQ or other QT-prolonging medications. We plan to incorporate the additional time required to follow up updated ECG reports and recommendations from cardiology into these estimates as these data enter the chart. Future guideline development groups should compare the potential benefits of new recommendations to the time burden and other costs of implementation.

Dark Adaptometry Screening for Hydroxychloroquine Retinopathy: A Pilot Study

Robert Yood[1], Elinor Mody[1], Bradley Daines[1], Kathryn Deliso[2], Eugenio Candal[1], Ahmed Ramram[1], Stephen Brimer[3], Alondra Msallem[2] and Larry Baitch[2], [1]Reliant Medical Group, Worcester, MA, [2]MCPHS University, Worcester, MA, [3]Saint Vincent Hospital, Worcester, MA

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Measures & Measurement of Healthcare Quality Poster (0623–0659)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Hydroxychloroquine (HCQ) is widely used in the treatment of rheumatic diseases. The use of HCQ is complicated by HCQ-induced retinopathy, which may lead to irreversible visual loss. Current guidelines recommend annual screening for ocular damage with optical coherence tomography (OCT) and visual field (VF) testing beginning after 5 years of treatment with HCQ.

Dark Adaptometry (DA) tests the ability of the retina to recover its sensitivity after exposure to a bright, calibrated flash of light. This test shows high sensitivity and specificity as a biomarker for macular degeneration, a disease of the central retina. We hypothesized that DA might be more sensitive to retinal changes consequent to HCQ treatment than currently recommended tests and thus be useful as a novel screening test for HCQ retinopathy. We performed a pilot study to establish this test's diagnostic potential.

Methods: Patients aged 20-70 were eligible for participation if they had documentation of current treatment with HCQ and at least one prescription annually for the preceding 3 or more years. Exclusion criteria included diabetes mellitus, treatment with tamoxifen, active ocular disease and patients with high myopia. Patients were also excluded if they had not had an eye examination, including VF or OCT within the prior 18 months.

DA was performed using the Rapid Test protocol on all patients. In this protocol, patient subjects who did not reach a criterion level of sensitivity prior to 6.5 minutes were deemed to have failed the test.

Results: Thirty patients aged were recruited from a large multispecialty group practice and an academic optometry clinic. HCQ daily dosages at the time of the DA study ranged from 1.8 to 6.8 mg/kg with a median of 4.0 mg/kg. Cumulative dosages ranged from 420g to 4700g. with a median of 930g. The median number of years since HCQ was first prescribed was 9. No subjects had symptoms of HCQ retinopathy or positive indications of retinopathy in OCT imaging or VF testing.

Fifty-four eyes were successfully tested in 26 of the 30 study subjects. Of the eyes tested, 36 (67%) passed and 18 (33%) failed the DA test. Of the subjects tested, 40% showed at least one abnormal DA time. Of those eyes passing the test, 5 eyes (9% of the cohort) showed a "late normal" DA time between 6.0 and 6.4 minutes. There was no significant correlation with DA time for daily dosage, cumulative dosage, patient age or duration of HCQ treatment.

Conclusion: The high number of subjects with abnormal DA times was quite unexpected, given the absence of visual symptomology or objective abnormalities on OCT and VF testing. These results suggest that DA may provide a more sensitive biomarker for ocular changes due to HCQ than conventional OCT and VF testing. However, we do not know how specific this test is for retinopathy, i.e., whether those abnormal delays will precede changes on ocular coherence tomography, visual fields, or the onset of visual disturbances in patients with continued exposure to HCQ. This pilot study therefore warrants a larger cohort, longitudinal study to establish the specificity of dark adaptometry prior to its acceptance as a screening test to improve the safety of treatment with HCQ.

Adherence to Hydroxychloroquine Dosing and Teleretinal Screening: Assessment and Quality Improvement

Brendan Cerk[1], Brian Toy[1], Betty Situ[1], Stavros Savvas[2] and Leanna Wise[3], [1]University of Southern California, Los Angeles, CA, [2]Keck School of Medicine of USC, Los Angeles, CA, [3]LAC+USC/Keck Medicine of USC, Pasadena, CA

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Measures & Measurement of Healthcare Quality Poster (0623–0659)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Hydroxychloroquine (HCQ) is used in many rheumatologic diseases. The American Academy of Ophthalmology (AAO) put forth guidelines in 2012 regarding retinal screening and dosing of HCQ. These include a retinal exam in the first year after initiation of HCQ and a maximum dose of 5mg/kg/day of actual body weight. The Los Angeles County + University of Southern California Medical Center (LAC+USC MC) serves a largely underinsured urban population. LAC+USC MC utilizes an online third-party system for ophthalmology referrals. Our aim is to evaluate the LAC+USC MC rheumatology clinic's effectiveness at pursuing ophthalmologic care for HCQ patients and adhering to the appropriate dosing recommendations put forward by the AAO. Using this data, we plan to evaluate the effectiveness of a HCQ dosing calculator in increasing adherence to appropriate dosing recommendations.

Methods: First, a retrospective chart review was performed of rheumatology clinic patients prescribed HCQ in the LAC+USC MC rheumatology clinic. Charts of patients with clinic visits between March 2018 and May 2018 were reviewed. Patients were included if they had a clear first-time HCQ initiation date. Following the retrospective chart

Table 1. Sample patient characteristics

Other	28 (25.9%)	13 (43.3%)	

[a] Mean ± SD reported; p-value by independent t-test.
[b] By Fisher's exact test

Results: One hundred and thirty-eight patients qualified for analysis in the initial retrospective chart review. Of the 138 patients, 30 (21.7%) received ophthalmologic assessment within the first year of HCQ use. Of the remaining patients who were not screened, 97 patients (89.8%) lacked a timely referral to ophthalmology. Thirty-nine (28.3%) patients were prescribed a HCQ dose higher than the AAO guidelines; the average amount in excess of the recommended dose was 24.3% (range 1-122%). Following implementation of the HCQ dosing calculator, forty-four patients qualified for analysis. Of these included patients, zero patients were prescribed a HCQ dose higher than the AAO guidelines.

Conclusion: Our findings demonstrate that providers are not meeting the guidelines for ophthalmologic screening when prescribing HCQ. Additionally, a large proportion of our patients are prescribed more than the recommended HCQ dose. We implemented a HCQ dosing calculator in order to address difficulty with individualized dosing as well as a lack of knowledge about the guidelines. The calculator was very successful in lowering the proportion of patients prescribed more than the recommended HCQ dose, with zero patients being inappropriately dosed after calculator implementation. We believe this promising method warrants further study and should be considered in other institutions. In the future we plan to address HCQ retinal screening deficiencies by educating providers on AAO guidelines and working with third party referral systems to ensure ease of referrals.

Improving Post-Rituximab Hypogammaglobulinemia Risk Assessments: A Fellows' Quality Improvement Initiative

Beth Rutstein[1], Melissa Argraves[2], Atiye Bilgic Dagci[2], Sarah Bayefsky[2], Julia Rood[2], Julie Chase[3], Jay Mehta[2], Melissa Lerman[2], Cory Stingl[4] and Jon Burnham[2], [1]Children's Hospital of Philadelphia, Wynnewood, PA, [2]Children's Hospital of Philadelphia, Philadelphia, PA, [3]The Children's Hospital of Philadelphia, Philadelphia, PA, [4]Children's Hospital of Philadelphia, Durham, NC

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Measures & Measurement of Healthcare Quality Poster (0623–0659)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Hypogammaglobulinemia following rituximab therapy is a potentially severe complication that can lead to infection-related morbidity and mortality. If recognized, clinicians may prevent infections by prescribing intravenous or subcutaneous immune globulin. Our goal was to improve hypogammaglobulinemia monitoring and documentation in pediatric rheumatology patients treated with rituximab therapy.

Methods: In September 2020, we identified patients prescribed rituximab within the previous 24 months and had a Rheumatology visit within the previous 6 months. We identified inconsistent IgG monitoring amongst providers and non-standardized documentation of hypogammaglobulinemia when identified. We then developed an IgG monitoring process based on adult guidelines and pediatric literature (Figure 1).

Our process measure, hypogammaglobulinemia risk assessment, was defined as 1) IgG testing based on algorithm recommendations, and 2) hypogammaglobulinemia documentation in the electronic health record problem list if IgG was low per scale. We aimed to increase the number of clinic visits fulfilling hypogammaglobulinemia risk monitoring between missed opportunities (goal > 6) by June 30, 2021. The outcome measure was the proportion of eligible patients with up-to-date hypogammaglobulinemia risk assessment (goal > 80%).

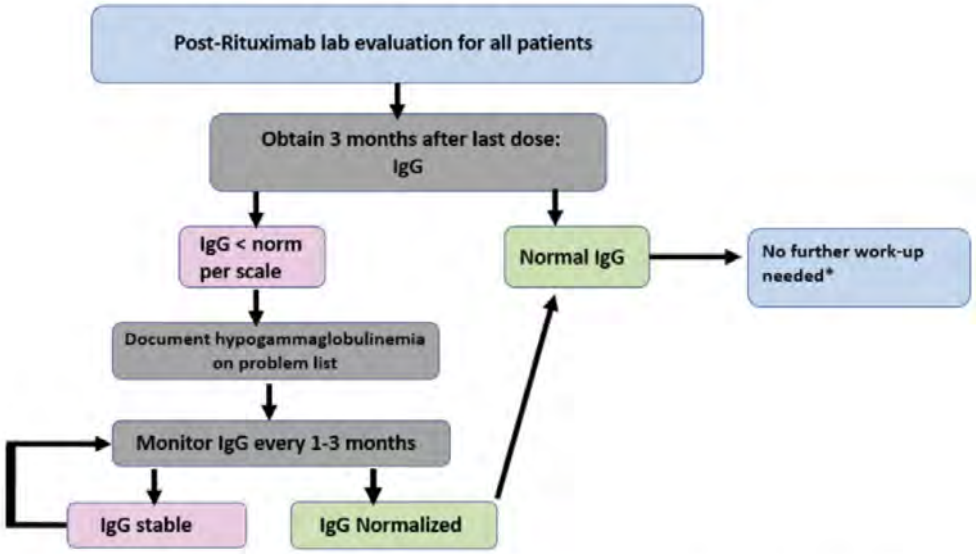

Figure 1. Standardized Post-Rituximab Hypogammaglobulinemia Monitoring Algorithm.
*Algorithm should be repeated with each Rituximab cycle

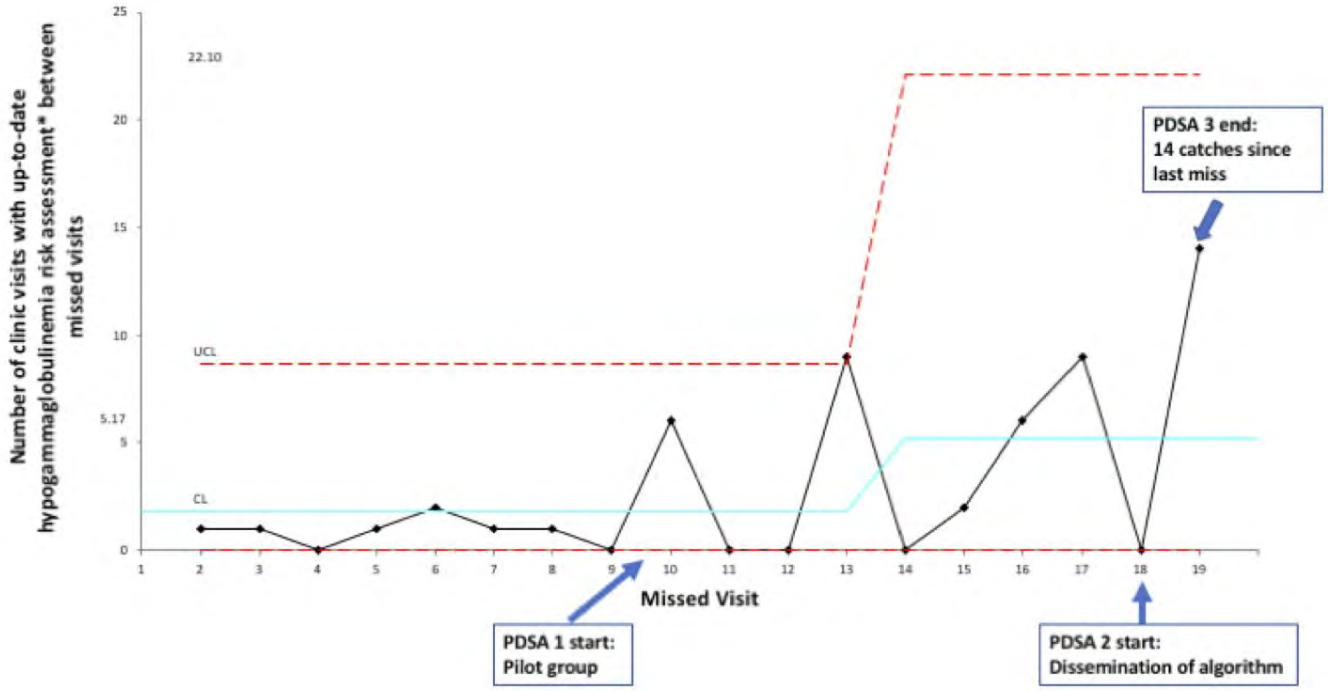

Figure 2. Number of clinic visits with documented up-to-date hypogammaglobulinemia risk assessment in between each missed visit. On the X-axis, visits in which an up-to-date hypogammaglobulinemia risk assessment was not documented for eligible patients is displayed chronologically from May 2020 through May 2021. Six months of baseline data (May – September 2020) demonstrated a median of 1.18 clinic visits with up-to-date documentation of clinical risk assessment for eligible patients between each missed clinic visit prior to intervention start. This increased to 5.17 visits between each missed visit by the end of PDSA 3.
* Hypogammaglobulinemia risk assessment = up-to-date IgG monitoring and documentation of hypogammaglobulinemia for IgG < normal per scale

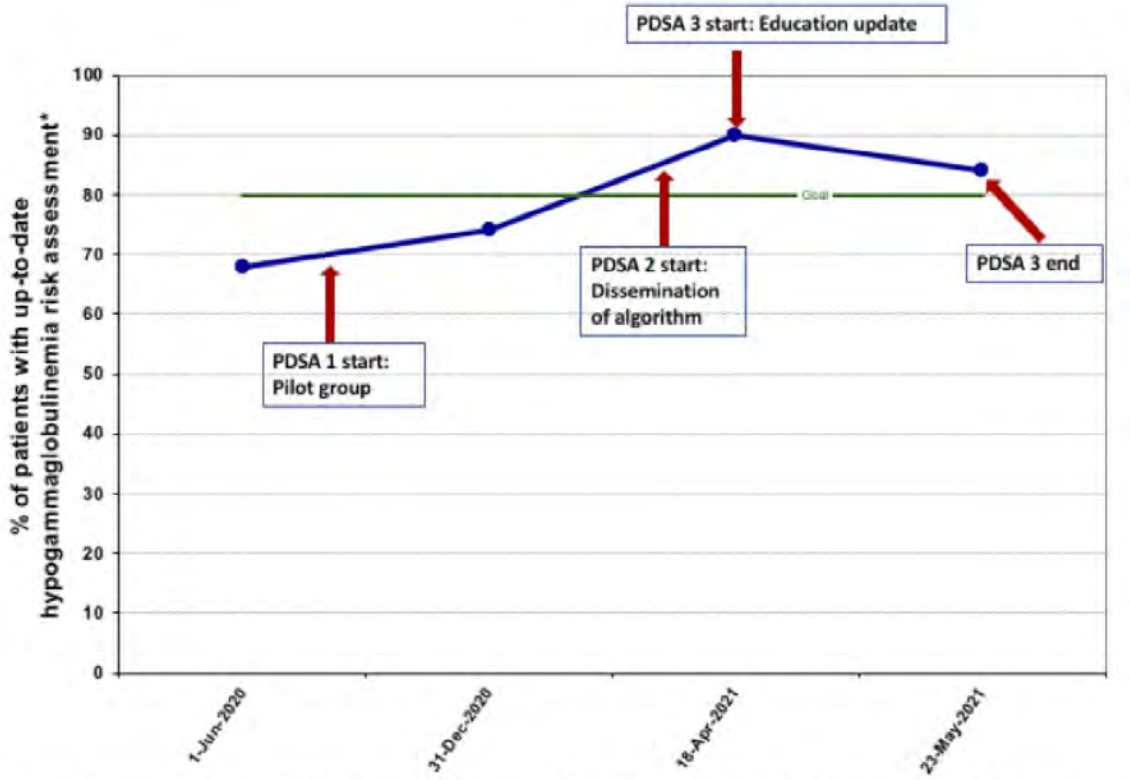

Figure 3. Improvement in Patient-Level Up-to-date Documented Hypogammaglobulinemia Risk Assessment Using Dissemination of a Standardized Algorithm and Division Education
* Hypogammaglobulinemia risk assessment = up-to-date IgG monitoring and documentation of hypogammaglobulinemia for IgG < normal per scale

We conducted the following "Plan-Do-Study-Act" (PDSA) cycles, beginning in September 2020: 1) pilot testing of algorithm, 2) division-wide dissemination of algorithm and provider-specific patient lists specifying those overdue for monitoring and/or documentation, and 3) education update reviewing divisional progress towards goals, algorithms, and provider-specific patient lists.

Data were analyzed for special cause variation using standard statistical process control and run chart methodology. Patients who received IgG replacement within the last 6 months, had transferred to an alternative practice, or were lost to follow-up (no visit within 12 months) were ineligible.

Results: Beginning in May 2020, the baseline median number of visits between missed hypogammaglobulinemia risk assessment opportunities was 1.18. Special cause variation criteria were met after the first PDSA cycle, with an increase in successful monitoring opportunities to 5.17 (Figure 2). Currently, we have successfully monitored 14 patients consecutively. Patients with an up-to-date clinical risk assessment increased from 68% (26/38) to 84% (21/25) (Figure 3). Documentation of identified hypogammaglobulinemia increased from 38% to 100%.

Conclusion: Provision of a standardized algorithm paired with intermittent provider-specific reminders improves identification and documentation of hypogammaglobulinemia in rheumatology patients who have received rituximab. We are nearing our risk assessment goal and will evaluate whether our improvements are sustained. Future directions include standardizing referrals to immunology for replacement immunoglobulin therapy and developing clinical decision support tools.

Abstract Number: 0649

Optimizing SARS-CoV-2 Vaccine Timing in Rituximab-Treated Patients with Autoimmune Rheumatic Diseases: A Quality Improvement Intervention

Daniel Magliulo[1], Stefanie Wade[2] and Vasileios Kyttaris[3], [1]Beth Israel Deaconess Medical Center, Boston, MA, [2]Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA, [3]BIDMC, Boston, MA

SESSION INFORMATION

Session Date: Sunday, November 7, 2021

Session Title: Measures & Measurement of Healthcare Quality Poster (0623–0659)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Table 1. Patient demographics, clinical, and immunologic data of autoimmune rheumatic disease patients receiving rituximab

Patient characteristics	Total (n=70)
Age (years), median (IQR)	61.5 (16)
Underlying disease:	
Rheumatoid arthritis, n (%)	31 (44.2)
ANCA-associated vasculitis, n (%)	16 (22.8)
Connective tissue disease*, n (%)	21 (30)
IgG4-related disease, n (%)	2 (2.8)
Rituximab Schedule	
Every 6 months, n (%)	60 (85.7)
Every 12 months, n (%)	10 (14.2)
Cumulative RTX (mg), median (IQR)	7000 (4000, 11500)
Concomitant DMARD, n (%)	38 (54.3)
Steroids ≥ 20mg/day, n (%)	2 (2.8)
B cell counts:	
Absolute CD19 count (#/uL), median (IQR): (n= 20)	15.33 (8.77, 19.73)
Absolute CD20 count (#/uL), median (IQR): (n= 20)	10.06 (5.99, 13.51)
History of hypogammaglobulinemia n, (%) (n=38)	19 (50)
Immunoglobulin M (mg/dL), median (IQR) (n=34)	47 (22.25, 67.5)
Immunoglobulin A, median (IQR) (n=35)	181 (113, 257.5)
Immunoglobulin G, median (IQR) (n=35)	901 (743, 1065)
Documented history of COVID-19 infection, n (%)	5 (8.3)
Influenza vaccine in 2020-2021 (yes/no) n (%) (n=53)	48 (90.5)
Patient group according to provider preference for SARS-CoV-2 vaccine:	
Universal recommendation for timing n (%)	40 (57.1)
Individualized approach to timing, n (%)	30 (42.8)
Patient reported data on SARS-CoV-2 vaccine (n=57)	
Refused, n (%)	0 (0)
Undecided, n (%)	2 (3.5)
Planned, n (%)	6 (10.5)
Received, n (%)	49 (85.9)
Timing of SARS-CoV-2 vaccination post RTX, median (IQR) (n= 49)	20.14 (12.4, 25.7)
SARS-CoV-2 nucleocapsid IgG (positive) n(%) (n=7)	1 (14.2)

*The connective tissue disease group is composed of systemic lupus erythematosus, inflammatory myopathies, anti-synthetase syndrome, overlap syndromes, and mixed connective tissue disease patients.

Table 2. Factors associated with SARS-CoV-2 vaccine timing after B-cell depleting therapy with rituximab

Clinical Factor	Vaccinated less than 20 weeks post RTX (n=24)	Vaccinated 20 or more weeks post RTX (n=25)	p-value
Provider preference for universal timing of vaccination, n (%)	11 (46)	19 (76)	0.04
Indication for RTX:			
Rheumatoid arthritis, n (%)	11 (46)	12 (48)	0.41
ANCA-associated vasculitis, n (%)	3 (12)	7 (28)	
Connective tissue disease*, n (%)	9 (38)	5 (20)	
IgG4-related disease, n (%)	1 (4)	1 (4)	
History of hypogammaglobulinemia, n (%)	8 (33)	8 (35)	1.00
Concomitant steroid dosing (daily prednisone equivalent), n (%)			
Less than 10mg daily	22 (92)	23 (92)	0.24
10-20mg daily	0 (0)	2 (8)	
Greater than 20mg daily	2 (8)	0 (0)	
Concomitant DMARD*, n (%)	14 (58)	14 (56)	1.00
Cumulative RTX dose (mg) median, (IQR)	8500 (5700, 13000)	5000 (3000, 8000)	
Planned to time vaccination (y/n), n (%)	21 (95)	24 (100)	0.48

* Concomitant DMARD list includes hydroxychloroquine, methotrexate, mycophenolate, leflunomide, azathioprine, sulfasalazine, intravenous immunoglobulin, one patient on omalizumab, and another on nintedanib and tacrolimus.

Background/Purpose: Experience with rituximab (RTX) in autoimmune rheumatic disease (AIRD) has shown a clear association with hypogammaglobulinemia, serious infections, and impaired humoral response to certain vaccines. The 2019 EULAR recommendations provide guidance to time future vaccines at least 24 weeks post-RTX and 4 weeks before the next course. We sought to educate faculty on the rationale for timing SARS-CoV-2 vaccines in AIRD patients on RTX and to assess timing of vaccination in clinical practice.

Methods: We performed a medical records review of AIRD patients treated with RTX from January 2020 through to February 2021 at our institution and conducted a quality improvement study to optimize vaccine timing for patients with AIRD on RTX. We first educated providers on the rationale for timing SARS-CoV-2 vaccines 24 weeks post RTX

Table 3. Patient reported side effects after SARS-CoV-2 vaccination

Reported symptom , n (%)	n=82*
Pain at injection site	43 (52.4)
Fatigue	33 (40.2)
Chills	13 (15.8)
Headache	13 (15.8)
Myalgias	10 (12.2)
Subjective fever	6 (7.3)
Arthralgias	6 (7.3)
Nausea	3 (3.6)
Swelling at injection site	2 (2.4)
Rash at injection site	2 (2.4)
Fever (documented >100.4° F)	2 (2.4)
Other (Suicidal ideations)	1 (1.2)
Lymph node swelling	0 (0)
Hives	0 (0)
Flare of Rheumatic disease	0 (0)

*If vaccine given in two shot series, symptoms were counted separately for each dose administered.

and recorded provider vaccine preference to either universally time all vaccines or to individualize the plan for each patient. We measured actual timing of vaccines through telephone survey of patients. In patients with available data, we then analyzed vaccine response in relation to vaccine timing and other clinical and immunologic parameters. This project was determined to be exempt by the institutional IRB.

Results: A total of 91 patients received RTX for AIRD during the COVID-19 pandemic. Seventy patients had plans to continue RTX at our institution in 2021. Of the 49 vaccinated patients, the median time of vaccination post RTX was 20.14 (12.4, 25.7) weeks with 14 (28.6%) patients vaccinated at least 24 weeks and 25 (51%) at least 20 weeks post RTX. Patients whose providers expressed universal intent to time vaccines were more likely to be vaccinated at least 20 weeks post-RTX than patients whose providers took an individualized approach to vaccine timing (p= 0.04). All patients who received Moderna or Pfizer vaccines received a second dose 2-7 weeks later. A higher cumulative RTX dose was associated with vaccination less than 20 weeks post-RTX (p= 0.03). Preliminary results for the 9 patients with SARS CoV2 Spike protein IgG Ab's revealed negative titers in the majority (78%) of patients despite a median time to vaccination post of 22.1 (19.7, 22.8) weeks.

Conclusion: While a majority of patients received dose 1 of the SARS-CoV2 vaccine more than 20 weeks after their last RTX infusion; most patients did not meet the primary endpoint of vaccination 24 weeks post-RTX despite a physician-directed educational program advocating for this. Patients of providers who indicated a preference to universally delay vaccination were more likely to receive their first vaccine dose at least 20 weeks post-RTX. Preliminary results are concerning for a low rate of SARS-CoV2 spike IgG Ab development in patients despite optimal vaccine timing and low steroid doses. These findings are of particular concern given emerging signals that RTX may be associated with particularly severe COVID-19 infections and warrant further study.

Abstract Number: 0650

Use, Procurement Cost, and Adverse Events from IVIg Use in Rheumatic Disease

Francisca Lambert-Fliszar[1], Evelyne Vinet[2], Sasha Bernatsky[1] and Arielle Mendel[3], [1]McGill University, Montréal, QC, Canada, [2]McGill University Health Centre, Mont Royal, QC, Canada, [3]McGill University Health Centre, Montréal, QC, Canada

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Measures & Measurement of Healthcare Quality Poster (0623–0659)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Intravenous immunoglobulin (IVIg) is used in several systemic rheumatic diseases due to postulated immunomodulatory properties. However, IVIg is a scarce and costly resource and poses a risk of adverse events (AEs). We evaluated the safety, effectiveness, and procurement cost of IVIg in an ambulatory rheumatic disease sample.

Methods: Using our centre's blood bank records, we identified consecutive tertiary clinic patients receiving IVIg for rheumatic disease between January 2015 and September 2020. We performed retrospective chart reviews of all clinical encounters, from IVIg initiation until 3 months following the last infusion. We evaluated demographic and disease

Table 1. Characteristics of patients with and without a potential IVIg-related adverse event

	No IVIg-related AE (n=15)	At least one IVIg-related AE (n=7)
Age, mean (SD)	51.9 (15.9)	56.5 (10.8)
Sex female n (%)	12 (80)	4 (57)
IVIg duration (months) mean (SD)	9.3 (9.6)	4.9 (2.8)
Diagnosis n (%)		
Inflammatory myositis	12 (80)	6 (86)
SLE	2 (13)	1 (14)
Sjogren's	1 (7)	-
Cutaneous vasculitis	-	-
Indication n (%)		
Myositis	12 (80)	6 (86)
Chillblains	1 (7)	-
Lupus nephritis	1 (7)	-
Interstitial nephritis and pancytopenia	1 (7)	-
Cutaneous vasculitis	-	1 (7)
Concurrent prednisone n (%)	12 (80)	5 (71)
Concurrent immuno-suppressants n (%)	10 (67)	5 (71)
Recommended dose* n (%) * <= 10 g above target dose	9/12 (75)	2/3 (67)

characteristics and clinical effectiveness of IVIg, based on the treating clinicians' assessments 3 months after IVIg initiation and 3 months after cessation. Potential AEs and their severity documented in clinical encounter notes were adjudicated by two independent physicians using pre-established rating scales. An AE was classified as related to IVIg if there was >50% confidence of an IVIg-related adverse event. Finally, we determined if appropriate (ideal body weight-based) dosing was used and estimated the yearly procurement costs (CAN$).

Results: Of 25 patients receiving IVIg for rheumatic disease over the study period, 22 had sufficient clinical records to be included. Mean age was 53 years (range 19-74) and 16 (72%) were women. The treatment indication in 18 patients (82%) was inflammatory myositis (i.e., dermatomyositis, antisynthetase syndrome, overlap and necrotizing myositis); the remaining indications were SLE (n=2), Sjogren's syndrome (n=1), and cutaneous vasculitis (n=1). Patients had a mean of 15 infusions (SD 14) spanning 1271 total hours.

Of 21 patients with at least 3 months of follow-up after IVIg initiation, 18 (86%) showed clinical improvement. Of these 18 'responders', 14 had clinical follow-up at 3 months following cessation of therapy and of these, 10 (71%) had stable or quiescent disease while 4 (29%) had relapsed.

We identified 11 potential AEs in 7 patients, representing 3.2 events per 100 IVIg infusions (95% CI 1.8-5.8). AEs included headache (6), urticaria (3, one with angioedema), chills with back pain (1), and hypertension (1); none of these required an emergency room visit or hospitalization. One patient was switched from IV to subcutaneous Ig. The appropriate IVIg dose could be calculated for 15 patients (height not recorded in the remainder). We found that 7 (47%) received > 100 g excess IVIg over their treatment period and the total cumulative excess was 1242g. The cost of IVIg ranged from 61-90$/g, giving a total estimated procurement cost of $1.48 million during the study period.

Conclusion: The majority of our rheumatic disease patients received IVIg for inflammatory myositis. Most patients (86%) improved 3 months into therapy and a significant proportion of those (29%) relapsed after stopping therapy. Nearly 1 in 3 patients had a potential IVIg-related AE. A treatment course cost up to 254,964$, and one potential area of improvement is using recommended ideal body weight-based dosing.

Abstract Number: 0651

Diagnostic Approach to Identifying Small Fiber Neuropathy in Patients with Sarcoidosis

Bassel Bou Dargham[1], Nima Madanchi[2], Kelsey Satkowiak[1], Huzaefah Syed[1] and Kelly Gwathmey[3], [1]Virginia Commonwealth University Medical Center, RICHMOND, VA, [2]Virginia CommonHealth University Medical Center, Richmond, VA, [3]Virginia Commonwealth University Health system, Richmond, VA

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Measures & Measurement of Healthcare Quality Poster (0623–0659)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Sarcoidosis is a multisystem granulomatous disease that can affect the nervous system in about 5% of patients. Sarcoidosis associated small fiber neuropathy (SSFN) presents with neuropathic pain, numbness, and dysautonomia resulting from damage to thinly myelinated Aδ and unmyelinated C fibers. Recent studies, using variable screening instruments, have found that the prevalence of SSFN may in fact be as high as 32.8% -81%. This variability is due to the lack of gold standard diagnostic criteria. This study explores the diagnostic approach to peripheral neuropathy in sarcoidosis patients at VCU Health Systems (VCUHS).

Methods: We searched for patients that were coded for both sarcoidosis (at least 2 visits coded with ICD-10: D86) and polyneuropathy (ICD-10 codes: G62.9, G63, G62.89) at VCUHS . In total, 211 unique medical record numbers were generated. We retrospectively reviewed clinical notes, electromyography (EMG), skin biopsies, and labs of all 211 patients in Cerner electronic health records.

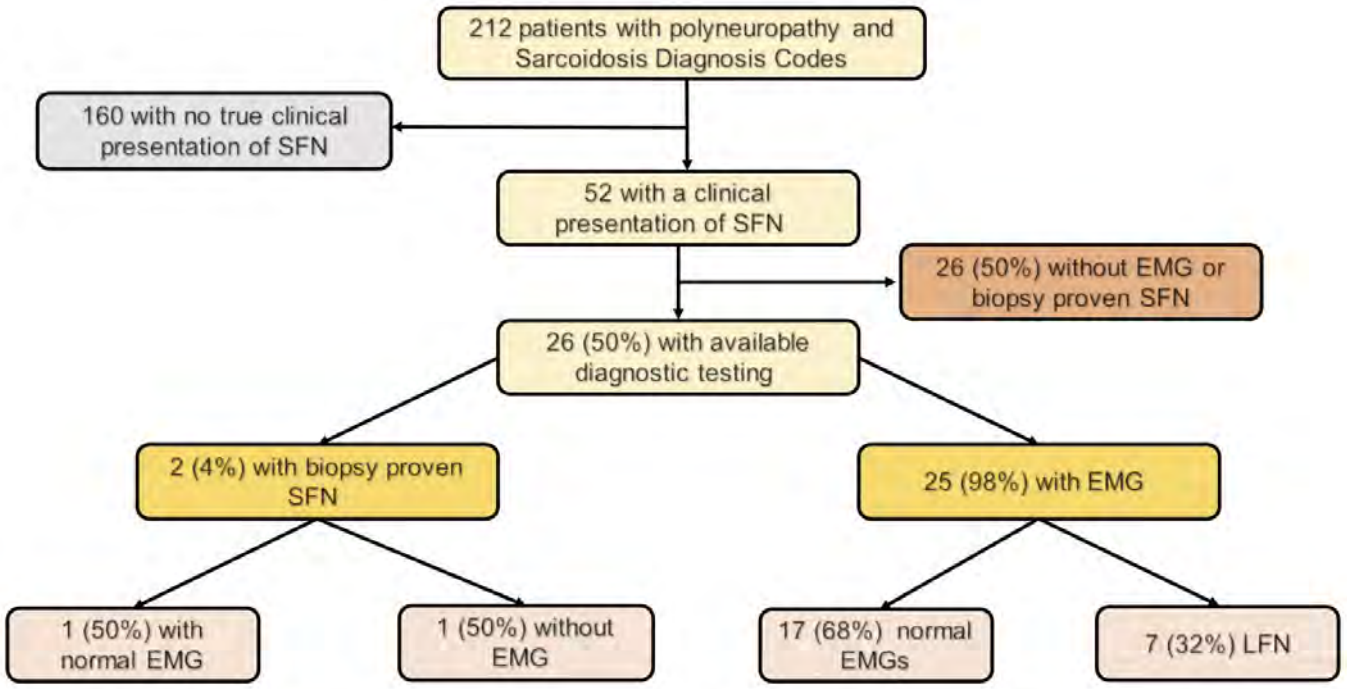

Figure 1. Flow chart of patient selection and methods used in diagnosing SSFN in patients with sarcoidosis. (SFN: small fiber neuropathy; EMG: electromyography; LFN: large fiber neuropathy).

Results: 52 patients had a clinical presentation of peripheral neuropathy upon further review. 69% were female, and 62% were African American. 35% had concomitant diabetes mellitus and 6% had vitamin B12 deficiency. There was no systematic diagnostic approach for any of the patients. 50% of patients had no studies (skin biopsy proven SFN or EMG). 96% of patients with available diagnostic testing had an EMG of which 68% were normal. The rest were consistent with large fiber neuropathy. 4% had skin biopsy proven SFN, half of which had an EMG which was normal. (Figure 1)

Conclusion: The majority of patients with small fiber neuropathy were diagnosed by their clinical presentation, without specific diagnostic criteria. Patients with SFN normally present with a normal EMG, however one patient with an abnormal EMG had a skin biopsy proven SFN, further emphasizing the need for more standardized diagnostic criteria. A SFN screening list has been previously validated in diagnosis of SSFN3, however it hasn't been correlated with other studies like skin biopsies. Given the debilitating effects of SSFN on physical functioning and ultimately the quality of life of patients with sarcoidosis, it is important to utilize a more standardized diagnostic approach to identify and manage these patients.

Abstract Number: 0652

Application of a GCA Probability Score to Patients Referred to a GCA Fast Track Clinic

Mmoloki Mathake[1], Julia Murdoch[2], Andrew Taylor[3], Jean-Louis deSousa[2], Kathy Jao[2], Rachel Li[2] and Helen Keen[4], [1]Fiona Stanley Hospital, Beckenham, Australia, [2]Royal Perth Hospital, Perth, Australia, [3]Fiona Stanley Hospital, Murdoch, Australia, [4]Fiona Stanley Hospital, Perth, Australia

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Measures & Measurement of Healthcare Quality Poster (0623–0659)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Giant cell arteritis (GCA) is the most common large vessel vasculitis, and may be associated with irreversible blindness(1). It is therefore essential to make an early and secure diagnosis. However, GCA often presents a diagnostic challenge; whilst biopsy has been considered the gold standard, in recent years, imaging (ultrasound, MR angiography, CT angiography and PET) has also been validated in GCA. Pre-test probability of disease remains a critical component of GCA assessment and clinical decision making. Recently, the Southend pre-test probability score (PTPS) has been developed to aid GCA assessment (2,3).

We aimed to retrospectively apply the PTPS to patients seen through our GCA Fast Track Clinic (FTC) to assess the utility of this score.

Methods: Patients presenting to the Royal Perth Hospital GCA FTC were consented for prospective data collection. A clinical diagnosis of GCA was based on history, examination, temporal artery ultrasound, and temporal artery biopsy or additional imaging in select cases. We retrospectively calculated the PTPS from data collected between November 2019 and May 2021. We risk stratified patients into low-risk (PTPS < 9), intermediate risk (PTPS 9-12), and high risk (PTPS > 12) groups, and correlated these with the final clinical diagnosis. We then dichotomised the PTPS

into (1) low risk or (2) intermediate/high risk groups, to determine the sensitivity, specificity, positive predictive value and negative predictive value.

Results: Of 104 patients, 25 (24%) received the clinical diagnosis of GCA. Using the PTPS, 45 (43%) of the 104 patients were classified low risk, 34 (32%) intermediate and 25 (24%) high risk for GCA. In the low risk category, GCA prevalence was 0%, in the intermediate group GCA prevalence was 15%, and in the high risk category the prevalence was 80% ($p< 0.001$).

The Southend PTPS (dichotomised) had a sensitivity of 100%, Specificity 56.9%, positive predictive value of 42.3% and negative predictive value of 100%.

Conclusion: The PTPS (applied retrospectively) successfully stratifies patients referred to our fast track clinic into high and low risk for GCA, when using the clinical diagnosis as the gold standard. This tool may have a role in screening referrals to the GCA FTC; the negative predictive value suggests this tool is valuable to exclude GCA.

Abstract Number: 0653

Adherence to the 2015 ACR Guidelines for the Management of Polymyalgia Rheumatica and Screening for Osteoporosis at a Tertiary Care Medical Center

Padmini Parameswaran[1] and Michael Lucke[2], [1]Allegheny Health Network Medical Education Consortium, Pittsburgh, PA, [2]Allegheny Health Network, Pittsburgh, PA

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Measures & Measurement of Healthcare Quality Poster (0623–0659)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Since the first description of polymyalgia rheumatica (PMR) in the early 1950s, the ideal dose and duration of glucocorticoid therapy has varied. In 2015, the American College of Rheumatology (ACR) released guidelines for the management of PMR, and included recommendations on the starting dose of prednisone between 12.5-25mg/day, and suggested tapering strategies to achieve 10mg prednisone/day within 4-8 weeks. In order to evaluate the real world application of these guidelines, we conducted a retrospective analysis of patients diagnosed with PMR and managed by rheumatologists at a single clinic at a tertiary academic center. We further evaluated the

Table 1. Demographics and Lab Data

Table 1: Demographics and Lab Data	
Race, n (%)	39 (95%) Caucasian 2 (4%) African American 1 (2%) Asian
Gender, n (%)	25 (60%) Female 16 (40%) Male
Age (median), [Range], years	67, 52-85
ESR (median) mm/hour	43
CRP (median) mg/dL	2.8

screening characteristics for osteoporosis in this population with long term steroid use with a focus on quality improvement.

Methods: Diagnosis codes for PMR were queried for a single rheumatology clinic comprising four physicians and three advanced practice providers. Patients were included if they had an initial diagnosis between January 2015 and June 2020, and had at least four encounters for this diagnosis with a rheumatologist. A retrospective chart review was performed by a single reviewing physician; cases were excluded if they lacked initial laboratory testing for ESR or CRP or had presence of an additional inflammatory rheumatic disease including giant cell arteritis at the time of PMR diagnosis. By consecutive chart review, data was collected on age, race, and sex, ESR and/or CRP. DXA scan performance or physician documentation of known osteoporosis was recorded. Initial prednisone dose, time to taper to 10mg, and total duration of prednisone dose until observation period closed in June 2020 were recorded. Those patients still on prednisone at the end of the study were excluded from analysis for total duration of prednisone used.

Results: Of the 74 screened patients, 41 patients were enrolled in the cohort for analysis. The cohort consisted of 95% Caucasians, 4% African Americans and 2% Asians; 60% of the enrollees were women (*Table 1)*. The age ranged from 52 to 85 years at the time of diagnosis, with a median of 67 years old. The average starting dose for prednisone was 18mg, within the recommended dose range by the ACR. Only 60% of patients had prednisone tapered to 10mg by week 8. By the end of the observation period, 82% of patients had discontinued glucocorticoids. Of these 34 patients, 41% completed treatment within 7-12 months, 32% within 13-24 months, 17% within 25-36 months and

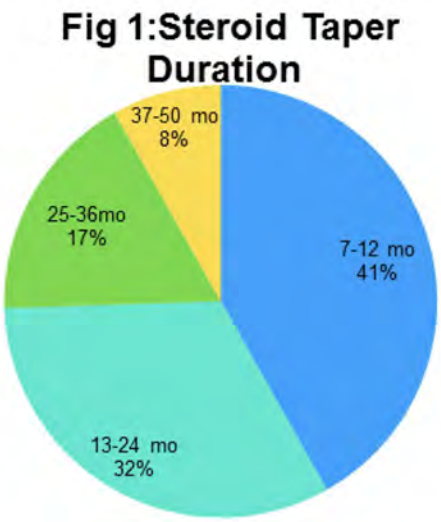

Figure 1. Duration of prednisone taper.

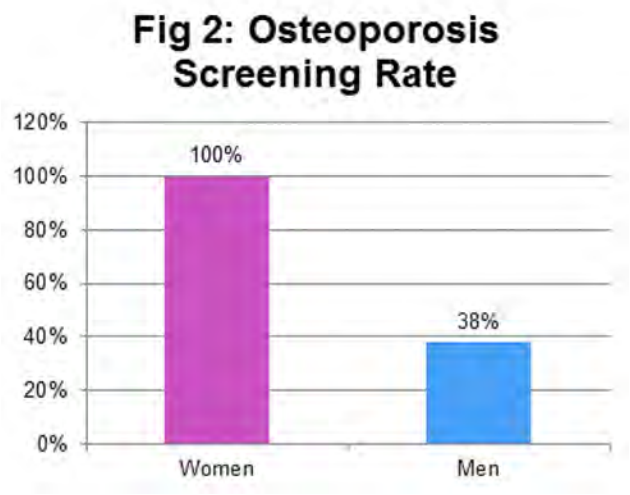

Figure 2. Osteoporosis Screening Rate.

8% between 37-50 months (*Fig 1)*. Osteoporosis screening was completed in 100% of women but only 38% of men despite the use of prednisone in most cases for longer than two years (*Fig 2*).

Conclusion: All rheumatology clinicians initiated prednisone treatment within ACR recommended dosing however goal taper prednisone dose of 10mg by 8 weeks was met by only 60% of patients. Male patients had markedly less DXA screening completed, suggesting that this population may be amenable to further quality improvement initiatives to limit steroid toxicity.

Assessing Provider Knowledge and Opinions of the 2017 Guidelines for Perioperative Management of Antirheumatic Medications in a Single Academic Center

Andrew Shaffer[1], Erica Mulcaire-Jones[2], Michael Battistone[3], Jeremy Gililland[4], Victor Carlson[4], Joshua Zimmerman[4], Kevin Lammert[4] and Dorota Lebiedz-Odrobina[4], [1]University of Utah, Sandy, UT, [2]Intermountain Healthcare, Salt Lake City, UT, [3]Salt Lake City VA, Salt Lake City, UT, [4]University of Utah, Salt Lake City, UT

SESSION INFORMATION

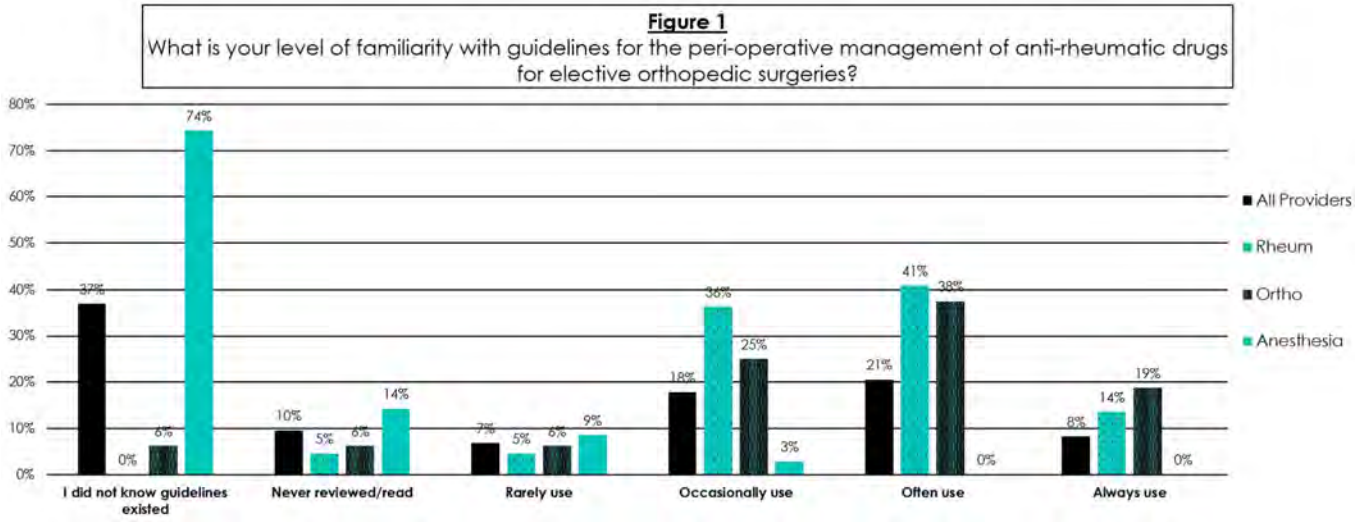
Session Date: Sunday, November 7, 2021

Session Title: Measures & Measurement of Healthcare Quality Poster (0623–0659)

Session Type: Poster Session B

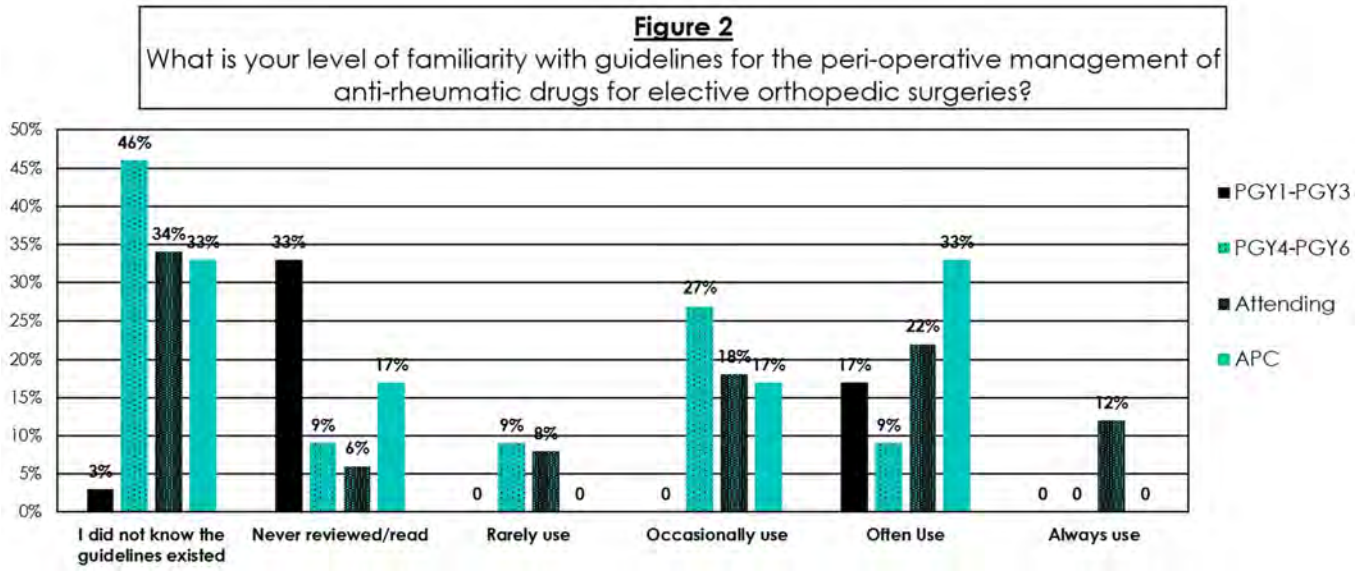
Session Time: 8:30AM–10:30AM

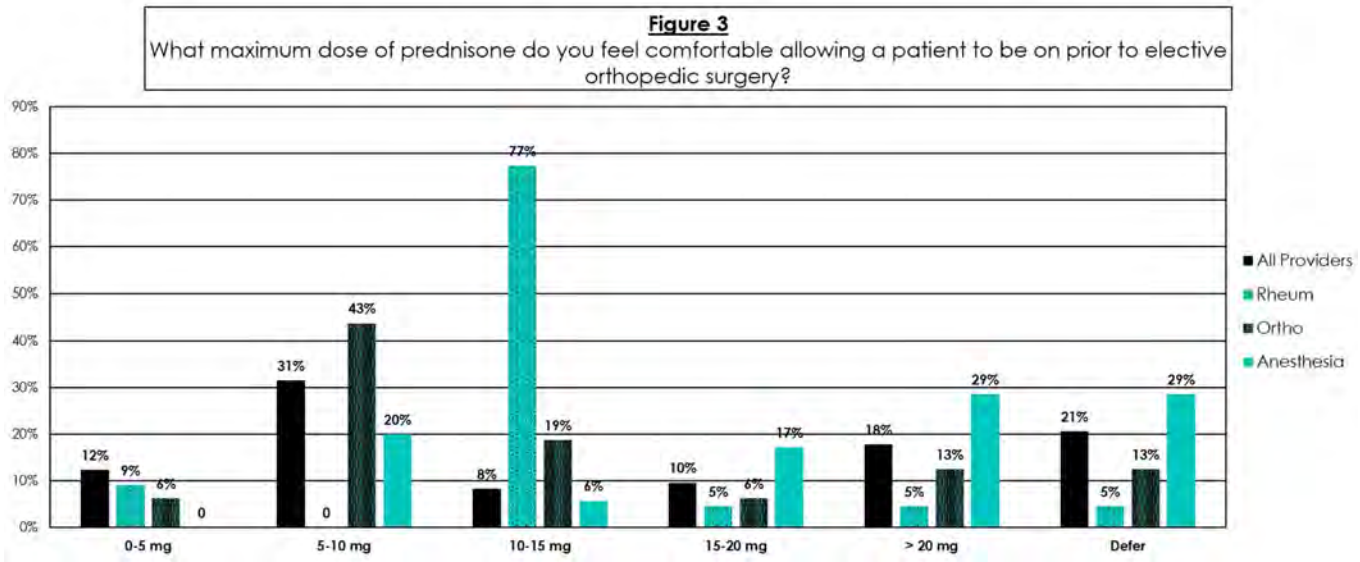
Background/Purpose: Guidelines for perioperative management of antirheumatic medications were released by the American College of Rheumatology (ACR) and American Association of Hip and Knee Surgeons (AAHKS) in 2017 (Goodman SM et al, 2017). Prior to this, no formal guidelines had been published. Their primary goal was to reduce infectious complications in the perioperative setting for elective total hip and knee replacements by guiding provider decision making. However, in order for the guidelines to standardize and improve patient care, providers must be familiar with them and take them into consideration during clinical decision making. In 2021, we surveyed a multispecialty provider cohort to determine provider knowledge and opinions of the ACR/AAHKS guidelines.



Methods: A 10-question survey was sent to all anesthesia, orthopedic surgery and rheumatology providers at a single academic center. Responses were stratified by specialty and level of training. Comparisons between groups were performed by chi-squared, Fisher's exact and Kruskal-Wallis testing.

Results: Seventy-three providers responded to the survey (22 rheumatologists, 16 orthopedic surgeons, 35 anesthesiologists). 6% of orthopedic surgeons and 74% of anesthesiologists were not aware that the guidelines existed. In contrast, all of the rheumatologists were aware that the guidelines existed. Awareness of the guidelines differed significantly between anesthesiologists and both orthopedic surgeons and rheumatologists ($p < 0.001$, figure 1). Awareness did not differ significantly by level of training (figure 2). The most common barrier to use of guidelines was lack of awareness that they existed (26% of respondents). When evaluating the understanding of the guidelines, 51% of respondents either did not correctly identify the recommended perioperative management of conventional synthetic disease modifying antirheumatic drugs (25%), or deferred the decision to another provider (26%). 18% of respondents indicated that they felt comfortable with patients on perioperative doses of prednisone ≥20mg prednisone/day, which is higher than the dose recommended by the guidelines (figure 3). 66% of respondents felt direct communica-





tion with a rheumatologist was a helpful intervention in making decisions regarding antirheumatic drug management. 63% of respondents felt rheumatologists should make the final decision on perioperative antirheumatic medications.

Conclusion: Increased awareness and understanding of the ACR/AAHKS guidelines is needed. This is particularly important for rheumatologists, who are the providers most often relied upon to make decisions related to the management of these medications. Direct communication with a rheumatologist is felt to be a preferred intervention in the decision-making process. As a next step, we plan to evaluate the adoption and impact of the guidelines on the rate of postoperative infectious complications after hip and knee arthroplasty.

Depression and Fatigue: Two Forgotten Associated Comorbidities in Patients with Rheumatoid Arthritis

Rosa Morlà[1], Beatriz Frade-Sosa[2], Núria Sapena[3], Roberto Gumucio[2], Raimon Sanmarti[2] and Jose A Gomez-Puerta[2], [1]Hospital Universitari Clinic de Barcelona, Barcelona, Spain, [2]Hospital Clínic de Barcelona, Barcelona, Spain, [3]Rheumatology Department, Hospital Clínic, Barcelona, Spain

SESSION INFORMATION

Session Date: Sunday, November 7, 2021
Session Title: Measures & Measurement of Healthcare Quality Poster (0623–0659)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Rheumatoid arthritis (RA) is frequently associated with different comorbidities. Depression and fatigue are common in RA patients with a prevalence of 17-39-%[(1)] and 40%[(2)] respectively. However, the factors that determine these comorbidities, especially their association with disease activity have been little studied.

We studied these two comorbidities: depression and fatigue in patients with RA, according to clinical activity, and the association between them.

Methods: Patients with RA (ACR/EULAR criteria, 2010) who agreed to participate in this study were included consecutively in the Rheumatology Department during a period of 3 months.

Table 2. Data from the Rho Spearman correlation analysis

	FACIT-F (0-52)	PHQ-9 (0-27)	ROS60 (0-60)	VASFatigue (1-10)	TJC (0-28)	SJC (0-28)	PATGL (0-10)	PhyGL (0-10)	CRP	ESR
FACIT-F (0-52)	1,000	r=-0,850 p<0,0001	r=0,766 p<0,001	r=-0,802 p<0,0001	r=-0,536 p<0,0001	r=-0,272 p=0,022	r=-0,517 p<0,0001	r=-0,428 p<0,0001	r=- 0,326 p=0,005	r=-0,334 p=0,004
PHQ-9 (0-27)	r=-0,850 p<0,0001	1,000	r=0,717 p<0,0001	r=0,721 p<0,0001	r=0,618 p<0,0001	r=0,392 p=0,001	r=0,616 p<0,0001	r=0,477 p<0,0001	r=0,287 p=0,018	r=0,304 p=0,012

Demographic variables (age, sex, BMI), years of disease duration, treatment, physical examination (TJC28, SJC28), patient (PATGL) and physician (PhyGL) global assessment, and laboratory tests (ESR, CRP) were collected. Patients completed 2 one-dimensional questionnaires: PHQ-9 for depression (0-27; cut-off point≥10) and FACIT-F for fatigue (0-52; lower scores indicate more fatigue) and the multidimensional health assessment questionnaire (MDHAQ) which includes a query for depression in the checklist review of 60 symptoms (ROS60) and one for fatigue measured in VAS of 0-10 (VAS_Fatigue). EULAR composite indices for clinical activity (DAS28-ESR and CRP, CDAI, SDAI) and self-reported clinical activity index with RAPID3 = function (FN) + pain (PN) + VGP were calculated.

Patients were compared in two groups according to disease activity (DAS28-ESR). Group 1: > 3.2 = moderate or high activity, and group 2: ≤3.2 = low activity or remission.

A bivariate statistical analysis was performed to compare groups (U Mann Whitney-test for quantitative variables and Chi^2-test for categorical). Finally, Spearman's Rho correlation was done.

Results: A total of 75 patients with RA were studied with a median of 14 years (IQR: 8-24) of disease duration, 84% women, with a median age of 63 (36-88) years and a BMI median of 24.22 (IQR: 22-27.4) and 64% with DMARDb treatment. 19 patients had moderate or high activity and 56 patients with low activity or remission. The clinical variables: TSC, SJC, laboratory tests (ESR, CRP) and all self-reported variables in MDHAQ (PN, FN, PTGL, self-RADAI, VAS_Fatigue, ROS60), PhyGL, FACIT-F and PHQ-9 showed significant differences between the two groups, with higher scores in patients of group 1. Also in the composite indices, as we expected (Table 1).

FACIT-F scores showed a very good negative correlation with VAS_Fatigue ($r = -0.802$; $p < 0.0001$), PHQ-9 ($r = -0.850$; $p < 0.0001$) and ROS60 ($r = -0.766$; $p < 0.0001$) and almost good with the rest of the variables (table 2). PHQ-9 scores showed high positive correlation with all the variables studied, remarkable in VAS_Fatigue ($r= 0.721$; $p < 0.001$) and in ROS60 ($r = 0.717$; $p < 0.001$) (Table 2).

Conclusion: In RA patients with a higher burden of disease (clinical, biological and self-reported) were observed high scores for fatigue and depression with a strong association to each other. These two comorbidities should be routinely studied in the follow-up of active RA patients.

A Survey Based Descriptive Study to Assess the Quality of Sleep in Rheumatic Patients

Kezia Sam[1], David Lans[2] and Fulvia Milite[1], [1]White Plains Hospital, White Plains, NY, [2]New York Medical College, Valhalla, NY, New Rochelle, NY

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Measures & Measurement of Healthcare Quality Poster (0623–0659)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Sleeping difficulties although common in rheumatic patients, have often been overlooked presuming it to be part of a chronic illness. We conducted a survey-based study comparing the quality of sleep in patients with rheumatic diseases vs. healthy individuals employing the Pittsburg Sleep Quality Index (PSQI) and analyzing other factors, especially pain that effects sleep quality. PSQI is a self-rated questionnaire which assesses the sleep quality over a 1-month time interval. A total score > 5 is indicative of poor sleep quality.

Methods: Adult patients in an outpatient setting with rheumatic conditions were handed out the survey that included PSQI questionnaire and additional questions related to other factors affecting sleep quality. The rheumatic conditions included were Rheumatoid arthritis, Osteoarthritis, Psoriatic arthritis, Fibromyalgia, Polymyalgia rheumatica (PMR), Spondyloarthritis and Systemic lupus erythematosus (SLE). Healthy subjects were also handed out the surveys. Participation was anonymous and voluntary. Data were analyzed using descriptive statistics, t-tests, ANOVA, and regression analysis.

Results: The results have been obtained from questionnaires completed by 120 patients. Among them, 60 had rheumatic diseases (83% female with mean age 64, 17% male with mean age 49) and 60 were healthy subjects (78% female with mean age 62, 22% male with mean age 54). There was a statistically significant difference in the PSQI scores of patients with rheumatic conditions vs. those without rheumatic conditions ($p=2.2 \times 10^{-16}$, 95% CI: 6.4, 8.5) (Figure 1). The mean PSQI score was highest for patients with fibromyalgia (13) and lowest for those with PMR (7) (Table 1). There was no statistically significant difference in the PSQI scores between men and women with rheumatic conditions (p=0.6058, 95% CI: -2.92, 1.76). There is no statistically significant difference in PSQI scores between

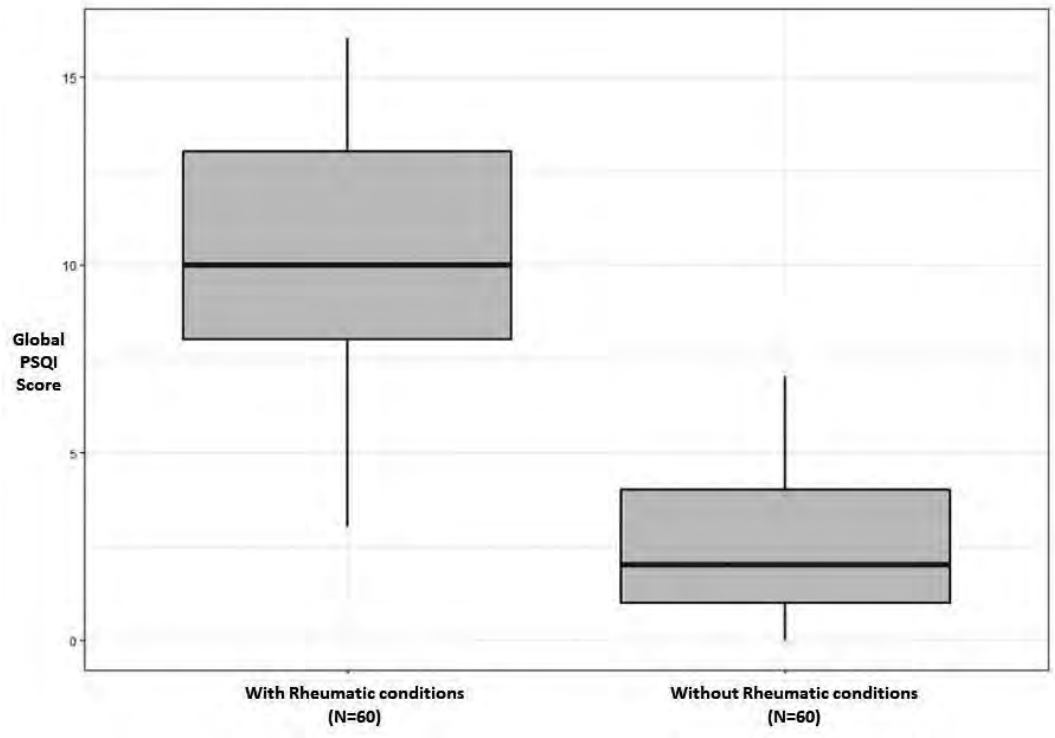

Figure 1. Box plot on PSQI scores of subjects with and without rheumatic conditions.

Table 1. Descriptive Statistics of Patients with Rheumatic Conditions and ANOVA Test Results

Rheumatic conditions	Number of Patients (N)	Mean PSQI Score	Std. Deviation of PSQI Scores
Fibromyalgia	7	12.86	2.73
SLE	3	11.67	2.52
Osteoarthritis	13	10.31	3.17
Polymyalgia Rheumatica	4	7.00	3.16
Psoriatic Arthritis	3	11.33	2.89
Rheumatoid Arthritis	27	9.11	3.46
Spondyloarthritis	3	11.33	6.35
Total	**60**	**10.02**	**3.57**

ANOVA Test Results

	Sum of Squares	df	Mean Square	F	Sig.
Between Groups	134.69	6	22.45	1.93	0.09
Within Groups	616.29	53	11.63		
Total	750.98	59			

patient groups with different rheumatic conditions, at 95% confidence interval (p value= 0.09) (Table 1 ANOVA Test Results). Based on regression analysis, the study confirmed that there is a linear relationship between PSQI Score and Pain Scale (Figure 2).

In addition to the PSQI questionnaire, questions on other factors contributing to poor sleep quality were included in the survey. 80% of the patients with rheumatic conditions were compliant with their medications. 25% of the subjects with rheumatic conditions received sleep education and 20% received sleep study referrals. Only 7% had the diagnosis of insomnia and 13% had the diagnosis of sleep apnea.

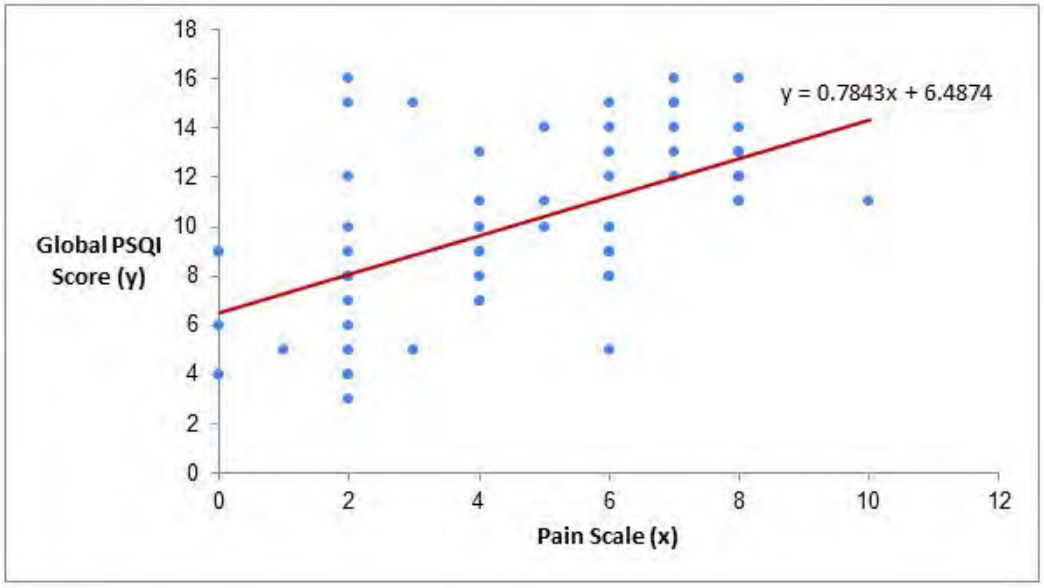

Figure 2. Regression Analysis of Global PSQI Score to Pain Scale for Patients with Rheumatic Conditions.

Conclusion: Poor sleep quality is often dismissed in patients with rheumatic diseases and often not taken into consideration as part of the management of patient care. Patients with rheumatic conditions have statistically significant poor sleep quality compared to those without rheumatic conditions. It is important to recognize those patients complaining of poor sleep and direct them to appropriate management keeping in mind that the better the quality of sleep, the higher the threshold for pain.

Assessing Patient Transition Outcomes from a Large Pediatric Rheumatology Center to Adult Healthcare

Mary Robichaux[1], Bernard Danna[2], Monique Maher[2], David McDonald[1], Kristiana Nasto[1], Alexander Alexander[1], Ariel Coleman[3], Danielle Guffey[1] and Tiphanie Vogel[1], [1]Baylor College of Medicine, Houston, TX, [2]Baylor College of Medicine, Texas Children's Hospital, Houston, TX, [3]Texas Children's Hospital, Houston, TX

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Measures & Measurement of Healthcare Quality Poster (0623–0659)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Transitioning children with chronic diseases from pediatric to adult healthcare can be a challenging task, with high morbidity and mortality. In response, we have developed a transition pathway called the Baylor Rheumatology Initiative: Developing and Guiding Engagement (BRIDGE). Through the BRIDGE, patients are introduced to a clinic-specific transition policy, and providers are incentivized to discuss transition planning beginning in early adolescence, with the goal of effective transition to an adult provider. The Transition Planning Tool (TPT) is an electronic medical record-based flowsheet; TPT use is encouraged at clinic visits for patients aged 14-19. Our objective was to assess baseline transition outcomes for a legacy group of transitioned patients and to assess the correlation between TPT utilization and the rate of successful transition.

Methods: Twenty-seven patients who transitioned during the establishment of the BRIDGE pathway were followed for 1 year post-transition to assess the characteristics of their transition. TPT data was reviewed retrospectively for each patient, examining extent of TPT use and completion of TPT elements. We rigorously defined the primary outcome of successful transition as meeting all 3 of the following criteria: 1) first adult rheumatology appointment within 3 months from last pediatric visit; 2) prescriptions refilled from the adult provider within 3 months from transition; and 3) no rheumatology-related emergency (ER) visits or hospital admissions within 1 year of transition. Comparisons were made using Wilcoxon rank sum, Chi-square, and Fisher's exact tests.

Results: The majority of transitioned patients were female (78%) and privately insured (67%). The most common diagnosis was SLE (33%). Forty-four percent of patients met all goals for successful transition; 67% attended an adult appointment within 3 months (81% did within 4 months), 59% refilled medications within 3 months, and 85% avoided a rheumatology-related admission or ER visit within 1 year. There was no statistical significance between successfully transitioned patients and those who were not in number of times the TPT was accessed, number of unique TPT questions successfully answered, age, sex, diagnosis, insurance type, or disease severity. However, unadjusted logistic regression indicated that completion of some TPT questions, specifically #8 regarding alcohol/non-prescription drug use and #13 knowing who the adult provider will be, was associated with a higher probability of successful transition.

Conclusion: Although there is no significant link between TPT use and successful transition in this legacy cohort, there are some positive signals. For our next step, we will compare these outcomes to those of patients who have been in our formalized BRIDGE program for 1 year or longer before transition. Additionally, over the next quality improvement cycle, we hope to achieve successful transition metrics for 75% of our patients.

ACCORD: A Novel Rheumatology Transition Clinic Structure for Adolescent and Young Adult Patients with Childhood Onset Rheumatic Disease

Rebecca Overbury[1], Kelly Huynh[2], Tracy Frech[1], John Bohnsack[1] and Aimee Hersh[1], [1]University of Utah, Salt Lake City, UT, [2]Intermountain Health Care, Salt Lake City, UT

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Measures & Measurement of Healthcare Quality Poster (0623–0659)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: The transition of health care from Pediatric to Adult providers for adolescents and young adults with childhood onset rheumatic disease continues to be associated with poor outcomes. In 2018, we initiated a novel transition clinic structure (ACCORD), integrating an Internal Medicine - Pediatrics trained Adult Rheumatologist in a Pediatric Rheumatology clinic to guide this transition. Our goal is to improve transition outcomes in childhood onset rheumatic disease. We report the preliminary outcomes of this intervention.

Methods: In the ACCORD clinic, the Adult Rheumatologist assumed medical management and guided the patient and their family through a transition curriculum. If they consented to do so, patients and their families were enrolled in a prospective observational outcomes research registry. Initial data from this transition clinic is reported. Descriptive statistics are employed.

Results: From November 2018 – December 2020, the ACCORD transition clinic Adult Rheumatologist saw 177 patients and enrolled 57 patients in the registry. From this registry, all patients reviewed the Transition Policy with the Adult Rheumatologist; 45 (78.9%) completed at least one Transition Readiness Assessment; 12 (21.1%) twice completed the Transition Readiness Assessment. 22 (38.6%) transitioned to an Adult Rheumatologist; 17 (29.8%) continued care post-transition with the ACCORD Adult Rheumatologist outside of the transition clinic. The median time between a last ACCORD clinic visit and a first Adult Rheumatology visit was 5.1 months (SD = 5.0, range 1.6 – 8.7). No transitioned patients enrolled in the Registry have failed to schedule with and be seen by an Adult Rheumatologist. There was no statistical significant difference in no-show rates between the ACCORD clinic and the general Pediatric Rheumatology clinic; both for patients of all ages, or for those limited to ≥ 16 years of age.

Conclusion: Our experience demonstrates the feasibility of our clinic model. Our registry shows transition rates of 100.0% and a median transition interval of 5.1 months. This is an improvement over transition rates reported elsewhere that did not implement our model. No-show rates in the ACCORD clinic are not different from our general Pediatric Rheumatology clinic. We believe this structure could be applied to other primary care and subspecialty clinics.

Understanding the Rheumatologic Population We Serve Through Objective Analysis of Referrals and Diagnoses: Does Perception Match Actual Data?

Kirsten Koons[1], Jonida Cote[2], Sanjeev Shrestha[3], Melissa Band[3], David Pugliese[4] and Eric Newman[3], [1]Geisinger Medical Center, Lewisburg, PA, [2]Geisinger Medical Center, Orefield, PA, [3]Geisinger Medical Center, Danville, PA, [4]Geisinger Medical Center, Wilkes Barre, PA

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Measures & Measurement of Healthcare Quality Poster (0623–0659)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Healthcare access in our Rheumatology Department is challenging. Fibromyalgia is perceived to occupy a large portion of clinic visits, leading to increased wait times for our rheumatic patients. We seek to understand our patient population and compare rheumatologist perception of wait times, types of disease referrals, and diagnoses to actual data.

Methods: Data on new clinic referrals between 1/1/19 - 6/30/19 were obtained via manual chart review in EHR. Table 1 lists definitions of rheumatic vs non-rheumatic diagnoses used to categorize disease. Rheumatologist perception of access to care and visit types seen was assessed via an 11-question survey (Table 2). Question 1 analyzed median wait time from date referred to seen while question 11 analyzed median visits per year of fibromyalgia patients. Their statistical analysis was calculated via Sign-test. Questions 2-10 analyzed types of conditions referred and diagnosed, referral accuracy, and fibromyalgia patients seen for a single visit. Statistical analysis was calculated using the mean via 1-proportion Z-test. A sub-analysis comparing actual diagnosis of self- vs physician-referrals was measured via Chi-Square test.

Results: There were 2,327 patient charts reviewed in EPIC. 94% of rheumatologists participated in the survey. Table 2 summarizes the results for questions 1-11. Median wait time from referral to clinic visit was 42 days. Discordance existed between physician perception and actual data for the percentage of patients referred and diagnosed with rheumatic disease, fibromyalgia and other disease. Physicians hypothesized that 47.5% of referrals are for rheumatic disease, 32.8% for fibromyalgia, and 24.4% for other disease compared to actual data of 62%, 7.8%, and 30.4%, respectively. They also hypothesized that 40% of patients are diagnosed with rheumatic disease, 38.4% with fibro-

Table 1. Our Definitions of Rheumatic versus Non-Rheumatic Diseases

Non-Rheumatic Diseases		Rheumatic Diseases (per ACR criteria)
Fibromyalgia/ Chronic Pain	Other	
1. Fibromyalgia 2. Myalgia 3. Chronic pain syndrome 4. Chronic non-inflammatory back pain	1. Osteoarthritis 2. Arthralgia/Arthritis/Joint pain (not clearly inflammatory) 3. Soft tissue disease (Tendinitis, Bursitis, Trigger finger, etc.) 4. Heritable diseases (Marfan's, EDS, Hypermobility, etc.) 5. Primary Raynaud's without underlying systemic CTD	1. Connective tissue diseases 2. Inflammatory arthritis (RA, undifferentiated, etc.) 3. Other inflammatory arthritis (infectious, paraneoplastic, drug-induced, etc.) 4. Inflammatory spondyloarthropathy 5. Inflammatory myopathies 6. Vasculitis (small, medium, large vessel) 7. Osteoporosis and other metabolic bone diseases (ex. Paget's, thyroid induced etc.)

myalgia, and 25.6% with other disease compared to 45.2%, 12.2%, and 45.9% of the actual diagnoses, respectively. Concordance existed for patients referred for non-rheumatic disease (13.5%), ultimately diagnosed with rheumatic disease (14.4%). Discordance existed between patients referred for rheumatic disease (51%), ultimately diagnosed with non-rheumatic disease (36%). 70% of fibromyalgia patients were seen for a single visit, concordant with physician perception. Fibromyalgia patients were seen less frequently per year than hypothesized (1 time vs 2). No association existed between type of referral (self vs physician) and ultimate diagnosis.

Conclusion: Timely rheumatologic care is essential to achieve the best outcomes and prevent disability. In order to achieve optimal patient access, we must first understand objective data on rheumatology referrals and diagnoses. Rheumatologist perception of high-volume fibromyalgia/chronic pain referrals was not reflective of the reality of visits in our clinic. Significantly less fibromyalgia/chronic pain was referred and ultimately diagnosed than hypothesized. Significantly more non-inflammatory disease, particularly osteoarthritis, was diagnosed than expected. This study helped us better understand the population we serve so we can more effectively redesign care to improve access and quality.

Table 2. Perception vs Observed Visit Types, Referrals, Diagnoses, and Wait times in Rheumatology Clinic

Question Number	Question	Physician Perception (Hypothesized)*	Observed Patient Data	P-value
Q1	Median wait time (days) from date referral placed to date seen in office	42	42 (IQR 13, 86)	0.7393
Q2	% Referred for Rheumatic disease	47.5%	62.0%	< 0.0001
Q3	% Referred for Fibromyalgia	32.8%	7.8%	< 0.0001
Q4	% Referred for Other Disease	24.4%	30.4%	< 0.0001
Q5	% Diagnosed with Rheumatic disease	40.0%	45.2%	< 0.0001
Q6	% Diagnosed with Fibromyalgia	38.4%	12.2%	< 0.0001
Q7	% Diagnosed with Other Disease	25.6%	45.9%	< 0.0001
Q8	% Referred for Non-Rheumatic disease but diagnosed with Rheumatic disease	13.5%	14.4%	0.3689
Q9	% Referred for Rheumatic disease but diagnosed with Non-Rheumatic disease	51.0%	36.0%	< 0.0001
Q10	% Fibromyalgia diagnoses alone seen for a single consult visit	67.7%	70.1%	0.4289
Q11	How many times per year are return patients with Fibromyalgia diagnosis alone seen	2	1 (IQR 1, 2)	< 0.0001

*Q2-Q10, physician perception hypothesized percentage is the mean of rheumatology physician perception estimates from the survey. Comparison analysis to observed data completed via 1-Proportion Z-Test. *Q1, Q11, physician perception hypothesized is the median of rheumatology physician perception estimates from the survey. Comparison analysis to observed data completed via Sign-Test.

Improving the Gout Flare Chart Review Using Linked Claims-EHR Data

Kazuki Yoshida, Tianrun Cai, Lily G. Bessette, Erin Kim, Su Been Lee, Luke E. Zabotka, Alec Sun, Jun Liu, DH Solomon, Katherine Liao and Seoyoung Kim, Brigham and Women's Hospital, Boston, MA

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Metabolic & Crystal Arthropathies – Basic & Clinical Science Poster I (0660–0682)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Recurrent gout flares are the most crucial outcome in studies of gout treatment. However, gout flares is challenging to identify in a large population because it is episodic with limited data to distinguish encounters for a gout flare vs routine follow-up for gout. The objective of this study was to determine whether integrating information extracted from the narrative notes from the electronic health record (EHR) data using natural language processing (NLP) can improve the efficiency for identifying gout glares over claims data alone.

Methods: The study population was defined by first linking Medicare claims data (2007-16) with EHR data from two tertiary care centers. Subjects with age≥65, ≥1 gout ICD9/10 code, and initiated the urate-lowering therapy (ULT; allopurinol or febuxostat) were included in the study. Chart reviews were performed on a random sample of the study population to create a gold standard set of notes describing gout flare. A list of terms related to gout flare was created informed by the chart review (**Table 1**). Terms were further mapped to concepts as defined by the Unified Medical Language System (UMLS). Narrative notes for all subjects were processed using NLP to identify all notes

Table 1. Key terms used to create the list of natural language processing (NLP) terms for identifying gout flare.

Domains	Terms

*These final terms were mapped to concepts as defined in the Unified Medical Language System (UMLS).

Table 2. Natural language processing (NLP) concepts ranked by largest difference in prevalence among months containing notes with describing gout flare compared to those without.

Rank	Concept ID	Name	Prevalence in month *without* gout flare mentioned	Prevalence in month *with* gout flare mentioned	Odds Ratio
1	C0332575	Redness	4.26%	42.86%	16.87 [3.40, 83.73]
2	C0149896	Primary Gout	4.26%	39.29%	14.56 [2.92, 72.58]
3	C0234233	Sore To Touch	4.26%	39.29%	14.56 [2.92, 72.58]
4	C0278140	Severe Pain	2.13%	17.86%	10.00 [1.10, 90.66]
5	C0041834	Erythema	6.38%	35.71%	8.15 [2.00, 33.09]
6	C0013604	Edema	19.15%	64.29%	7.60 [2.63, 21.96]
7	C0000737	Abdominal Pain	2.13%	10.71%	5.52 [0.55, 55.89]
8	C1517205	Flare	8.51%	28.57%	4.30 [1.16, 15.97]
9	C0268108	Chronic Gouty Arthritis	2.13%	7.14%	3.54 [0.31, 40.91]
10	C1565489	Renal Insufficiency	2.13%	7.14%	3.54 [0.31, 40.91]

Concept ID: concept unique identifier from the Unified Medical Language System (UMLS).

containing terms/concepts related to gout flare. Claims data were also used to segment notes by time period in two ways (claims time filter): (1) identify notes within the 12-month baseline before date of ULT initiation through ULT discontinuation; (2) notes occurring in months with ≥1 ICD9/10 gout code from claims within (1). We tested whether NLP and the application of temporally based claims-based rules could improve the prevalence of notes describing gout flares compared to ICD alone.

Results: A random sample of 69 patients with 10,845 notes was examined. NLP concepts representing signs and symptoms of a gout flare, e.g. redness, severe pain, differed the most among notes describing gout flares compared to those that were not (**Table 2**). After processing notes using NLP, 708 (6.5%) of 10,845 notes had concepts relevant to gout flare (**Table 3**); of the 708 notes, 24.4% described a gout flare. Applying claims time filter 1 alone to the 10,845 notes selected 2,198 (20%), of which 271 also had relevant NLP concepts. Claims time filter 2 selected 691 notes (6.4%), of which 169 also had relevant NLP concepts. Using a combination of NLP and claims time filter 2, which gave notes in months where an ICD9/10 gout code was used (nested within the 12-month baseline and during ULT use), resulted in 54% prevalence of gout flares among the selected notes.

Table 3. Reduction in the number of notes after applying NLP and claims-based time filters, and prevalence of notes with physician mentions of gout flares within the chose notes.

	Unfiltered	NLP Filter	NLP Filter + Time Filter 1	NLP Filter + Time Filter 2
N of patients	69	52	41	33
N of notes chosen	10,845	708	271*	169**
N of notes with physician mentions of gout flares	-	173 (24.4%)	121 (44.2%)	92 (54.4%)

Abbreviations: NLP filter: natural language processing filter (see **Table 1**); Time filter 1: 12-month baseline prior to drug initiation plus on-drug follow-up; Time filter 2: 12-month baseline prior to drug initiation plus on-drug follow-up AND ICD9/10 gout code (ICD9 274.00–03, 81, 82, 39, 9; ICD10 M10).

-: These were not directly checked as we avoided manually reviewing notes not passing the natural language processing (NLP) content-relevancy filter, which was designed to be very inclusive.
* 2,198 notes (66 patients) when the time filter 1 was applied in isolation.
** 691 notes (42 patients) when the time filter 2 was applied in isolation.

Conclusion: Certain NLP concepts may be useful in discriminating notes describing gout flare among a population of subjects with gout on ULT therapy. The combination of NLP as well as the use of claims data with a time component, e.g., segmented by months, can assist in selecting relevant notes describing a gout flare. Together, these provide data for the development of a gout flare phenotyping algorithm with month-level precision.

Abstract Number: 0661

Effect of Omega-three Supplementation on Serum Urate and Gout Flares in People with Gout; A Pilot Randomized Trial

Lisa Stamp[1], Rebecca Grainger[2], Chris Frampton[1], Jill Drake[1] and Catherine Hill[3], [1]University of Otago, Christchurch, Christchurch, New Zealand, [2]University of Otago, Wellington, New Zealand, [3]Queen Elizabeth Hospital, Woodville, Australia

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Metabolic & Crystal Arthropathies – Basic & Clinical Science Poster I (0660–0682)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), also known as omega-3 fats act as alternate COX substrates to arachidonic acid (AA). Their metabolism results in production of prostaglandins which are less inflammatory than those derived from AA. Thus omega-3 fatty acids can act as a "natural" anti-inflammatory drug. Regular use of anti-inflammatory doses of omega 3 fish oil may be particularly useful as a prophylaxis against gout flares during the introduction of urate lowering therapy, and acceptable to patients due to tolerability and lack of major adverse effects compared to other prophylactic medications. The aim of this study was determine the effect of omega-three supplementation with fish oil on serum urate (SU), weight and body mass index (BMI) in people with gout.

Methods: A pilot 6-month, randomized, open-label clinical trial was undertaken in people with gout with serum urate ≥6mg/dL/l. Forty participants were randomized to receive 6.2g omega-3 fish oil daily (manufactured by Melrose (Mt Waverley, Victoria, Australia)or no fish oil for 24 weeks. Blood was obtained monthly for SU and red cell EPA (20:5n-3) DHA (22:6n-3) were measured using a blood spot collection system. The primary efficacy outcome was the change in SU between baseline and week 24 (or the final visit for those who discontinued fish oil or were lost to follow-up). Secondary outcomes included (i) change in weight and BMI between baseline and week 24, (ii) mean number of flares per month between baseline and week 24, (iii) percentage of participants with flares at each month, (iv) cessation of fish oil therapy prior to week 24 due to adverse effects or intolerance and (v) change in oxypurinol, HBA1c, cholesterol, HDL, and LDL concentrations between baseline and week 24 for people on allopurinol.

Results: Five participants in the fish oil group discontinued the oil; three were unable to tolerate the taste, one commenced dabigatran and one found it inconvenient to take it. The baseline demographic and clinical features were well matched between randomized groups. There was no statistically significant difference in the mean (SEM) decrease in SU between baseline and week 24 between randomized groups: fish oil -0.021 (0.02) mmol/l vs. control -0.006 (0.02) mmol/l. There was no significant difference in change in weight or BMI between baseline and week 24 between randomized groups (Figure). There was a statistically significant correlation between red cell omega-three concentrations and the total number of flares per participant between week 12 and week 24; total omega-three r= -0.75 ($p \leq 0.001$),

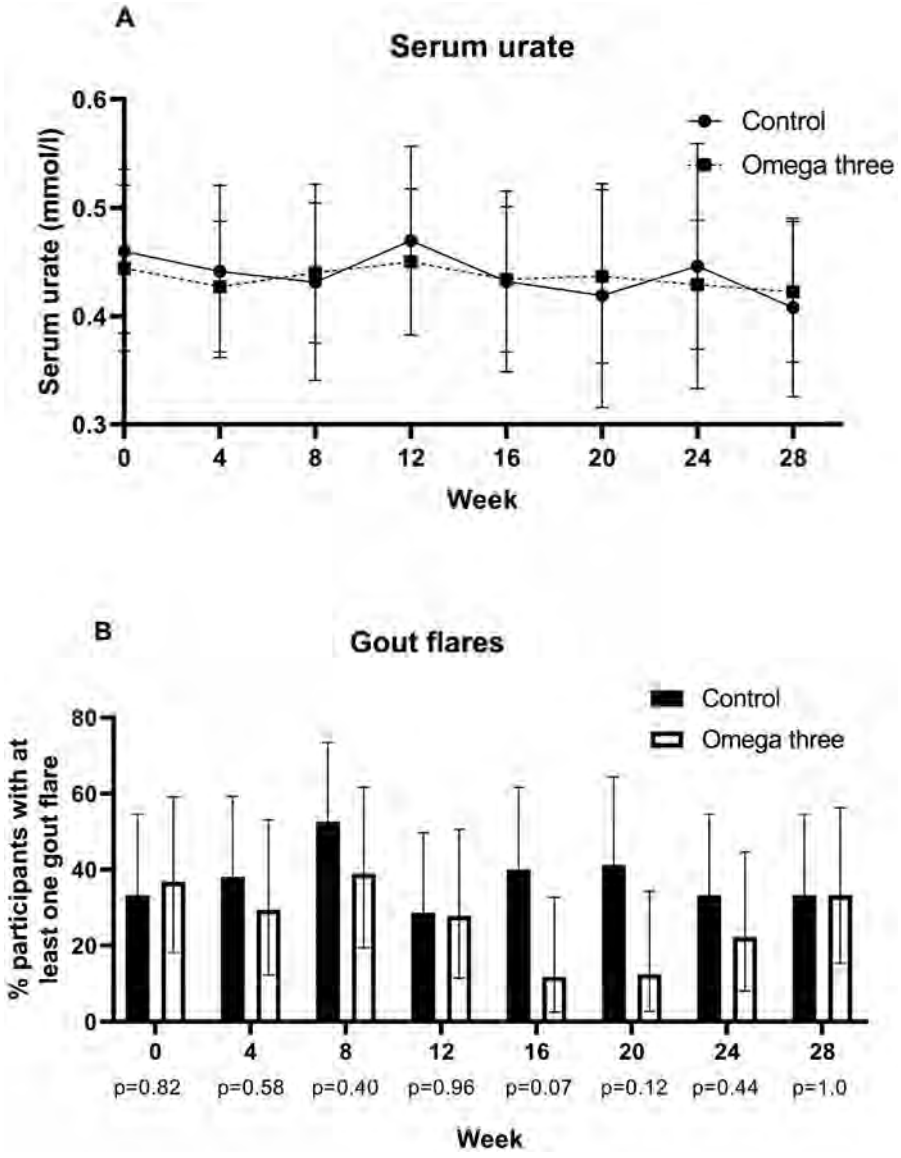

Figure 1. A) Serum urate and B) percentage of participants with at least one flare in the preceding four weeks over the study period in controls and those receiving omega three fish oil.

EPA r= -0.75 (p≤ 0.001) and DHA r= -0.76 (p≤ 0.001). In the omega-three fish oil group four participants reported gastrointestinal adverse effects definitely or probably related to the omega-three supplementation.

Conclusion: The lack of untoward effect of omega three fish oil supplementation on SU and BMI together with the relationship between higher omega-three concentrations and lower gout flares supports the development of further adequately powered clinical trials to determine the role of omega-three supplements as prophylaxis against gout flares in people starting urate lowering therapy.

Session Title: Metabolic & Crystal Arthropathies – Basic & Clinical Science Poster I (0660–0682)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Background/Purpose: Use of serum urate (SU) as a treatment target and outcome measure has become controversial in light of the American College of Physician Gout Guidelines which advocated a "treat-to-symptom", rather than a "treat-to-target SU" approach to management. The choice of SU as a treatment target measure implies that achievement of target SU is causally associated with improvement in patient-centered outcomes such as reduction

Table 1: Baseline demographics and clinical features for the NZ (15) and Nottingham studies (14). Data are present as n (%) or mean (SD).

	SU Responder		SU Non-Responder	
Variable	Nottingham	NZ	Nottingham	NZ
	(n=290)	(n = 53)	(n=227)	(n = 18)
Age (years)	62.7 (11.0)	61.5 (11.5)	63.1 (11.9)	55.9 (13.9)
Male, n (%)	259 (89.3%)	47 (89%)	202 (89%)	17 (94%)
Ethnicity, n (%)				
NZ European/European	280 (96.6%)	25 (47%)	221 (97.4%)	6 (34%)
Maori		17 (32%)		4 (22%)

Body mass index (kg/m^2)	29.5 (5.2)	34.8 (7.1)	30.2 (4.8)	37.2 (9.3)
Flare frequency in the preceding year	4.0 (4.8)	5.9 (11.8)	4.1 (4.9)	10.1 (17.1)
Tophus	36 (12.4%)	19 (36%)	22 (9.7%)	6 (34%)

in the number of gout flares. The aim of this study was to assess the causal relationship between achieving target SU and occurrence of gout flares.

Methods: Individual patient data from two randomized trials were analyzed to determine the relationship between SU and flares. Study one (Nottingham, UK) was a 2-year randomized trial comparing nurse-led and GP-led gout care (n=517) (1). Study two (New Zealand) was a 2-year open label randomized trial assessing the safety and efficacy of allopurinol dose escalation (2, 3). Individuals who on average achieved SU < 6mg/dL at 6, 9 and 12 months post-baseline were defined as "SU responders". The primary endpoint was the proportion of participants having at least one gout flare from 12 to 24 months. The secondary endpoint was the actual number of flares from 12 to 24 months (collected as a number between 0 and 4 per month) and tophus regression. The individual patient data sets from New Zealand and Nottingham were combined and analyses undertaken for the primary and secondary outcome measures. These analyses were undertaken using the models as above with the addition of a fixed factor to account for New Zealand and randomization within the Nottingham dataset.

Results: Significantly fewer SU responders experienced a gout flare in months 12-24 compared to SU non-responders; unadjusted OR 0.20; 95%CI 0.15 to 0.29. In the Nottingham study, there was no effect of randomization on the relationship between serum urate response group and the presence or absence of gout flares (p=0.13) indicating that the reduction in SU is responsible for the absence of flares. The mean number of flares in months 12-24 was significantly lower in SU responders compared to SU non-responders, unadjusted mean difference -1.64; 95%CI -1.85 to -1.44. This association was also independent of the randomized treatment allocation. Combining the individual data for both NZ and Nottingham revealed those participants with a tophus at baseline, 38/55 (69.1%) of SU responders lost the sentinel tophus compared to 8/22 (36.4%) of the SU non-responders (OR 3.9; 95%CI 1.4 to >11.1).

Conclusion: We have shown using individual patient data from 2 RCTs that achieving an average SU < 6mg/dL over a 6-month period is likely causally associated with the subsequent absence of gout flares, a reduction in the number of gout flares, and resolution of tophi in people with gout during the second year of treatment.

Disappearing Digits: A National Retrospective Matched Cohort Study Examining the Risk of Lower Extremity Amputation in Gout

Quint Soto[1], Alison Petro[1], Bryant England[1], Harlan Sayles[1], Lindsay Helget[1], Punyasha Roul[1], Tuhina Neogi[2], James O'Dell[1], Brian LaMoreaux[3] and Ted Mikuls[1], [1]University of Nebraska Medical Center, Omaha, NE, [2]Boston University School of Medicine, Boston, MA, [3]Horizon Therapeutics plc, Deerfield, IL

SESSION INFORMATION

Session Date: Sunday, November 7, 2021
Session Title: Metabolic & Crystal Arthropathies – Basic & Clinical Science Poster I (0660–0682)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Gout is associated with a number of comorbidities such as diabetes that are known risk factors for peripheral vascular disease. These comorbidities along with manifestations that mimic infection could place patients with gout at an increased risk of undergoing lower extremity amputation (LEA). The goal of this study was to determine if patients with gout are at a higher risk of undergoing LEA and to determine if this risk is independent of diabetes and other comorbidities.

Methods: We performed a retrospective matched cohort study using national Veterans Health Administrative (VHA) data from January 1999 to July 2015. Patients with gout were identified by the presence of ≥2 ICD9 codes (274.X). Gout patients were matched up to 1:10 by birth year, sex, and calendar year to patients without gout. Patients receiving LEA prior to the index date were excluded. LEA was defined using ICD9 procedure and common procedural terminology (CPT) codes and categorized as toe, transmetatarsal, below-the-knee, or above-the-knee. Diabetes and other comorbidities (e.g., peripheral vascular disease) were identified using ICD9 codes. Patients were followed until LEA or censoring due to death or end-of-study. Non-gout comparators developing gout later could "switch over", contributing at-risk time for gout after matching to 10 new controls. Associations of gout with LEA were examined using multivariable Cox proportional hazards regression accounting for demographics, body mass index, and comorbidities. In secondary analyses, patients were examined in 4 groups based on the presence/absence of gout and diabetes.

Results: We identified 556,521 gout patients and 5,368,397 matched non-gout controls. Patients had a mean age of 67 years and were predominantly male (99%). There were 4,970 LEAs over 4.2 million pt-yrs of follow-up in patients with gout and 24,583 LEAs over 40 million patient-years of follow-up in controls. The risk of LEA (overall and

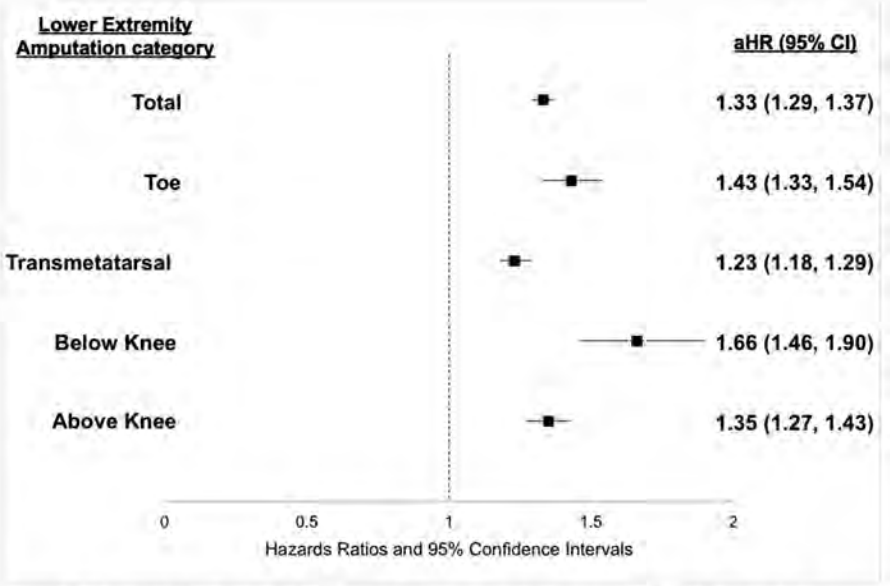

Figure 1: Associations of gout with undergoing lower extremity amputation, total and by type of surgery; adjusted hazard ratios and 95% confidence intervals generated with multivariable Cox proportional hazards regression adjusted for age, sex, race/ethnicity, body mass index, hypertension, cardiovascular disease, peripheral artery disease, cancer, cerebrovascular disease, chronic lung disease, dementia, diabetes and renal disease.

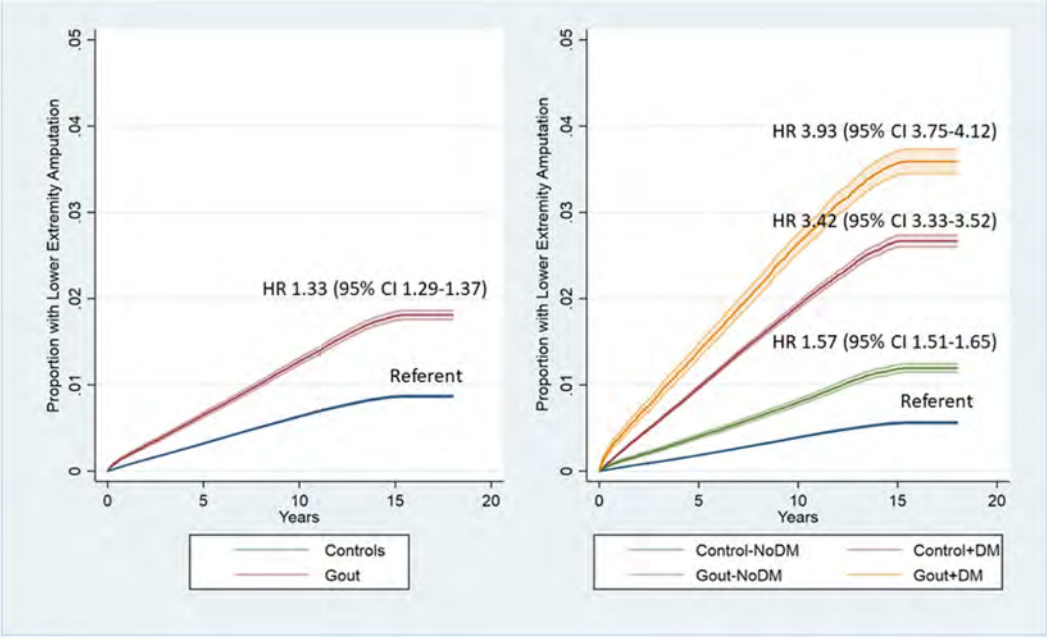

Figure 2: Cumulative incidence of lower extremity amputation based on gout vs. non-gout (left panel) and a combination of gout and diabetes (right panel). Hazard ratios and 95% confidence intervals shown calculated with multivariable Cox proportional hazards regression adjusted for age, sex, race/ethnicity, body mass index, hypertension, cardiovascular disease, peripheral artery disease, cancer, cerebrovascular disease, chronic lung disease, dementia, diabetes (left panel only) and renal disease.

Abbreviations: DM, diabetes mellitus

by category) in patients with gout is shown in **Figure 1**. After accounting for covariates, gout was associated with a significant increase in LEA risk (HR 1.33; 95% CI 1.29-1.37). This risk was highest for below-the-knee amputations (HR 1.66; 95% CI 1.46-1.90). Of other risk factors, diabetes (HR 3.23; 95% CI 3.15-3.32) was most strongly associated with LEA. Results based on dual gout and diabetes statuses are shown in **Figure 2**. In the absence of diabetes, patients with gout demonstrated a 1.57-fold increased risk (95% CI 1.51-1.65) of LEA. The highest risk of LEA was among patients with gout and diabetes, exceeding the risk posed by diabetes alone.

Conclusion: Patients with gout are at a 33% increased risk for undergoing LEA, with an even higher risk for below-the-knee amputations. This risk is independent of other comorbidities that have been associated with LEA including diabetes. Further research is needed to better understand the surgical indications for these procedures, whether tophi (which can mimic osteomyelitis) are associated with heightened risk, and to what degree LEA might be prevented in this patient population through enhanced diagnostics or improved gout management.

Which Attributes Are the Most and Least Important to Patients When Considering Gout Flare Burden over Time? A Best-worst Scaling Choice Study

Jeremy Holyer[1], William Taylor[2], Angelo Gaffo[3], Graham Hosie[1], Anne Horne[1], Borislav Mihov[1], Isabel Su[1], Gregory Gamble[1], Nicola Dalbeth[1] and **Sarah Stewart**[1], [1]University of Auckland, Auckland, New Zealand, [2]University of Otago Wellington, Auckland, New Zealand, [3]University of Alabama at Birmingham Medical Centre, Birmingham, AL

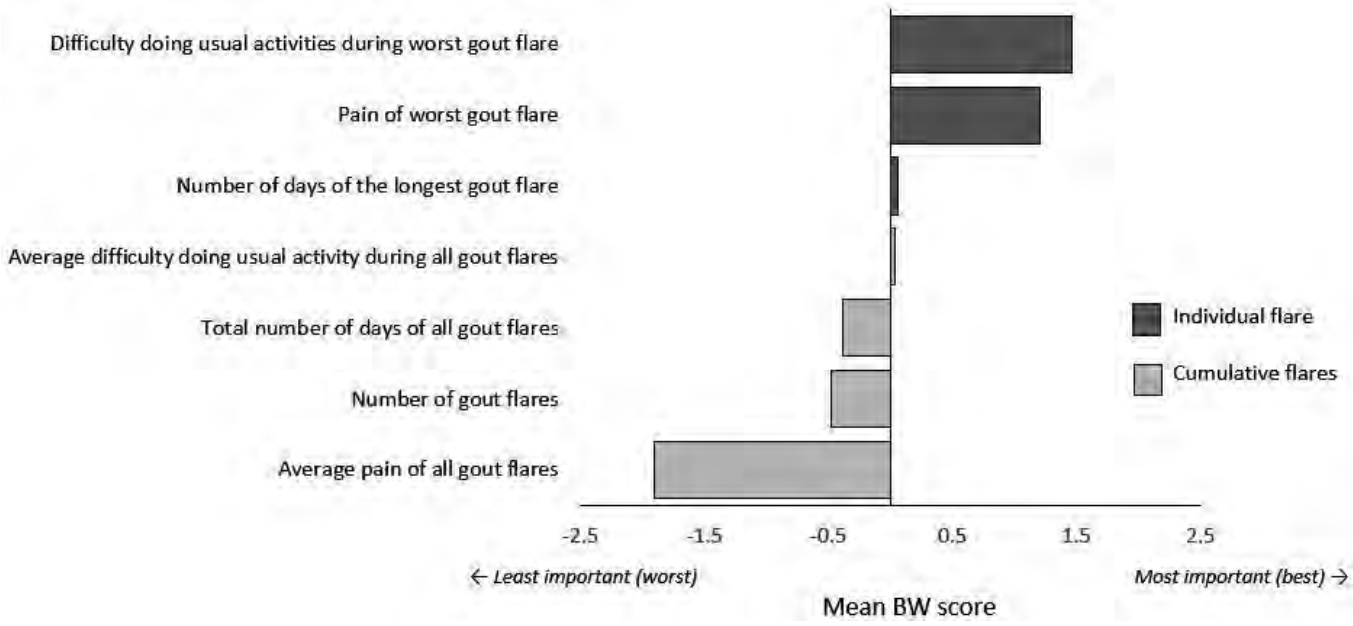
SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Metabolic & Crystal Arthropathies – Basic & Clinical Science Poster I (0660–0682)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Several factors contribute to the patient experience of gout flares, including pain intensity, duration, frequency, and disability. It is unknown which of these factors are most important to patients when considering flare burden over time, including those related to the cumulative experience of all flares, or the experience of a single worst flare. This study aimed to determine which flare attributes are the most and least important to the patient experience of flare burden over time.

Methods: Participants were recruited from existing databases of patients who had previously participated in research at the Clinical Research Centre, University of Auckland, Aotearoa/New Zealand. Participants with gout completed an anonymous online survey. Questions were aimed at identifying which attributes of gout flares were the most and least important over a hypothetical six-month period. Four attributes represented the cumulative burden of all flares (average pain of all gout flares, number of gout flares, total number of days of all gout flares, and average difficulty doing usual activities during all gout flares) and three attributes represented the burden of individual flares (pain of the worst gout flare, number of days of the longest gout flare, and difficulty doing usual activities during the worst gout flare). A best-worst scaling method was used to determine the importance hierarchy of the included attributes. Best (B) and worst (W) scores were calculated for each attribute representing the number of times that attribute was chosen as most and least important, respectively. The mean best-minus-worst (BW) score was also calculated to rank the attributes from most to least important, with positive values indicating the attribute being chosen more often as most important, and negative values indicating the attribute being chosen more often as least important.

Results: Fifty participants were included. The majority of participants were New Zealand European middle-aged males and 90% had experienced at least one gout flare in the previous 12 months, with 58% experiencing one to four gout flares in the previous 12 months. Difficulty doing usual activities during the worst flare and pain of the worst flare were ranked as the most important, while average pain of all flares was considered the least important. Overall, attributes related to the single worst gout flare were considered more important than attributes related to the cumulative impact of all flares (**Figure**).

Conclusion: When thinking about the burden of gout flares over time, patients rank activity limitation and pain experienced during their worst gout flare as the most important contributing factors, while factors related to the cumulative impact of all flares over time are relatively less important. Future studies investigating gout flare prevention should consider capturing outcomes related to the worst gout flare experienced during the follow-up period, specifically those related to activity limitation and pain.



Bar chart showing mean Best-Worst (BW) scores for each attribute. Positive scores indicate that attribute was chosen more frequently as the most important, while negative scores indicate that attribute was chosen more frequently as the least important.

Pegloticase Treatment for Uncontrolled Gout in Kidney Transplanted Patients: Results of an On-going Multicenter, Open-Label, Efficacy and Safety Study

Abdul Abdellatif[1], Lin Zhao[2], Paul M. Peloso[3], Katya Cherny[2], Brad Marder[2], John D. Scandling[4] and Kenneth Saag[5], [1]Kidney Hypertension Transplant Clinic Clear Lake Specialties, Webster, TX, [2]Horizon Therapeutics plc, Deerfield, IL, [3]Horizon Therapeutics plc, Gurnee, IL, [4]Stanford Medicine, Department of Nephrology, Stanford, CA, [5]University of Alabama at Birmingham, Birmingham, AL

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Metabolic & Crystal Arthropathies – Basic & Clinical Science Poster I (0660–0682)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Gout in kidney transplant (KT) recipients can be severe and particularly challenging to manage. Pegloticase (pegylated recombinant uricase) rapidly metabolizes urate and is a highly effective therapy for uncontrolled gout, but its efficacy can be limited in some pateints by the development of anti-drug antibodies. The addition of immunomodulators as co-therapy with pegloticase has been shown to improve response rates.[1-2] Few cases of pegloticase use in solid organ transplant patients have been reported and the phase 3 pegloticase trials excluded organ transplant recipients.[3-5] This ongoing Phase 4, open-label trial (PROTECT NCT04087720) examines the safety and efficacy of pegloticase in KT patients with uncontrolled gout.

Methods: Pegloticase treatment (8 mg IV infusion q2w for 24 wks) in KT recipients (KT >1 year ago, eGFR ≥15 mL/min/1.73m^2) with uncontrolled gout (serum urate [SU] ≥7 mg/dL, urate lowering therapy contraindication/inefficacy, and either tophi, chronic gouty arthritis, or ≥2 flares in past yr). Primary endpoint is proportion of pegloticase responders during Month 6 (SU < 6 mg/dL for ≥80% of time). Other endpoints included: eGFR and health assessment questionnaire (HAQ) pain (most severe: 100) and disability (max: 3) scores.

Results: At the time of analysis, 20 patients were enrolled (mean±SD; age: 53.9±10.9 yrs, KT 14.7±6.9 yrs ago, SU: 9.4±1.5 mg/dL, gout duration: 8.4±11.6 yrs; all on stable doses of ≥2 immunosuppresive medications) and 10 completed treatment, 3 discontinuted treatment (1 withdrew consent, 2 withdrew due to COVID-19 concerns), 2 patients met SU monitoring rules (pre-dose SU >6 mg/dL at 2 consecutive visits, nonresponders) and discontinued pegloticase, 5 were ongoing treatment. All patients experienced initial substantial reductions in SU, which was sustained in the majority; 2 met monitoring rules. No notable eGFR changes were observed. In patients who completed treatment, HAQ pain and disability improved by 26.7 ± 30.3 and 0.2 ± 0.5, respectively, at Week 24 (n=10). 7 SAEs (2 cellulitis, duodenal ulcer, sepsis, a-fib, diverticulitis, and localized infection), all deemed unrelated to pegloticase, were reported in 5 patients. No anaphylaxis or infusion reaction events have occurred.

Conclusion: On-going results from the PROTECT trial demonstrate promising outcomes treating uncontrolled gout in KT recipients with pegloticase with a substantial decrease in SU levels after initiating pegloticase therapy, which is maintained for the majority of patients. Patients also demonstrate a clinically meaningful reduction in pain (HAQ pain) and disability (HAQ-DI) with a stable eGFR. This phase 4, multicenter, open-label, efficacy and safety study will reach completion in Fall 2021.

Abstract Number: 0666

Process Mapping Gout Hospitalizations: A Deep Dive into an Avoidable Epidemic

Mark Russell[1], Benjamin Ellis[2], Benjamin Clarke[1], Deepak Nagra[1] and James Galloway[3], [1]King's College London, London, United Kingdom, [2]Imperial College Healthcare NHS Trust, London, United Kingdom, [3]Kings College London, London, United Kingdom

SESSION INFORMATION

Session Date: Sunday, November 7, 2021

Session Title: Metabolic & Crystal Arthropathies – Basic & Clinical Science Poster I (0660–0682)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Background/Purpose: Hospital admissions for gout flares have increased dramatically in recent years. Strategies to reduce hospitalizations and improve uptake of urate-lowering therapy (ULT) are needed. We performed an in-depth review of gout hospitalizations at our centre, incorporating stakeholder input and process mapping, to identify strategies to prevent admissions.

Methods: We retrospectively reviewed all emergency department (ED) attendances and hospital admissions for gout flares at two large hospitals in London, UK, from 1st October 2020 to 31st December 2020. Primary and secondary admission diagnoses of gout were included. Data on multiple aspects of hospital and post-discharge care were analysed, including ULT initiation/uptitration, discharge delays and re-admission rates. A process map of the inpatient journey was constructed with input from multiple stakeholders, including patients and clinicians, and strategies to address care barriers were identified.

Results: Detailed case reviews were performed on 68 ED attendances or hospital admissions for gout flares. There was initial diagnostic uncertainty in 32 patients (47%); however, specialist input was rarely sought in ED, and joint aspiration was performed in only 9 patients, with a median delay of 3 days. For the 22 admitted patients, the median length of stay was 11 days (8 days for primary admissions; 17 days for secondary admissions). 18 patients (82%) had discharge delays, including delays in seeking rheumatology input and treatment of comorbid conditions. Forty patients (59%) had pre-existing gout, of whom 25% were on ULT at presentation (mean serum urate level, 6.6 mg/dL). ULT initiation and/or uptitration occurred in 7 patients (10%) during admission or in ED. Of 60 patients with post-discharge follow-up data available, 20 (33%) initiated and/or uptitrated ULT within 6 months (median delay, 32 days), 35 patients (58%) remained on no ULT, and only 2 patients (3%) achieved target serum urate levels. Seven patients (10%) re-presented to hospital within 6 months of discharge.

Through iterative process mapping and stakeholder input, strategies to address care barriers observed during gout hospitalizations were identified. Strategies included initiation of ULT during flares, treat-to-target ULT uptitration coordinated between secondary and primary care, provision of disease-specific patient education and flare management packs, and timely specialist input with joint aspiration and steroid injection as indicated.

Conclusion: We identified multiple barriers to optimal hospitalized gout care and strategies to address them. Effective implementation of evidence-based interventions during hospitalizations for gout could transform care for patients, reduce length of stay, and prevent re-admissions.

Active Screening for Gout Permits Identifying a Larger Cardiovascular Population at High Mortality Risk

Silvia Ruiz-Simón[1], Irene Calabuig[2], Miguel Gómez-Garberí[3] and **MARIANO ANDRES**[4], [1]Universidad Miguel Hernández, Alicante, Spain, [2]Hospital General Universitario de Alicante, Alicante, Spain, [3]Hospital Universitario San Juan de Alicante, San Juan de Alicante, Spain, [4]Hospital General Universitario de Alicante-ISABIAL, Alicante, Spain

SESSION INFORMATION

Session Date: Sunday, November 7, 2021

Session Title: Metabolic & Crystal Arthropathies – Basic & Clinical Science Poster I (0660–0682)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Background/Purpose: We have recently noted by active screening that about a third of gout cases in the cardiovascular population is not registered in records (Calabuig, *Front Med* 2020), highlighting the value of field studies. This study aims to assess whether gout screening in patients hospitalized for cardiovascular events may also help identify patients at higher risk of mortality after discharge.

Methods: A retrospective cohort field study carried out on 266 patients admitted for cardiovascular events in the Cardiology, Neurology and Vascular Surgery units of a tertiary centre in Spain. The presence of gout was established by records review and face-to-face interview, according to the 2015 ACR/EULAR criteria. The occurrence of mortality during follow-up and its causes were obtained from electronic medical records. The association between gout and subsequent mortality was tested using Cox regression models. Whether covariates affected the gout-associated mortality was also studied.

Results: Of 266 patients recruited at baseline, 17 were excluded due to loss to follow-up (>6mo), leaving a final sample of 249 patients (93.6%). Thirty-six cases (14.5% of the sample) were classified as having gout: twenty-three (63.9%) had a previously registered diagnosis, while 13 (36.1%) had not and was established by the interview.

After discharge, the mean follow-up was 19.9 months (SD ±8.6), with a mortality incidence of 21.6 deaths per 100 patient-years, 34.2% by cardiovascular causes.

Gout significantly increased the risk of subsequent all-cause mortality, with a hazard ratio (HR) of 2.01 (95%CI 1.13 to 3.58). The association remained significant when the analysis was restricted to gout patients with a registered diagnosis (HR 2.89; 95%CI 1.54 to 5.41).

The adjusted HR for all-cause mortality associated with gout was 1.86 (95% CI 1.01-3.40). Regarding the causes of death, both cardiovascular and non-cardiovascular were numerically increased.

Secondary variables raising the mortality risk in those with gout were age (HR 1.07; 1.01 to 1.13) and coexistent renal disease (HR 4.70; 1.31 to 16.84), while gender, gout characteristics or traditional risk factors showed no impact.

Conclusion: Gout was confirmed as an independent predictor of subsequent all-cause mortality in patients admitted for cardiovascular events. Active screening for gout allowed identifying a larger population at high mortality risk and may help tailor optimal management to minimize the cardiovascular impact.

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Metabolic & Crystal Arthropathies – Basic & Clinical Science Poster I (0660–0682)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Patient-centered management is becoming increasingly important in gout, but there are limited studies exploring patients' perspectives and preferences. We aimed to investigate patients' perspectives and preferences regarding gout and gout management, and their impacts on adherence to urate lowering therapy (ULT).

Methods: A paper-based survey was performed in patients with gout seen at the rheumatology outpatient clinics of 16 tertiary hospitals. The survey included questions regarding demographics, comorbidities, gout attacks, current treatment and adherence, and patients' perspectives and preferences regarding gout and gout management. Multivariate regression analysis was performed to determine the factors associated with ULT adherence.

Results: Of 809 surveyed patients with gout, 755 (94.5%) were using ULT. Among those using ULT, 89.1% had ≥ 80% adherence to ULT. Majority of the patients knew management strategies to some extent (94.8%), perceived gout as a life-long disease (91.2%), and were making efforts toward practicing at least one lifestyle modification (89.2%). Most patients (71.9%) obtained information about gout management during their clinic visits. Approximately half of the patients (53.6%) preferred managing their disease with both ULT and lifestyle modification, 28.4% preferred ULT only, and 17.4% preferred lifestyle modification only. Adherence was better in patients with older age (odds ratio [OR] 1.03), those with better knowledge of gout management strategies (OR 3.56), and those who had preference for ULT (OR 2.07).

Conclusion: Patients' perspectives and management preferences had high impacts on adherence to ULT in gout. Consideration of patients' perspectives and preferences is important for achieving the desired clinical outcome in gout.

Patients' perspectives and preferences regarding gout and gout management

	Total (N=809)	Patients receiving ULT (n=755)		
		ULT adherence≥80% (n=673)	ULT adherence<80% (n=82)	*P*

Early-Onset Gout (EOG) Patients Are an Important and Recalcitrant Phenotype Warranting Further Investigation: A Systematic Review

Anthony Amatucci[1], Brian LaMoreaux[2] and **David Bulbin**[3], [1]Horizon Therapeutics, West Orange, NJ, [2]Horizon Therapeutics plc, Deerfield, IL, [3]Geisinger Health System, Danville, PA

SESSION INFORMATION

Session Date: Sunday, November 7, 2021

Session Title: Metabolic & Crystal Arthropathies – Basic & Clinical Science Poster I (0660–0682)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Background/Purpose: Data suggests that the number of patients with early-onset gout (EOG), defined as patients under the age of 40 years, is increasing[1]. There is a paucity of data related to the clinical features, comorbidity profile, and response to treatment for patients presenting with EOG although international guidelines recommend urate lowering therapy be initiated at time of diagnosis[2,3].

Methods: A systematic review of the literature was conducted to examine publications and abstracts providing insight into the overall profile of EOG patients. A comprehensive search was conducted in the PubMed Database and ACR Archived Abstracts to identify relevant publications. Identical Search Terms were used in both databases, and a full review of EOG literature identification and inclusion/exclusion criteria can be found in **Figure 1**.

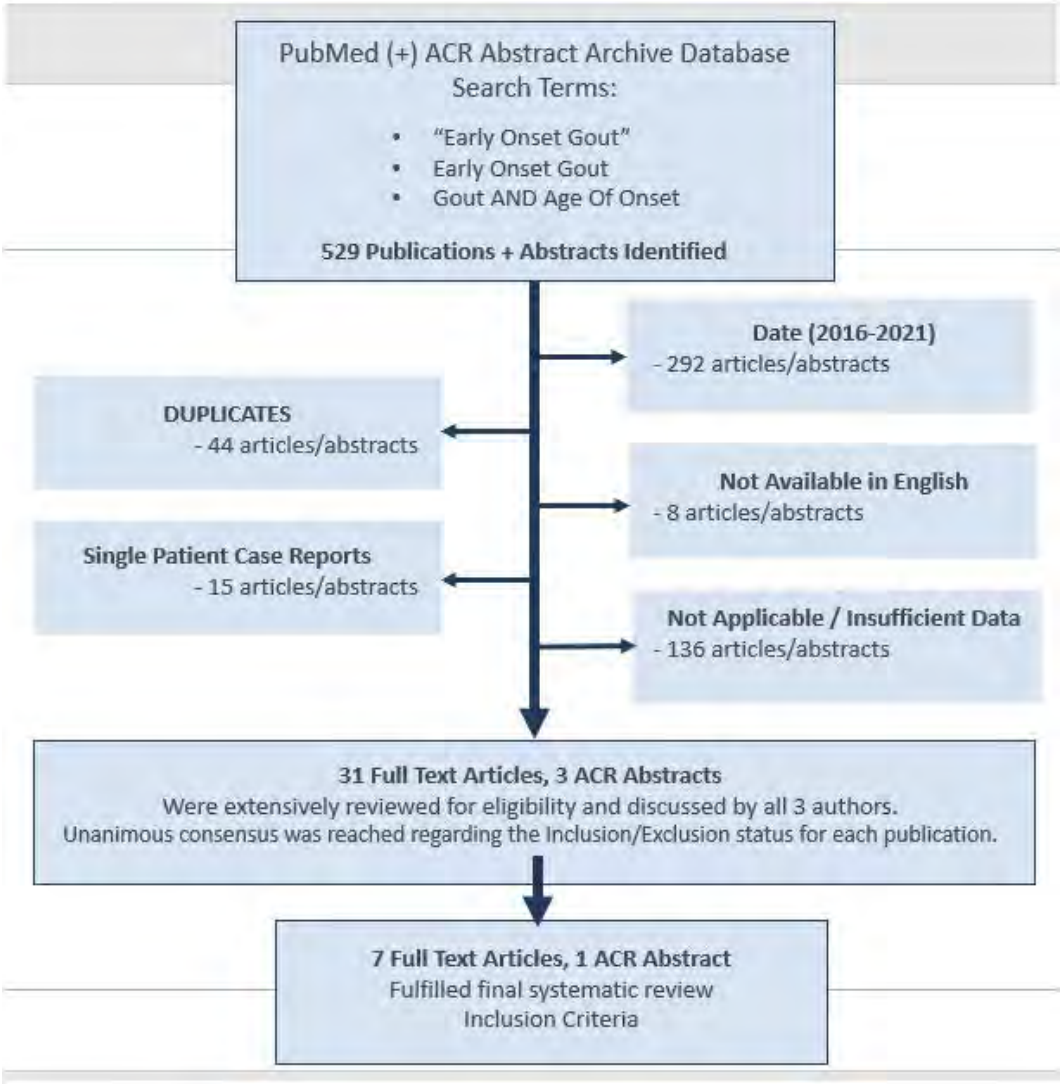

Figure 1. Flowchart of Early-Onset Gout Literature Identification and Selection.

Table 1. Clinical Features Analysis: Early-Onset Gout vs. Common Gout/Late-Onset Gout

Study	Patients, (n)	Gout PRECEDES onset of Cadio-Metabolic Comorbidities / Lower number of Comorbidities at Disease Onset	More Likely to have Preserved Renal Function	More Severe Joint Disease (recent flares frequency, polyarticular disease)	Less likely to achieve SU < 6mg/dL Or Higher baseline SU*
Pascart et al. (2019) GOSPEL 4 – Patients with early onset gout develop earlier severe joint involvement and metabolic comorbid conditions	985	✓	✓	✓	✓
Yan et al. (2019) Clinical Characteristics of Early-Onset Gout in Outpatient Setting	327	✓	✓	✓	✓
Zhang et al. (2016) Clinical Characteristics of early- and late-onset gout: a cross sectional observational study from a Chinese gout clinic	778	✓	✓	✓	✓*

Results: The search retrieved 529 references (**Fig 1**). 31 articles and 3 abstracts were reviewed for eligibility. 8 publications were included in the final review. 5 focused on the clinical characteristics of EOG patients; 3 of the 5 were retrospective or cross-sectional analyses comparing EOG patients to a group of Common Gout (CG) patients. All three cohorts with comparisons produced consistent insights into the clinical manifestations of EOG patients: either gout preceded the onset of cardio-metabolic comorbidities or fewer comorbidities were present at the time of gout diagnosis in EOGs; a large majority of EOGs had preserved renal function; EOGs had more severe joint disease (assessed by flare rates/polyarticular disease); finally all reported EOGs were less likely to achieve a target serum urate (SU) < 6 mg/dL or had higher SU levels at baseline compared to CG patients (**Table 1**). The remaining 3 publications focused on EOG patients' genetic predisposition for acquiring gout, concluding both ABCG2 and non-ABCG2 dysfunctional polymorphisms are more prevalent and likely contribute to the development of EOG.

Conclusion: The data reviewed examining EOG vs. CG comparators all produced consistent results. EOG patients are recalcitrant to ULTs, and present with more severe disease compared to CG patients.

SNPs (ABCG2, and other common and rare SNPs) that encode genetically dysfunctional urate transporters likely play an extensive role in development of EOG. The reviewed clinical and genetic data support the theory that gout operates within a "Common Disease, Multiple Common and Rare Variant" model.

EOG patients presented with less cardio-metabolic comorbidities upon diagnosis, suggesting a temporal separation between EOG diagnosis and development of other comorbidities. This suggests a window of opportunity to impact the development of comorbidities associated with gout.

Abstract Number: 0670

Hemochromatosis Is Associated with CPPD Through Iron's Effect on Bone

Jennifer Velasco, Claudia Gohr, Elizabeth MItton-Fitzgerald and Ann Rosenthal, Medical College of Wisconsin, Milwaukee, WI

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Metabolic & Crystal Arthropathies – Basic & Clinical Science Poster I (0660–0682)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Hemochromatosis (HH) is one of the strongest known risk factors for calcium pyrophosphate (CPP) crystal deposition. The pathogenic mechanisms causing CPP crystal formation in HH patients remain unknown. CPP crystal formation is associated with increased levels of inorganic pyrophosphate (PPi). This process is controlled by transporters of extracellular ATP such as ANK, and a series of ectoenzymes that hydrolyze ATP or degrade PPi. Recently, alterations in bone such as increased osteoclastogenesis, have also been implicated in CPPD. Most end organ damage in HH is attributed to iron deposition; and *in vitro* studies mimic HH by exposing cells or tissues to high levels of iron. Prior work showed no clear effects of iron on factors affecting CPP crystal formation in articular cartilage. We sought to investigate the hypothesis that iron contributes to CPP crystal formation by stimulating osteoclastogenesis. We also explored other effects of iron on PPi regulatory factors in osteoclasts and osteoblasts.

Methods: RAW264.7 cells (pre-osteoclasts) were incubated with 10-20 ng/ml RANKL and 10-100 μM ferric ammonium citrate (FAC) or no additives for 4-6 days. Osteoclast formation was assessed using a quantitative TRAP assay. Many of the effects of iron are attributed to increased reactive oxygen species (ROS). We measured ROS in RAW

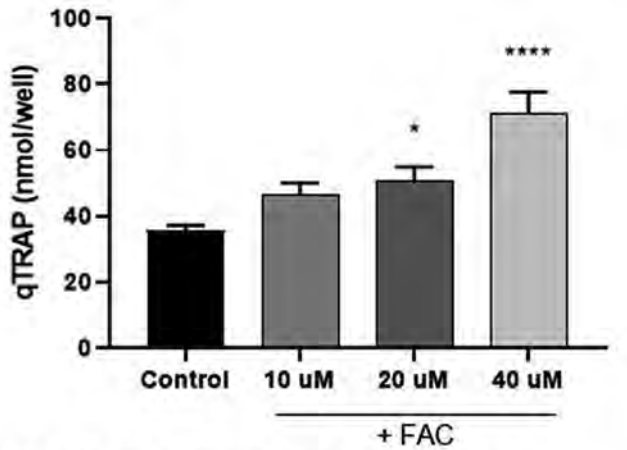

Figure 1. Iron increases osteoclastogenesis in pre-osteoclasts. RAW cells were incubated with 10 ng/ml RANKL and 10-40 μM FAC or no additives for 6 days. Osteoclast formation was assessed using a quantitative TRAP assay. Statistically significant differences were observed at 20 μM ($p=0.03$) and 40 μM ($p<0.0001$) FAC compared to control.

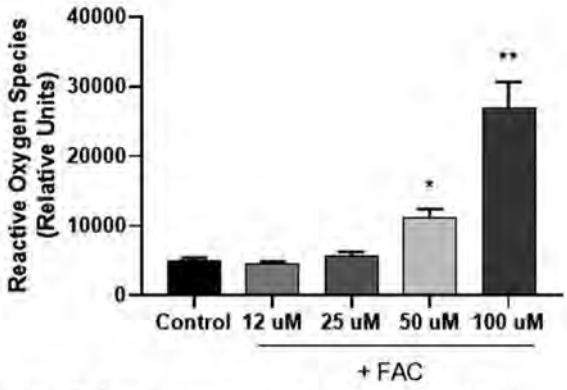

Figure 2. Iron increases reactive oxygen species in osteoclasts. RAW cells were incubated with 20 ng/ml RANKL and 12-100 μM FAC or no additives for 4 days. ROS formation was assessed using DCFDA dye. Statistically significant differences were observed at 50 μM (p=0.04) and 100 μM (p=0.002) FAC compared to control.

cells using DCFDA dye (Sigma). Because high levels of RANKL on osteoblasts stimulate osteoclast formation, we measured RANKL on osteoblasts in the presence of iron. Human osteoblasts (fOBs, Cell Applications) were exposed to 10-100 μM FAC or no additives for 9 days. RANKL levels were measured using RT-PCR. Other factors known to contribute to bone PPi homeostasis were measured in fOBs, including alkaline phosphatase (AP) activity, ANK levels, and levels of PPi. ANK was measured with RT-PCR and AP activity was measured with an assay from Abcam. PPi was measured in the conditioned media of fOBs and RAW cells using a highly sensitive radiometric assay.

Results: Ten-40 μM FAC significantly increased TRAP activity on RAW cells incubated with submaximal concentrations of RANKL at 6 days ($p< 0.0001$, N=15). Forty μM FAC increased TRAP activity by 2-fold (Figure 1). FAC also increased ROS ($p< 0.0001$, N=5) (Figure 2). Similar concentrations of FAC had no effects on fOB RANKL levels at 9 days in the absence or presence of differentiation factors (Data not shown). There was a small but significant decrease in alkaline phosphatase in fOBs at 100 μM FAC. Levels were 4.03± 1.3 nmol/well in fOBs with no iron exposure and 2.35± 0.6 U with FAC (p=0.02, n=5). FAC had no effects on ANK mRNA, and PPi levels were unmeasurable in both RAWs and fOBs. FAC toxicity was monitored using an LDH assay and was not significant at the concentrations tested.

Conclusion: We confirm here that iron increases TRAP positive osteoclasts *in vitro*. Increased osteoclast number is associated with premature severe CPPD caused by a loss of function mutation in osteoprotegerin. Further work will be necessary to determine the mechanisms through which osteoclast excess causes CPPD, but these findings add additional support to the hypothesis that some forms of CPDD are related to primary abnormalities in bone.

Concomitant Immunomodulation and Pegloticase Therapy: Experiences with a Variety of Immunomodulatory Agents in Two Community Rheumatology Practices

Aaron Broadwell[1], John Albert[2], Brian LaMoreaux[3] and Lissa Padnick-Silver[3], [1]Rheumatology and Osteoporosis Specialists, Shreveport, LA, [2]Rheumatic Disease Center, Milwaukee, WI, [3]Horizon Therapeutics plc, Deerfield, IL

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Metabolic & Crystal Arthropathies – Basic & Clinical Science Poster I (0660–0682)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Patients with uncontrolled or refractory gout have heavy disease burden,[1] but few treatment options. Pegloticase is effective for lowering serum urate (SU) in these patients, though efficacy is limited by anti-drug antibody development in some patients.[2] Administering pegloticase in conjunction with an immunomodulating therapy meaningfully increased the number of patients with sustained urate lowering while on treatment.[3] However, case data in the literature remain limited. The current study reports experience from two busy rheumatology practices where immunomodulating therapy is routinely prescribed in patients undergoing pegloticase treatment.

Methods: Patients who underwent concomitant pegloticase/immunomodulation therapy (initiated 2017 or later) were included. Patient and treatment characteristics were examined, along with the proportion of patients who were considered pegloticase responders (≥12 pegloticase infusions and SU < 6 mg/dL at infusion 12). Patients who remained on therapy, but had not yet reached infusion 12 were not included in responder rate analyses. All patients received pre-infusion prophylaxis (125 mg IV methylprednisolone or 100 mg hydrocortisone, 180 mg oral fexofenadine or 25 mg IVP diphenhydramine). Estimated glomerular filtration rate (eGFR) was also examined before therapy and at last infusion. Data are presented as mean±SD or %.

Results: 34 patients (79% male, 62.4±16.3 years) with uncontrolled gout (SU = 9.1±2.0 mg/dL, 91% had tophi, 14.7±13.4 year gout history) were included. The most common comorbidities were hypertension (76%), obesity (71%), osteoarthritis (68%), and chronic kidney disease (CKD, 47%). Baseline eGFR was 65.4±25.2 ml/min/1.73 m^2 and 41% had eGFR< 60 ml/min/1.73 m^2. A mean of 14.6±7.1 pegloticase infusions were administered over 28.5±14.9 weeks. Immunomodulator co-therapy was initiated prior to (5.3±3.0 weeks, n=32) or at (n=2) first pegloticase infusion and included subcutaneous (subQ) methotrexate (MTX; 15.4±4.9mg/week [range: 10-25 mg/week], n=20), oral MTX (15.3±3.6 mg/week [range: 7.5-20 mg/week], n=9), oral mycophenolate mofetil (MMF; all 1000 mg/day, n=3), and oral azathioprine (AZA; all 100 mg/day, n=2). Overall treatment responder rate was 89.3% (n=28). Response rates were 93% for subQ MTX (n=14), 89% for oral MTX (n=9), 100% for MMF (n=3), and 50% for AZA (n=2). eGFR remained essentially unchanged during therapy (+10.3±16.9 ml/min/1.73 m^2) and CKD stage remained stable or improved in 85% of patients (Stage 1 to 2 [n=1], Stage 2 to 3a [n=1], Stage 3a to 3b [n=2],). 34 gout flares occurred in 19 patients (56%), no infusion reactions or infections were noted, and no new safety concerns were identified.

Conclusion: These data provide further support for concomitant immunomodulator/pegloticase therapy, showing similar efficacy rates to both an open-label trial with oral MTX (79%)[4] and a systematic literature review of all immunomodulators (83%).[3]

Session Title: Metabolic & Crystal Arthropathies – Basic & Clinical Science Poster I (0660–0682)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Two recent analyses of the Global Burden of Disease Study reported on the rising global burden of gout (Safiri A&R 2020, Xia Rheumatology 2020). Addressing obesity, a major modifiable risk factor for gout, may help alleviate this burden. However, it is also recognized that there is a significant genetic contribution to the risk of hyperuricemia and gout according to genome-wide association studies (GWAS) (Tin Nat Genet 2019). It is unknown whether obesity affects gout risk differently among genetically predisposed individuals. Our objective was to prospectively investigate the association between obesity and the risk of incident gout according to genetic predisposition in two large US cohorts over >32 years, stratified by sex.

Methods: We investigated the joint effects of obesity and genetic predisposition on the future risk of incident gout in 18,247 women in the Nurses' Health Study (NHS) over 34 years and 10,899 men in the Health Professionals Follow-Up Study (HPFS) over 32 years. We derived a genetic risk score (GRS) using 114 serum urate single nucleotide polymorphisms from the latest GWAS (Tin), with higher GRS indicating higher genetic predisposition for hyperuricemia. We determined gene-body mass index (BMI) interactions among men and women separately. We also calculated the population attributable risk (PAR) for excess weight according to GRS stratum.

Results: We ascertained 1361 incident cases of self-reported gout in NHS and 1704 in HPFS. The baseline clinical gout risk factors were similar regardless of genetic predisposition within each cohort (**Table 1**). Among women, the multivariable relative risks (RR) of gout were 1.0, 1.24 (0.98 to 1.57), and 2.60 (2.09 to 3.24) among those with GRS below the mean and 1.55 (1.25 to 1.91), 2.74 (2.24 to 3.35), and 4.65 (3.80 to 5.68) among those with GRS above the mean for BMI categories < 25, 25-30, and >30, respectively (**Figure 1 and Table 2**). There was significant additive interaction with rate difference (RD) between BMI >30 relative to BMI ≤25 being 3.94 and 1.70/1000 person-years (PY) for GRS above and below the mean, respectively, resulting in relative excess risk due to interaction (RERI) of

Table 1. Baseline Gout Risk Factors by Genetic Scores in HPFS and NHS Participants

	HPFS		NHS	
	Genetic Score of 114 SNPs		Genetic Score of 114 SNPs	
	Below Mean (n = 5468)	Above Mean (n = 5431)	Below Mean (n = 9165)	Above Mean (n = 9082)
Age, years, mean (SD)	54.3 (8.6)	54.2 (8.7)	47.1 (6.9)	47.0 (6.9)
Systolic blood pressure, mm Hg, mean (SD)	128.7 (12.5)	128.7 (12.5)	123.9 (14.4)	124.2 (14.6)
Diastolic blood pressure, mm Hg, mean (SD)	81.3 (7.2)	81.2 (7.1)	78.8 (7.6)	79.1 (7.7)
Reported hypertension, %	21	21	15	17
BMI, kg/m^2, mean (SD)	25.6 (3.2)	25.6 (3.1)	24.5 (4.5)	24.5 (4.4)
Physical activity, MET-hours/week, mean (SD)	20.2 (23.5)	19.9 (23.7)	14.6 (20.8)	14.0 (19.3)
Alcohol, g/d, mean (SD)	12.1 (15.6)	12.4 (16.3)	6.5 (10.2)	6.6 (10.5)
Sweetened soft drink intake, servings/d, mean (SD)	0.3 (0.5)	0.3 (0.5)	0.3 (0.6)	0.3 (0.6)
Meat intake, servings/d, mean (SD)	1.6 (0.8)	1.6 (0.9)	1.1 (0.8)	1.1 (0.8)
Seafood intake, servings/d, mean (SD)	0.3 (0.3)	0.3 (0.3)	0.2 (0.2)	0.2 (0.2)
Low-fat dairy foods intake, servings/d, mean (SD)	1.0 (1.1)	1.0 (1.0)	0.9 (1.0)	0.9 (1.0)
High-fat dairy foods intake, servings/d, mean (SD)	1.3 (1.3)	1.3 (1.3)	1.4 (1.3)	1.4 (1.3)
Diuretic use, %	10.0	10.1	9.6	10.1

Values are age-adjusted (except for age).

1.48 (95% CI, 0.82 to 2.13) (p< 0.01). The results for men were similar in that the RR of excess weight appeared larger among men with GRS above the mean than below the mean (**Figure 1 and Table 2**); there was a similar trend, with a RD of 7.57 and 5.01/1000 PY for GRS above and below the mean, respectively, resulting in RERI of 0.58 (95% CI, -0.08 to 1.23) (p=0.08). Among women, excess weight accounted for a larger proportion of gout cases among those with GRS above the mean (PAR 48.5%, 95% CI, 38.8 to 55.9) compared to those with GRS below the mean (PAR 29.0%, 95% CI, 10.5 to 42.1). The PARs for men were similar within GRS strata (31.6% and 29.7%, respectively).

Conclusion: In these large prospective studies of men and women, we found a significant interaction between obesity and genetic predisposition among women, and a trend towards this in men. Maintaining healthy weight is an important gout prevention strategy, particularly among those with underlying genetic risk.

Table 2. Joint Association of Body Mass Index and Genetic Risk Score on the Relative Risk of Incident Gout

	HPFS [Men]			Additive Interaction (RERI)*			Multiplicative Interaction*		
	BMI					P			P

The Impact of Allopurinol on Blood Pressure and Renal Outcome in Gout Patients: A Retrospective Study

Aniqa Faraz[1], Sabeeh Islam[2], Joseph Grisanti[3] and Shumaila Iqbal[4], [1]University at Buffalo-CHS Sisters of Charity, Grand Island, NY, [2]Brigham and Women's Hospital Cardiology, Boston, MA, [3]Buffalo Rheumatology & Medicine, Orchard Park, NY, [4]University of Cincinnati, Cincinnati, OH

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Metabolic & Crystal Arthropathies – Basic & Clinical Science Poster I (0660–0682)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: The relationship between change in serum uric acid level and progression of chronic kidney disease and hypertension is still conflicting. In this study, we aim to determine if lowering uric acid had any beneficial effect on blood pressure (BP) and kidney function in gout patients.

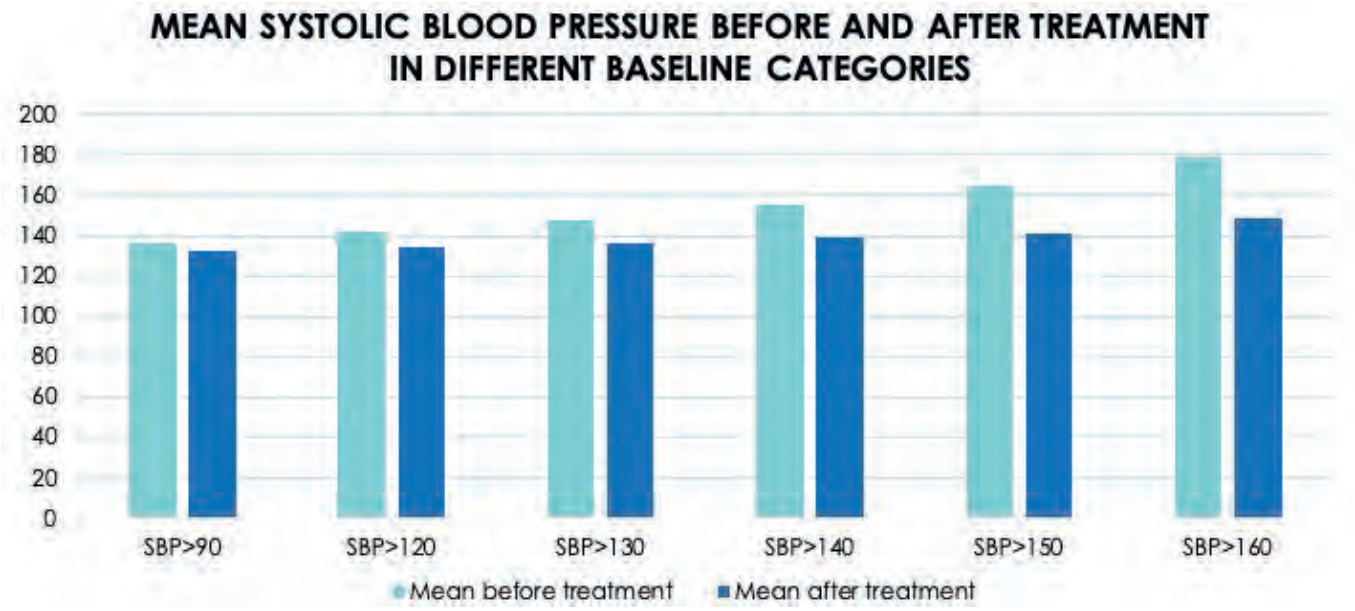
Methods: This was a retrospective study conducted in an outpatient clinic-based setting from December 2019 to December 2020. We obtained ethical approval from the Institutional Review Board of our hospital.

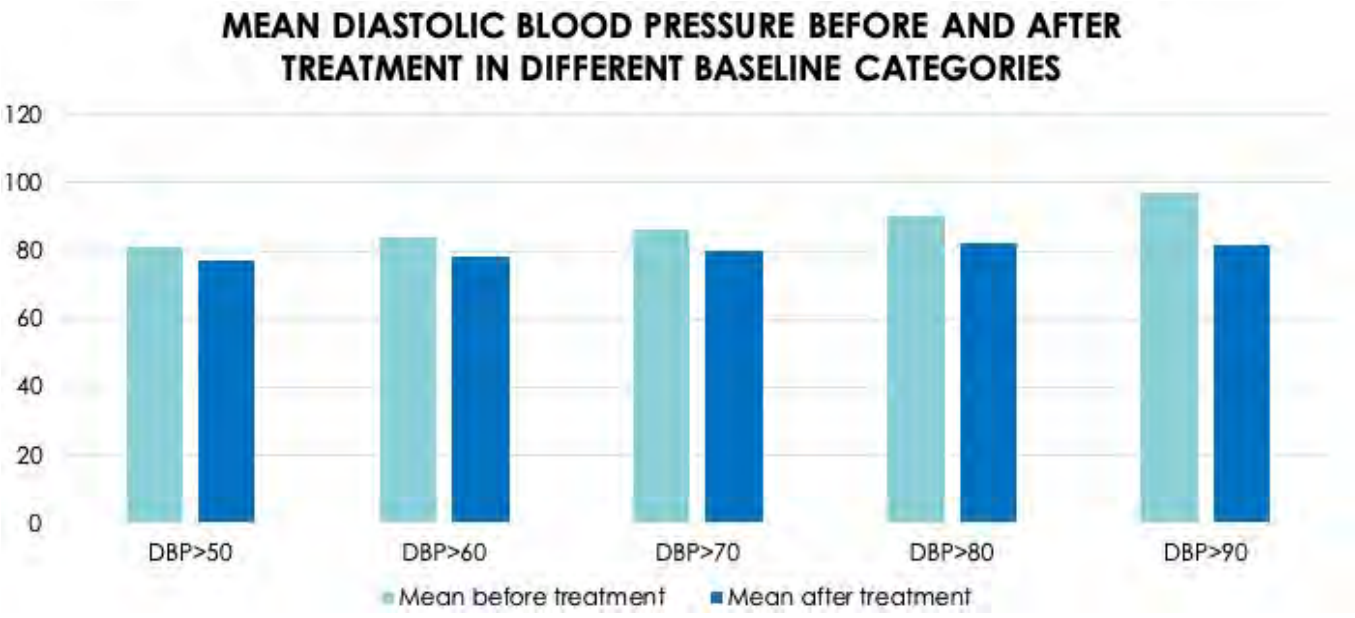
We recruited 77 patients on allopurinol therapy for gout based on the inclusion/exclusion criteria. All patients satisfied the 2015 Gout Classification Criteria by the American College of Rheumatology. Clinical determinants included mean BP (MBP), systolic BP (SBP), diastolic BP (DBP), estimated glomerular filtration rate (eGFR), creatinine, and uric acid. The change in clinical determinants was charted before initiation of allopurinol therapy and after being on treatment for 3-6 months. Patients clinical data was further divided into different subgroups based on gender male or female, age < 60 or >60, diabetic or non-diabetic, hypertensive or non-hypertensive, eGFR < 30, 30-59 and >60, SBP into six, and DBP into five subsets based on baseline SBP and DBP respectively. Potential confounders, like baseline co-morbidities and the antihypertensive treatment, were also charted. Patient data were recorded and analyzed through Excel sheets to obtain a p-value to explain the statistical significance.

Results: Patients on allopurinol treatment for gout for 3-6 months, showed a significant reduction in MBP 3.2 mm Hg (p-value 0.034) particularly in the group >60 years of age. SBP mean reduction was 3.7 mm Hg but didn't reach statistical significance. However, in the subgroup of patients with eGFR< 30, the reduction of SBP was statistically significant with a p-value of 0.05. DBP reduction was statistically significant in all patients with a mean reduction of 3.8 mm Hg (p-value 0.008). When we analyzed subgroups separately based on baseline SBP and DBP the greatest change was seen for the highest baseline systolic and diastolic BP and was statistically significant. The eGFR improved in subgroups of female, age >60, eGFR < 30, and eGFR 30-59, and creatinine improved in a subgroup of

The mean of different clinical determinants before and after treatment with Allopurinol

Clinical Determinants	Mean Before Treatment	Mean After Treatment	P-value
Mean Blood Pressure	98.5	95.3	0.034
Systolic Blood Pressure	136.3	132.6	0.087
Diastolic Blood Pressure	80.5	76.7	0.008
Estimated GFR	66.4	66.5	0.963
Creatinine	1.2	1.2	0.704
Uric Acid	8.1	5.6	<0.001





eGFR < 30, but didn't reach statistical significance. The uric acid reduction was highly statistically significant in all groups (p-value < 0.001).

Conclusion: Through this study, we were able to find a statistically significant change in MBP, DBP, and SBP (in a subgroup of patients with eGFR< 30) with allopurinol treatment. Though we were not able to demonstrate any statistically significant effect on eGFR and creatinine, there was an improvement noted in kidney function in a few subgroups. Such a result could be due to the small sample size for our study. The effect of allopurinol can be utilized in the future for BP control in hyperuricemic patients.

A Behavioral Intervention to Improve Gout Outcomes in African Americans with Gout: A 12-month Multicenter, Randomized Controlled Trial

Jasvinder Singh[1], Kenneth Saag[1], Joshua Baker[2], Amy Joseph[3], Seth Eisen[4] and Terence Shaneyfelt[1], [1]University of Alabama at Birmingham, Birmingham, AL, [2]University of Pennsylvania, Philadelphia, PA, [3]Washington University / St. Louis VA, St Louis, MO, [4]Washington University School of Medicine, St Louis, MO

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Metabolic & Crystal Arthropathies – Basic & Clinical Science Poster I (0660–0682)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Gout outcomes and severity are worst in African Americans compared to Caucasians with gout. Racial Disparities in gout are well-described. Few or no data exist for African Americans with gout from observational studies or randomized controlled trials (RCTs). Our objective was to assess if a culturally appropriate gout storytelling intervention is superior to an attention control for improving gout outcomes.

Methods: In a 12-month, multicenter, randomized controlled trial (RCT), African American (AA) Veterans with gout were randomized to gout storytelling intervention vs. a stress reduction video (1:1 ratio). The primary outcome was urate-lowering therapy (ULT) adherence measured with the MEMSCap™, an electronic monitoring system to measure medication adherence. Secondary outcomes included gout flares, serum urate, gout-specific health-related quality of life (HRQOL), and medication satisfaction

Results: The 306 male AA Veterans with gout, who met the eligibility criteria were randomized to the gout storytelling intervention (n=152) or stress reduction video (n=152; control); 261/306 (85%) completed the 1-year study. The mean age was 64 years, body mass index (BMI) was 33 kg/m^2, and gout disease duration was 3 years. The ULT MPR by MEMSCap™ (primary outcome) was similar in the intervention vs. control groups at each time point: 3-months, 73% versus 70%; 6-months, 69% versus 69%; 9-months, 66% versus 67%; and 12 months, 61% versus 64% (p >0.05 each). The number of gout flares in the last month were similar in the treatment versus control groups except at 9-months: 3-months, 1.4 versus 1.4 (p=0.55); 6-months, 1.3 versus 1.6 (p=0.53); 9-months, 0.7 versus 1.3 (p=0.03); and 12-months, 0.7 versus 1.0 (p=0.20; Figure 1). Serum urate levels and patient satisfaction with treatment were similar in the two groups at 6- and 12-months with no significant differences. Gout-specific health-related quality of life scores on GAQ-GIS were also similar in the treatment versus control group except lower/better scores in two subscale scores in the treatment group: gout medication side effects at 3-months, 32.8 vs. 39.6 (p=0.02); and unmet gout treatment need at 3-months, 30.9 vs. 38.2 (p=0.003), and at 6-months, 29.5 vs. 34.5 (p=0.03; Figure 1), respectively.

Conclusion: A culturally appropriate gout storytelling intervention was not superior to attention control for improving gout outcomes in AA Veterans with gout. More studies are needed to determine the subset of minorities with gout that can benefit from behavioral interventions such as this. We also need to design more effective behavioral interventions for people with gout, especially those with worse outcomes, such as racial/ethnic minorities.

SESSION INFORMATION

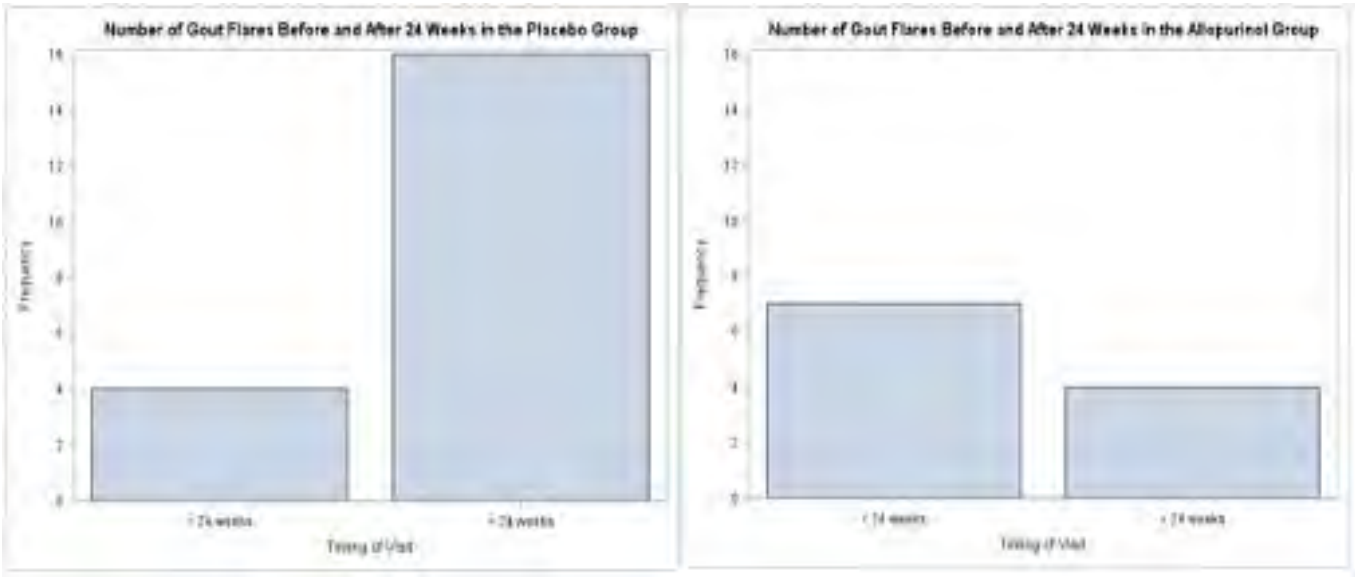
Session Date: Sunday, November 7, 2021

Session Title: Metabolic & Crystal Arthropathies – Basic & Clinical Science Poster I (0660–0682)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Background/Purpose: The CKD-FIX randomized controlled trial showed that allopurinol did not slow decline of estimated glomerular filtration rate (eGFR) over 104 weeks in patients with chronic kidney disease (CKD) at risk of progression. The aim of this pre-specified analysis was to assess if allopurinol prevents incident gout in the CKD-FIX trial population.



Number of gout flares before and after 24 weeks; placebo group shown in left panel, allopurinol group shown in right panel.

Methods: In the CKD-FIX trial, 369 adults with CKD stage 3 or 4, no history of gout, and risk of kidney disease progression (urinary albumin-to-creatinine ratio ≥265 mg/g or eGFR decrease ≥3.0 mL/min/1.73 m^2 in the preceding year) were randomized to receive placebo (n=184) or allopurinol up to 300mg daily (n=185). Gout flares were self-reported using a questionnaire at each study visit over 104 weeks. Additionally, the association of incident gout and baseline serum urate (normouricemia and hyperuricemia [based on a serum urate cut point of >6.8mg/dL], or as tertiles]) was analyzed.

Results: Three patients withdrew immediately after randomization. The remaining 363 patients (mean eGFR 31.7 mL/min/1.73 m^2, mean serum urate 8.2 mg/dL) were included in the analysis. At the end of the 12-week dose-escalation phase, 126 (69.2%) of 182 patients in the allopurinol arm were receiving 300mg daily. A total of 22 (6.1%) participants experienced 31 discrete flare episodes over 104 weeks (placebo group 20 flares in 13 patients; allopurinol group 11 flares in 9 patients). There was no significant difference between placebo and allopurinol groups in gout incidence. However, there were differences in timing of gout flares, with more flares in the allopurinol group in the first 24 weeks, and conversely more flares in the placebo group after 24 weeks (Figure, P=0.02). Across both groups, the most common affected joint region was the ankle. Of those participants who developed incident gout during follow-up, 19 (86%) had hyperuricemia at baseline. There was no association between incident gout and baseline serum urate stratified by hyperuricemia and normouricemia (P=0.14), however, there was an association between incident gout and baseline serum urate tertile, with the highest incidence of gout in those with serum urate in the highest tertile, that is, above 8.7mg/dL (P=0.004).

Conclusion: In people with CKD at risk of progression, incident gout is uncommon, and is associated with serum urate above 8.7mg/dL. Compared with placebo, allopurinol does not change the incidence of gout over a two year period, with more flares in the first 24 weeks of treatment, and fewer flares after 24 weeks.

SESSION INFORMATION

Session Date: Sunday, November 7, 2021

Session Title: Metabolic & Crystal Arthropathies – Basic & Clinical Science Poster I (0660–0682)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Table 1. Key phrases and parameters used to identify acute gout flare in the gout flare alert. *Past medical history included the following terms (not case-sensitive): pmh, pmhx, hx, past medical history. †Pain locations included the following musculoskeletal sites: ankle, arm, elbow, leg, feet, finger, foot, hand, hip, knee, shoulder, thumb, toe, wrist

	Current gout in Chief Complaint	Both pain location + gout in Chief Complaint	Pain location in Chief Complaint + gout in problem list
Description	The term 'gout' listed before the past medical history* in the chief complaint	Both the term 'gout' and a 'pain location'† listed in chief complaint	'Pain location'† listed in the chief complaint or in the structured nursing form and 'gout' listed in the problem list
Examples	- captures "out of gout meds" - does not capture "pain in left knee past medical history gout" - does not capture "chest pain past medical history gout"	- does not capture "out of gout meds" - captures "pain in left knee past medical history gout" - does not capture "chest pain past medical history gout"	- captures "pain in left knee" with 'gout' listed in problem list - does not capture "chest pain" with 'gout' listed in problem list

Background/Purpose: Patients with acute gout are frequently treated in emergency departments (ED) and represent a typically underserved and understudied population. A key limitation of conducting gout research in the ED is the timely ability to identify potential gout patients during an ED encounter. The objective of our study was to develop a multi-criteria electronic medical record (EMR)-based gout flare alert for acute gout flares and determine its diagnostic properties for gout flare identification among ED patients.

Methods: The alert used EMR data entered by ED nursing staff and the medical problem list. The alert was triggered by: the term 'gout' preceding the past medical history in the chief complaint field, the term 'gout' and a musculoskeletal problem in the chief complaint, or the term 'gout' in the problem list and a musculoskeletal chief complaint (Table 1). We validated the presence/absence of gout through manual EMR review using adjudicated expert consensus (assessed with kappa coefficient) as the gold standard. We abstracted ED cases of possible gout patients in whom gout flare symptoms were not documented but who might have had gout based on other clinical parameters (e.g., those with an ICD-10 code for gout at the ED visit (M10.X), those who had an arthrocentesis performed in the ED and had an order placed for uric acid crystal analysis in the synovial fluid, and any patient who had an order for colchicine during their ED visit) to identify possible false negative cases.

Results: From January 1 to February 1, 2020, there were 38 patients with acute gout flare identified by the components of the gout flare alert and an additional 93 were identified as potentially having an acute gout flare and were

Table 2. Test characteristics of the electronic medical record gout flare alert system and the individual components of the algorithm. *listed are each of three components of the overall alert algorithm

	Alert cases identified n (%)	Sensitivity (95% CI)	Specificity (95% CI)	PPV (95% CI)	NPV (95% CI)
Gout Flare Alert, n = 38	38 (29)	70 (51 – 88)	80 (72 – 87)	42 (26 – 58)	93 (87 – 98)
Gout Flare Alert Subset #1*: Both pain location + gout in chief complaint	26 (20)	39 (19 – 59)	84 (77 – 91)	35 (16 – 53)	87 (80 – 93)
Gout Flare Alert Subset #2*: Current gout in chief complaint	8 (6)	22 (5 – 39)	97 (94 – 100)	63 (29 – 96)	85 (79 – 92)
Gout Flare Alert Subset #3*: Pain location in chief complaint + gout in problem list	8 (6)	17 (2 – 33)	96 (93 – 100)	50 (15 – 85)	85 (78 – 91)

included in the analysis of the alert characteristics. The positive predictive value (PPV) of the alert was 42% (95% CI [26 – 58%]) and the negative predictive value (NPV) was 93% (95% CI [87 – 98%]). The gout flare alert had a sensitivity of 70% (95% CI [51 – 88%]) and specificity of 80% (95% CI [72 – 87%]) (Table 2). Prevalence of a true gout flare was 16/38 (42%) among patients in whom the gout flare alert fired and 7/93 (8%) among patients in whom the gout flare alert did not fire. The kappa coefficient for agreement between the consensus expert determination of acute flare and the documented ED diagnosis of flare was 0.9. A second alert validation procedure occurred between October 24, 2020 to November 24, 2020. During this period, the gout flare alert had a lower overall PPV of 24% likely due to fewer gout flare cases seen in the ED due to the COVID-19 surge in our region.

Conclusion: We developed, refined, and validated a multi-component EMR gout flare alert with reasonable predictive properties to detect patients with an acute gout flare during the ED visit. This screening tool achieves good sensitivity and NPV, which preferentially increases the number of detected cases and allows the ED team to rule out false positives with secondary data. An automated EMR alert may help identify patients with acute gout flare in real time upon presentation to the ED. These patients may be approached for study recruitment or quality improvement strategies beyond the standard of care.

Abstract Number: 0677

Pro-Inflammatory Diet and Increased Risk of Incident Female Gout: 30-Year Prospective Cohort Study of >170,000 Pre- and Post-Menopausal US Women

Natalie McCormick[1], Chio Yokose[2], Na Lu[3], Amit Joshi[1] and Hyon K. Choi[4], [1]Massachusetts General Hospital, Boston, MA, [2]Massachusetts General Hospital, Waltham, MA, [3]Arthritis Research Canada, Vancouver, BC, Canada, [4]Massachusetts General Hospital, Lexington, MA

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Metabolic & Crystal Arthropathies – Basic & Clinical Science Poster I (0660–0682)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Globally, the prevalence of gout is rising in females more than males,[1] but data on modifiable risk factors for female gout are scarce. Emerging evidence suggests inflammation may drive the progression from hyperuricemia to clinical gout,[2] but the role of extrinsic, modifiable sources of chronic inflammation on gout risk, such as diet, is unknown. Greater dietary inflammatory potential has been independently associated with increased risk of incident cardiovascular disease (CVD)[3] and type 2 diabetes (T2D),[4] conditions with higher prevalences among females with gout. We prospectively examined the relation between dietary inflammatory potential and gout risk in two large cohorts of US women over 30 years.

Table 1. Hazard Ratio (HR) of Incident Gout According to Quintiles of Inflammatory Diet Score

	Q1: (Lowest)	Q2	Q3	Q4	Q5: (Highest)	P for trend
N cases	662	812	998	1223	1588	
Person-years	863,160	864,059	863,926	863,411	862,713	
Incidence rate (per 1000 person-years)	77	94	116	142	184	
Incidence rate ratio	1.00 (Ref)	1.23	1.51	1.85	2.40	
Age-adjusted HR (95% CI)	1.00 (Ref)	1.22 (1.10 to 1.35)	1.50 (1.36 to 1.66)	1.86 (1.69 to 2.04)	2.48 (2.26 to 2.71)	<0.001
Multivariable HR (95% CI)*	1.00 (Ref)	1.18 (1.06 to 1.30)	1.37 (1.24 to 1.51)	1.59 (1.45 to 1.75)	1.89 (1.72 to 2.07)	<0.001
Multivariable HR (95% CI) (+ BMI)**	1.00 (Ref)	1.11 (1.00 to 1.23)	1.25 (1.13 to 1.38)	1.39 (1.26 to 1.53)	1.53 (1.39 to 1.68)	<0.001

*Multivariable (MV) models adjusted for age (month), White race, smoking, menopause, hormone use, physical activity (MET h/week), history of hypertension, and diuretic use. **MV + BMI models additionally adjusted for body mass index (BMI), a likely causal intermediate.

Methods: We studied 77,425 women from Nurses Health Study (NHS) (1986-2016) and 93,454 from NHS II (1989-2017) who were free of gout at baseline. Dietary intake and covariates were ascertained by validated questionnaires every 2-4 years, along with new cases of physician-diagnosed gout (every 2 years). Inflammatory potential of diet was evaluated using a food-based, empirical dietary index of inflammatory potential score (EDIP), pre-defined based on circulating levels of IL-6, C-reactive protein, adiponectin, and TNFαR2.[5]

We assigned an EDIP score for each woman, adjusted for total energy intake, and used Cox proportional hazards models to prospectively examine the relation between quintiles of cumulative average EDIP scores (reflection of *habitual* diet) and incident gout, adjusting for potential confounders. We further adjusted for body mass index (BMI), a potential causal intermediate, and conducted subgroup analyses.

Results: We documented 5,283 cases of incident gout over 4,317,270 person-years, including 3,670 in the NHS (mean age of 50 years at baseline; 49% post-menopausal) and 1,613 in NHS II (mean age 36 years; 3.6% post-menopausal). In pooled multivariable-adjusted (MV) analyses, women in the highest EDIP quintile had nearly two-times greater risk of gout (MV HR 1.9, 95% CI: 1.7 to 2.1) compared to women in the lowest quintile (**Table 1**). This remained positive with further adjustment for BMI, a likely causal intermediate (MV HR 1.5, 95% CI 1.4 to 1.7).

Effects were similar for the older and younger cohorts, with MV HRs of 1.9 (95% CI 1.7 to 2.1, p for trend < 0.001) and 1.9 (1.6 to 2.2, p < 0.001) before BMI adjustment, in the NHS I and II, respectively, and 1.6 (1.4 to 1.7, p < 0.001) and 1.5 (1.3 to 1.8, p < 0.001), respectively, after BMI adjustment. Estimates did not differ significantly across other subgroups.

Conclusion: In these large prospective cohorts of both older and younger women, habitual pro-inflammatory dietary pattern was independently associated with increased risk of incident gout, beyond the pathway through adiposity. Our findings support a role for chronic inflammation in development of female gout, similar to CVD[1] and T2D.[2]

Table 2. Hazard Ratio (HR) of Incident Gout According to Quintiles of Inflammatory Diet Score, by subgroups

	Q1: (Lowest)	Q2	Q3	Q4	Q5: (Highest)	P for interaction
Age, years						
< 60	1.00 (Ref)	1.20 (1.01 to 1.43)	1.37 (1.15 to 1.62)	1.61 (1.37 to 1.90)	1.97 (1.69 to 2.30)	0.16
≥ 60	1.00 (Ref)	1.16 (1.02 to 1.32)	1.36 (1.21 to 1.54)	1.58 (1.40 to 1.78)	1.83 (1.63 to 2.05)	
Body mass index, kg/m^2						
< 25	1.00 (Ref)	1.20 (1.01 to 1.42)	1.27 (1.07 to 1.51)	1.59 (1.34 to 1.88)	1.67 (1.40 to 1.99)	
25-29.9	1.00 (Ref)	1.08 (0.90 to 1.30)	1.13 (0.95 to 1.35)	1.27 (1.07 to 1.51)	1.55 (1.31 to 1.82)	0.68
≥ 30	1.00 (Ref)	1.09 (0.91 to 1.32)	1.36 (1.15 to 1.62)	1.44 (1.22 to 1.69)	1.58 (1.35 to 1.85)	
Physical activity, MET h/week						
< 25	1.00 (Ref)	1.18 (1.05 to 1.32)	1.39 (1.24 to 1.55)	1.60 (1.44 to 1.78)	1.91 (1.72 to 2.11)	0.68
≥ 25	1.00 (Ref)	1.18 (0.94 to 1.48)	1.29 (1.03 to 1.62)	1.56 (1.25 to 1.95)	1.86 (1.49 to 2.31)	
Alcohol use						
No	1.00 (Ref)	1.07 (0.82 to 1.38)	1.14 (0.89 to 1.46)	1.23 (0.97 to 1.56)	1.64 (1.31 to 2.05)	0.48
Yes	1.00 (Ref)	1.18 (1.06 to 1.32)	1.40 (1.26 to 1.56)	1.68 (1.51 to 1.86)	1.87 (1.68 to 2.08)	

Adhering to a diet with lower inflammatory potential may modulate systemic and metabolic inflammation, potentially reducing gout risk and these life-threatening comorbidities among women.

Abstract Number: 0678

Is There a Difference in Self-reported Flare Frequency Between Men and Women?

Naomi Schlesinger[1], Nicholas A Sumpter[2], Nicola Dalbeth[3], Lisa Stamp[4] and Tony Merriman[5], [1]Rutgers Robert Wood Johnson Medical School, New Brunswick, NJ, [2]University of Otago, Dunedin, New Zealand, [3]University of Auckland, Auckland, New Zealand, [4]University of Otago, Christchurch, Christchurch, New Zealand, [5]University of Alabama at Birmingham, Dunedin, New Zealand

SESSION INFORMATION

Session Date: Sunday, November 7, 2021
Session Title: Metabolic & Crystal Arthropathies – Basic & Clinical Science Poster I (0660–0682)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: There is increasing recognition of gout among women. The postmenopausal rise in serum urate levels in women increases the risk for the development of gout. Compared with men with gout, women with gout are older and had a more significant burden of comorbid conditions, including hypertension, diabetes, chronic kidney disease, obesity, and diuretic use (1). The risk of flares is associated with older age and cardiometabolic comorbidities. Female gout patients with cardiometabolic comorbidities were 60% more likely to have flared as compared with 10% in men (2,3). The profiles of women and men with gout are markedly different. Do women, especially women older than 65, have more frequent gout flares than men?

Methods: Using three cohorts of European gout patients from New Zealand (NZ European; 715 male, 147 female), USA (Ardea; 1,121 male, 57 female), and several European countries (GlobalGout; 726 male, 83 female) respectively, we analyzed sex differences between the number of self-reported flares in the last 12 months. We also filtered for individuals older than three age thresholds: > 65, > 75, and > 85 years old. Since there was significant skew in the flare data, we performed a non-parametric Wilcoxon rank-sum test in each cohort to statistically test for a difference in the mean number of flares between males and females. Bonferroni corrected P-value of 0.017 (0.05 / 3) was used for significance testing.

Results: There was a non-significant difference in flare rate between males and females within each cohort (Ardea p = 0.11, GlobalGout p = 0.51, NZ European p = 0.055). Figure 1 shows the distribution of flares in the past 12 months among males and females in each cohort, demonstrating the non-significant difference in flare rate between male-sand females within each cohort. In addition, no significant difference in flare rate between sexes when filtering for individuals older than either of three age thresholds: > 70 years old: 401 male, 125 female – p-value = 0.76; > 75 years old: 188 male, 76 female – p-value = 0.61.

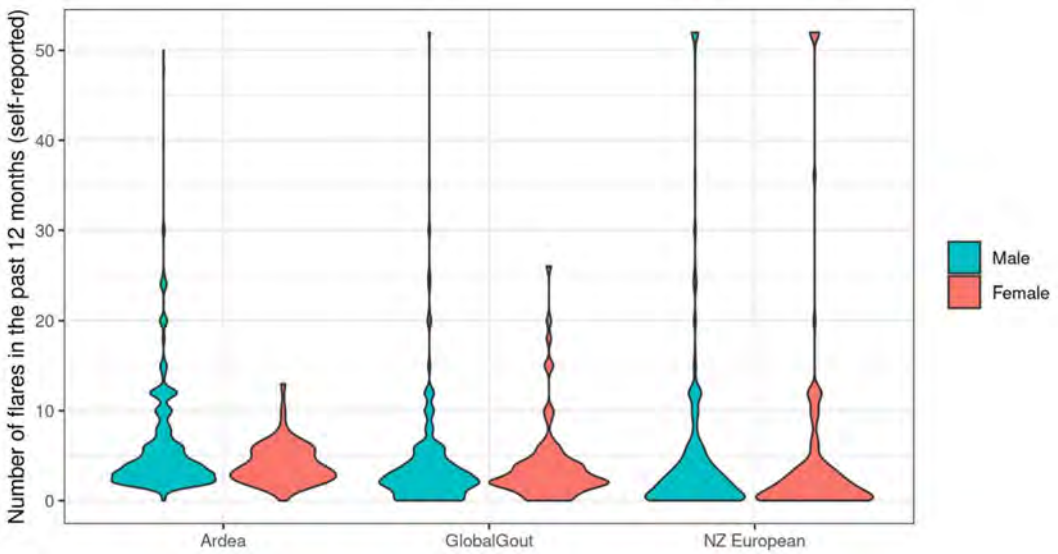

Figure 1. Violin plots showing distribution of self-reported flares in the past 12 months among males and females in three European gout cohorts.

Conclusion: In this large cohort of gout patients, we found the rate of self- -reported gout flares in women similar to those of men.

Cardiovascular Risk Associated with Treatment of Allopurinol and Benzbromarone in Patients with Gout

Yeonghee Eun, Seonyoung Kang, Seulkee Lee, Hyungjin Kim, Jaejoon Lee, Eun-Mi Koh and Hoon-Suk Cha, Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, Republic of Korea

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Metabolic & Crystal Arthropathies – Basic & Clinical Science Poster I (0660–0682)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Previous studies have shown that cardiovascular risk is increased in patients with gout. There are many studies on the effect of uric acid lowering therapy on CV risk in gout patients, but few studies have compared allopurinol and benzbromarone. A nationwide population-based cohort study is designed to compare cardiovascular risk according to the treatment of allopurinol and benzbromarone in Korean gout patients.

Methods: We used South Korea's database of the Health Insurance Review and Assessment service (HIRA) to identify gout patients 18 years of age or older who newly started allopurinol or benzbromarone between 2009 and 2015. The start date of allopurinol or benzbromarone is defined as the index date. We excluded patients who have been prescribed uric acid lowering agents or have been on dialysis for one year prior to the index date. During the study period, patients who used uric acid lowering agents other than allopurinol and benzbromarone or who used both drugs in combination were also excluded from the study. The primary outcome of the study was the occurrence of a composite cardiovascular endpoint, which included coronary revascularization, hospitalization due to MI, ischemic stroke, and transient ischemic attack (TIA). Cox proportional hazard regression analysis and Kaplan-Meier curves were used for the analysis.

Results: 257,097 allopurinol initiators and 7,868 benzbromarone initiators were included in the study. The mean age was 54.4 years, 86% were male. The mean adherence of drug administration was 68.2% for allopurinol initiators and 75.5% for benzbromarone initiators. In baseline, the benzbromarone initiator had more cardiovascular comorbidities and related drug administration than the allopurinol initiator. In allopurinol and benzbromarone initiators, the adjusted hazard ratio (aHR) of the composite CV endpoint was 1.01 (95% CI 0.83-1.21), which was not significantly different. No significant difference was found between the two groups in each of the items of the composite CV endpoint and

hospitalization for heart failure. The results did not change even when 1:3 propensity score matching was performed for baseline characteristics. In subgroup analysis of high risk patients with cardiovascular disease, there was no significant difference between allopurinol and benzbromarone initiators. However, when the analysis was limited to the group taking allopurinol ≥200mg and benzbromarone ≥50mg, there was no difference in primary outcome and other outcomes, but the risk of coronary revascularization was higher in benzbromarone initiator (aHR 1.58, 95% CI 1.16-2.14).

Conclusion: In our study, there was no significant difference in cardiovascular risk between allopurinol initiator and benzbromarone initiator. In the high risk group of cardiovascular disease, there was no difference in risk between the two drugs.

Gout Stigma: Investigating the Existence of Gout Stigma and Its Impact on Patient Perceptions and Treatment Decisions

N Lawrence Edwards[1], Brian LaMoreaux[2], Joseph Vitriol[3] and Adam Magerman[3], [1]University of Florida College of Medicine, Gainesville, FL, [2]Horizon Therapeutics plc, Deerfield, IL, [3]Horizon Therapeutics, Deerfield, IL

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Metabolic & Crystal Arthropathies – Basic & Clinical Science Poster I (0660–0682)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Pegloticase is FDA-approved for uncontrolled gout and effectively lowers uric acid levels by conversion of circulating uric acid to allantoin, which is readily removed renally.1 One potential factor contributing to the hesitancy among rheumatologists in recommending pegloticase is the longstanding stigma associated with gout patients and perceptions of their ability or willingness to adhere to pharmacological treatments.3 Although rheumatologists may not explicitly endorse negative gout related stereotypes, it is possible that such stigma may unconsciously influence their perceptions of patients' illness and treatment efficacy, attributions for contributing factors, and treatment decisions. Therefore, we investigated, among practicing rheumatologists, the existence of stigmas associated with gout (compared to rheumatoid arthritis), perceptions of patient behavior, and treatment decisions in these conditions.

Methods: A sample of 27 practicing rheumatologists participated in an online survey that evaluated their causal beliefs, illness perceptions, and treatment recommendations for patients with gout, uncontrolled gout (UG), and rheumatoid arthritis (RA). Questions also focused on rheumatologists' perceptions of patient adherence in gout, UG, and RA, as well as the responsibility of patients' for their condition. All participants completed questions with reference to gout, UG, and RA, which were blocked and presented in random order. This design allows for an assessment of how rheumatologists' beliefs, perceptions, and recommendations vary across disease condition and its potential impact on treatment recommendations.

Results: Mean-level (95% CI) responses across disease condition are represented in the Figure. Responses to questions about gout and UG did not differ significantly ($p > 0.10$). However, patients with gout/UG vs RA were perceived as significantly more responsible for their own disease condition and less likely to adhere to prescribed treatments

($p < 0.05$). Additionally, patient personal behavior, diet, BMI, and lack of treatment adherence were perceived as greater contributing factors to gout/UCG vs RA; $p < 0.01$. Similarly, change in diet, increased exercise, and weight loss was perceived as more beneficial to the management of gout/UG vs. RA; $p < 0.01$, whereas biological pharmacological treatment was perceived as more effective at managing RA vs. gout or UG; $p < 0.01$.

Conclusion: Despite advanced training and high knowledge of gout, rheumatologists' causal beliefs and illness perceptions for patients with gout/UG compared to RA reflect negative gout related stereotypes, with implications for treatment recommendations. Patients with gout/UG vs. RA were perceived as more responsible for their own condition and less likely to adhere to or benefit from biological pharmacological treatment.

Assessing Patterns of Inpatient Gout Management: Pathway for Optimal Patient Treatment Outcomes

Evan Dombrosky[1], Yashswee KC[2], Joshua Gavin[3], Youssef Roman[3] and Nehal Shah[3], [1]Virginia Commonwealth University Health System, Glen Allen, VA, [2]Loyola University, Oak Park, IL, [3]Virginia Commonwealth University Health System, Richmond, VA

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Metabolic & Crystal Arthropathies – Basic & Clinical Science Poster I (0660–0682)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: Gout is the most common inflammatory arthropathy worldwide. Despite having evidence-based guidelines, inconsistent management approaches remain a significant barrier to adequate treatment and prevention. As a result, recurrent gout flares lead to increased utilization of the healthcare system. The aim of this project was to assess inpatient gout management patterns at our health center with a focus on presence of urate lowering therapy (ULT), patient education, and follow-up. We hypothesized that patients admitted to the hospital with a gout flare had indications for ULT and should receive adequate discharge instructions or follow-up regarding gout.

Methods: We conducted a retrospective chart review of inpatients admitted to our tertiary care academic medical center between January 2017 and December 2019 using ICD-10 codes for gout flare (M10.9), as well as a serum uric acid (SUA) level greater than 7.0 mg/dL. Patients who either did not have a documented gout flare or died during their admission were excluded. Patient demographics, comorbidities, laboratory values including mean SUA, treatment modalities, discharge instructions, and follow-up plans were recorded. Continuous variables were summarized by means and standard deviations while categorical variables were summarized with frequencies and percentages. Simple logistic regression models were fit for each potential predictor to determine if an individual relationship existed with whether urate lowering therapy was given. A multivariable model was fit with appropriate predictors and control variables.

Results: Of 205 charts reviewed, 149 (73%) were analyzed. More than 50% of the patients had chronic kidney disease, congestive heart failure, dyslipidemia, or hypertension. 59 (40%) patients had ULT prescribed at time of discharge. Of those prescribed ULT, 47 (80%) were prescribed allopurinol at a dose less than 300 mg/day. The mean (SD) SUA of patients was 10.4 mg/dL (2.6) with a median of 10.2 mg/dL. Amongst all patients included in the

study, 46 (31%) had discharge instructions regarding gout and 85 (57%) were recommended to follow-up with their primary care physician or a rheumatologist. A univariate regression model suggested that both the number of flares (p=0.0039) and age (p=0.0012) were associated with whether ULT was prescribed. While controlling for age, the multiple logistic regression model demonstrated the odds of being prescribed ULT are 1.69, 95% CI (1.085, 2.629) for each additional gout flare after the first.

Conclusion: Only 40% of our studied patients received ULT despite all being at least conditionally recommended for ULT per the ACR 2020 gout guidelines. Of those prescribed ULT, 80% were on allopurinol dose less than 300 mg/day. We suspect ULT is both under prescribed and under dosed. ULT was more likely to be prescribed to patients who suffered from more than one gout flare during the study period, though these patients may have benefitted from earlier pharmacologic intervention. Furthermore, very few patients received discharge plans including education and follow up to reduce further gout flares. Our study reflects a significant opportunity to improve management of gout in the inpatient setting and upon hospital discharge.

Abstract Number: 0682

Gout Management and Outcomes During the COVID-19 Pandemic in Late 2020-2021: A Cross-sectional Internet Survey

Jasvinder Singh[1] and N Lawrence Edwards[2], [1]University of Alabama at Birmingham, Birmingham, AL, [2]University of Florida College of Medicine, Gainesville, FL

SESSION INFORMATION
Session Date: Sunday, November 7, 2021
Session Title: Metabolic & Crystal Arthropathies – Basic & Clinical Science Poster I (0660–0682)
Session Type: Poster Session B
Session Time: 8:30AM–10:30AM

Background/Purpose: To assess gout management during the COVID-19 pandemic since September 2020.

Methods: We assessed urate-lowering therapy (ULT) use, healthcare utilization, gout-specific health-related quality of life (HRQOL; 0-100 range; higher scores = lower/pooper HRQOL), health literacy, illness perception, psychological distress using patient health questionnaire-4 (2 questions each for depression and anxiety; 0-6 each), and resilience using on Connor-Davidson Resilience Scale (CD-RISC2; range 0-8; higher=more resilient) scale in people with self-reported physician-diagnosed gout in a cross-sectional Internet survey.

Results: Among the 121 survey respondents with self-reported physician-diagnosed gout, 60% were prescribed urate-lowering therapy (ULT) and 33% were taking ULT daily since September 2020. The mean age of respondents was 62.8 years (standard deviation [SD], 12.6), 65% were male, and 82% were White. Regular daily use of gout medications was reported during the COVID-19 pandemic since September 2020 as follows: allopurinol, 31%; febuxostat, 4%; probenecid, 2%; colchicine, 7%; NSAIDs, 9%; glucocorticoids, 4%. Gout flares were common, i.e., 76% reported ≥1 gout flare. Overall, 29% of respondents reported more difficulty with managing their gout since September 2020.

Gout-specific HRQOL deficits were evident for all scales: (1) gout concern overall, 72.9 (SD, 25); (2) unmet gout treatment need, 54.2 (SD, 24.7); (3) gout concern during flare, 55.5 (SD, 24.5); (4) gout well-being during flare, 55.4 (SD, 23.6); and (5) gout medication side effects, 56.5 (SD, 25.5).

Table 1. Multivariable association of depression and anxiety with gout outcomes during COVID-19 pandemic in 2020-2021

	Depression (PHQ-2 score of 3 or more; **ref category**, score 0-2)	Anxiety (PHQ-2 score of 3 or more; **ref category**, score 0-2)
	Odds ratio (95% Confidence Interval)	
Regular ULT use	**0.29 (0.09 to 0.99)**	0.46 (0.13, 1.62)
Difficulty with getting healthcare for gout in		
Clinic	**6.50 (1.61 to 26.2)**	**9.94 (1.93 to 51.2)**
Emergency room or urgent care	**21.54 (1.90 to 244)**	**36.79 (1.75 to 734)**
Hospital	**37.29 (2.97 to 468)**	**20.39 (1.60 to 260)**
Difficulty getting gout flares treated	**14.85 (2.67 to 82.8)**	**23.91 (3.20 to 178)**
Difficulty avoiding gout flares,	**5.41 (1.21 to 24.11)**	3.56 (0.62, 20.46)
Difficulty avoiding complications from gout	**8.42 (2.10 to 33.77)**	**7.89 (1.67 to 36.35)**
Difficulty with daily activities	**3.88 (1.22 to 12.29)**	**5.72 (1.41 to 23.32)**
Difficulty with performing work	**5.30 (1.61 to 17.43)**	**5.02 (1.24 to 20.37)**
Bold represents statistically significant Odds ratios each with a p-value <0.05		

Psychological distress was moderate in 10% and severe in 14% (mild, 27%; none/normal, 50%). Resilience score was 6.5 (SD, 1.9). Health literacy was high with mean score of 18.5 (SD, 2.5; range 4-20).

Adjusted for age, and sex, compared to no depression or anxiety, depression with PHQ-2 score ≥3, and anxiety with PHQ-2 score of ≥3, were significantly associated with: (1) difficulty with getting healthcare for gout in clinic, emergency room or urgent care, and in-hospital; (2) difficulty getting gout flares treated, avoiding gout flares, and avoiding complications from gout; and (4) difficulty with daily activities, and performing work; and depression, but not anxiety with regular ULT use (**Table 1**).

Conclusion: Respondents with gout reported healthcare gaps, psychological distress, illness perception and HRQOL deficits since September 2020 during the COVID-19 pandemic. Anxiety and depression were associated with poorer ULT adherence and more difficulty managing gout. Interventions to address psychological comorbidity in gout are needed during the COVID-19 pandemic.

SESSION INFORMATION

Session Date: Sunday, November 7, 2021

Session Title: Muscle Biology, Myositis & Myopathies Poster (0683–0722)

Session Type: Poster Session B

Session Time: 8:30AM–10:30AM

Background/Purpose: Anti-melanoma differentiation-associated protein 5 (MDA5) positive dermatomyositis (DM) is associated with rapidly progressive interstitial lung disease (RP-ILD) and high mortality. This multi-centre retrospective study aimed to evaluate whether RP-ILD was associated with increased mortality in anti-MDA5 positive DM in Hong Kong and to identify predictors for mortality and RP-ILD.

Methods: Anti-MDA5 positive DM patients were identified from the Hong Kong Myositis Registry and the Clinical Data Analysis and Reporting System. Diagnosis of DM was based on Bohan and Peter's criteria or EULAR/ ACR 2017 classification criteria. Diagnosis of CADM was defined as typical cutaneous features of DM confirmed by rheumatologist or dermatologist but minimal or no clinical features of myositis (hypomyopathic and amyopathic) with reference to the Sontheimer's criteria. Detailed clinical characteristics were reviewed. RP-ILD was defined as rapid progression of dyspnea or imaging finding of ILD within 1 month of onset of respiratory symptoms. Risk factors for mortality and RP-ILD were identified.

Results: Among the 101 recruited patients, 87 (86.1%) had ILD and 42 (41.6%) had RP-ILD. Over a period of 19.1±21.9 months, 38 (37.6%) patients died, in which 31 patients (81.6%) died within three months of diagnosis. Multivariate Cox regression analysis revealed that RP-ILD (HR 17.6, 95%CI 5.96-51.9), smoking (HR 6.40, 95%CI 1.43-28.7), ferritin level >2800pmol/L (HR 6.37, 95%CI 2.40-16.9) and fever at diagnosis (HR 3.11, 95%CI 1.14-8.53) were independent predictors of mortality. Early rituximab use was associated with better survival (HR 0.10, 95% CI 0.01-0.82). With regards to RP-ILD, multivariate Cox regression analyses showed that independent predictors included age >50 years (HR 3.02, 95%CI 1.43-6.38), baseline neutrophil to lymphocyte ratio (NLR) >7.5 (HR 2.45, 95%CI 1.05-5.71) and lactate dehydrogenase (LDH) level >300IU/L (HR 3.34, 95%CI 1.36-8.21). We proposed a prediction model, based on NLR >7.5, age >50 years old and LDH >300IU/L ("NAL"), to stratify risk of development of RP-ILD.

Conclusion: Anti-MDA5-associated RP-ILD is significantly associated with poor survival rates. The "NAL" model maybe useful to predict the development of RP-ILD in anti-MDA5 positive DM patients.

	N= 101
Anti-MDA5 positive DM patients, no.	101
Female, no. (%)	54 (53.5%)
Age of onset, years, mean (± SD)	52 (13)
Smoker, no. (%)	9 (8.9%)
Ethnicity, no. (%)	
Chinese	98 (97%)
Diagnosis	
DM, no. (%)	33 (32.7%)
CADM, no. (%)	68 (67.3)
PM, no (%)	0 (0%)
ILD, no. (%)	87 (86.1%)
RPILD, no. (%)	42 (41.6%)
Fever at presentation, no. (%)	51 (50.5%)
Cutaneous features	
Violaceous rash over elbow	23 (22.8%)
Violaceous rash over knee	7 (6.9%)
Cutaneous ulcer	21 (20.8%)
Cutaneous vasculitis	36 (35.6%)
Laboratory findings	
Lactate dehydrogenase, IU/L, mean	477
C-reactive protein, mg/dL, mean (normal <5)	16
Lymphocytes count ≤0.5	28 (27.7%)
Ferritin (ng/mL), mean	7834
Treatments and outcomes	
Steroid	98 (97%)
Cyclophosphamide, initial treatment	36 (35.6%)
Rituximab, initial treatment	34 (33.7%)
Overall Mortality, no. (%)	38 /101 (37.6%)
3- month survival rate	(73/101) 72.3%
1- year survival rate	(64/101) 63.4%

Patients' demographic, clinical features, treatments and outcomes

Variable	Hazard ratio	95% Confidence interval	P-value
Age at diagnosis >50 years old	3.020	1.431-6.376	**0.004**
Fever	1.570	0.781-3.158	0.205
Infection at diagnosis	1.792	0.874-3.674	0.111
NLR >7.5	2.445	1.046-5.714	**0.039**
LDH >300 IU/L at diagnosis	3.343	1.362-8.205	**0.008**
CRP >18 mg/dL at diagnosis	1.421	0.593-3.409	0.431

Results of multivariate Cox regression analyses for RP-ILD

Risk score	No. of RP-ILD	RP-ILD rate, %	% within RP-ILD
0	2	2.0%	4.8%
1	9	8.9%	21.5%
2	28	27.7%	66.7%
3	42	41.6%	100%

Prediction model for RP-ILD based on age >50, NLR >7.5 and LDH >300 IU/L at diagnosis
